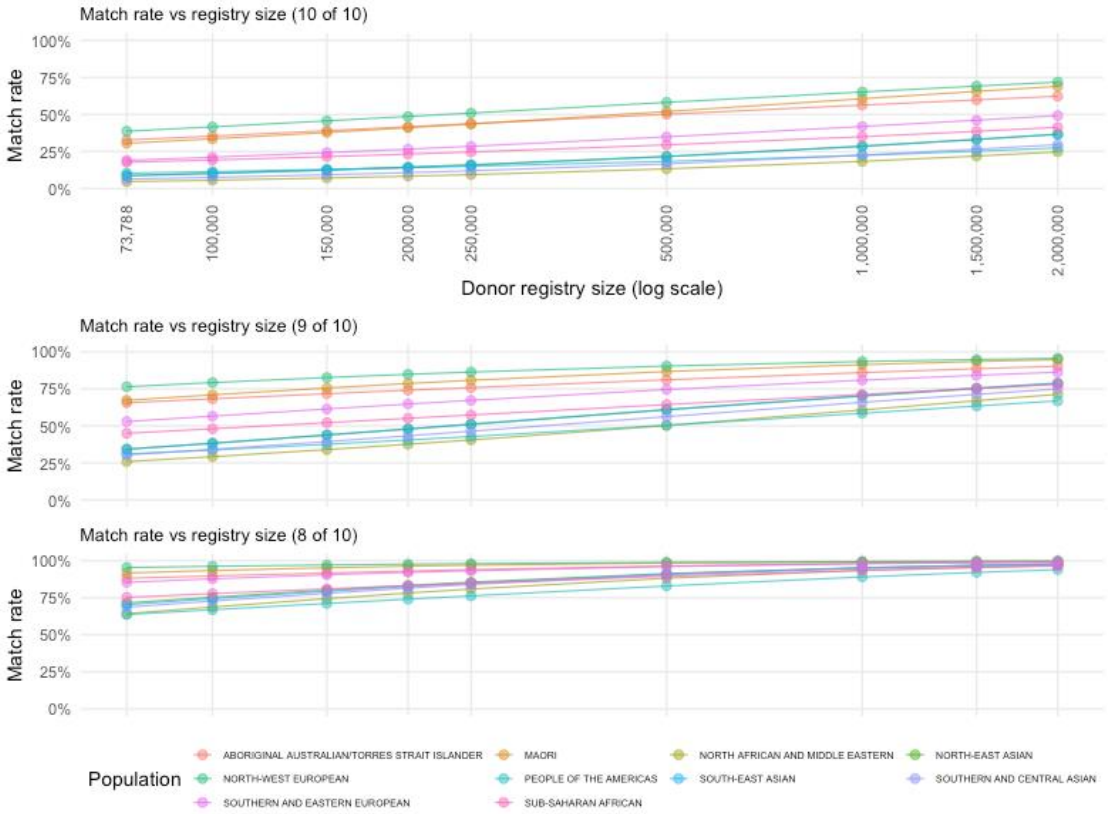
Methods: High-resolution HLA-A, -B, -C, -DRB1, -DQB1 (±DPB1) data from 103,106 donors registered since 2015 with Stem Cell Donors Australia and the New Zealand Bone Marrow Donor Registry were analysed to estimate five- and six-locus haplotype frequencies in nine major ancestry groups. Using established NMDP haplotype frequency and population genetics modeling methods, we simulated unrelated donor searches for Australian/New Zealand HSCT

patients from the same period across match stringencies (10of10, 9of10, 8of10 and 8of8, 7of8, 6of8), incorporating donor age. We then modeled registry expansion from the current ≤35-year-old Australasian donor pool (73,788) up to 2,000,000 donors and evaluated the incremental impact of including NMDP (US) donors. We also evaluated the accuracy of self-reported ancestry for the Australian donor cohort since the introduction of online enrolment. Finally, we implemented an optimization framework in which registry growth across ancestries is guided by an equity parameter (λ) that trades off maximizing overall matches versus minimizing ancestry-based variation in match rates.

Results: In the current combined Australian/New Zealand donor pool, 10of10 (or 8of8) match rates exceeded ~40–50% for North-West European patients but were <25% for many Asian and Oceanian (First Nations) groups, with 7of8 and 9of10 match rates ranging from ~36–86% across ancestries. Restricting to donors ≤35years reduced fully matched rates by only ~2–3 percentage points in the best-served groups while preserving overall patterns of disparity. Adding NMDP donors moderately increased match likelihoods for underrepresented ancestries, particularly at the single-mismatch levels (7of8 and 9of10), and significantly raised ≥6/8 or ≥8of10 match probabilities to ~90% for all populations. Registry-growth simulations (**Figure 1**) showed diminishing returns beyond ~500,000 donors for lower stringency thresholds, but continued gains for 9of10 and 10of10 matching, especially for minority groups, even at 2,000,000 donors. For an economically feasible Australian registry growth target, equitable gains in transplant access for all nine ancestry groups is only fully achieved from projected mismatching at 1-2 alleles. In equity-optimized simulations (higher λ), donor recruitment shifted toward Asian, African, and non-European groups, halving the variation in match rates between ancestries, whereas purely throughput-optimized growth preserved current disparities. Balanced strategies (λ ≈ 0.5) achieved high overall match rates with substantially reduced inequity and realistic donor compositions.



Conclusions: For Australia and New Zealand, registry composition and donor availability are stronger determinants of equitable access than registry size alone. Targeted recruitment of younger donors prioritising underrepresented ancestries, combined with access to the global donor pool, improves match likelihoods across populations. Compared with equity gains achieved through registry expansion, the models show the ability to use 1–2 allele–mismatched donors represents the most practical and impactful strategy for reducing disparities in donor access for Australasian HCT patients.

DEMOGRAPHICS MATTER: VARIATION IN DONOR AVAILABILITY DURING CONFIRMATORY TYPING

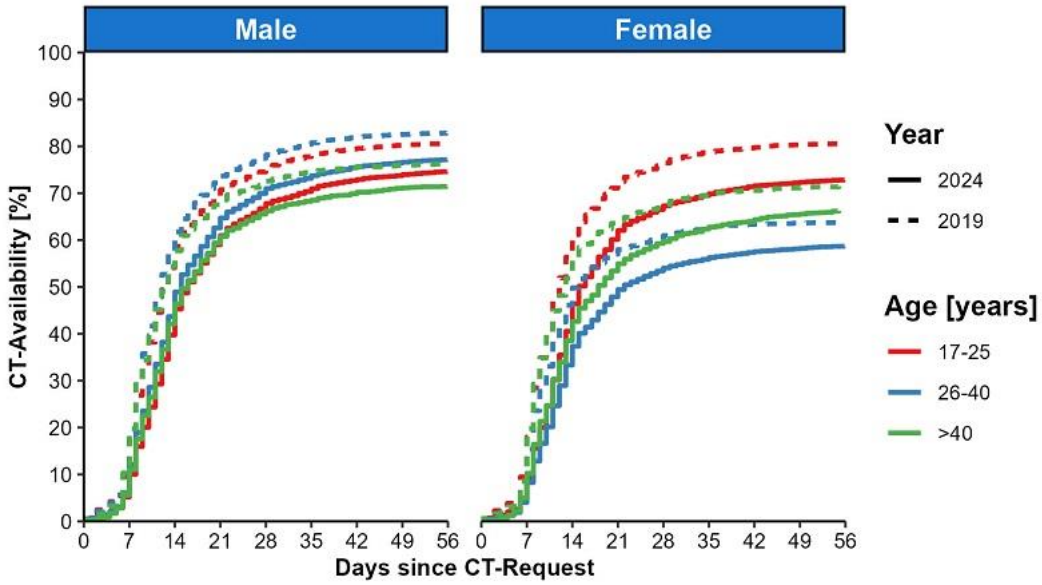
Ute Verena Solloch[1], *Henning Baldauf*[2], *Susanne Seitz*[1], *Jürgen Sauter*[1], *Stefanie Bernas*[1], *Julia Stolze*[3], *Karen Ende*[3], *Deborah Buk*[3], *Thilo Mengling*[1], *Johannes Schetelig*[2,4]

[1]DKMS Group, Tübingen, Germany, [2]DKMS Group, Dresden, Germany, [3]DKMS Donor Center, Tübingen, Germany, [4]University Hospital Carl Gustav Carus, TU Dresden, Dresden, Germany

Background: The availability of suitable donors is essential to ensure that patients with severe blood disorders receive hematopoietic stem cell products in time. Donor availability during confirmatory typing (CT), which includes confirmation of HLA compatibility and health assessment, facilitates efficient donor selection.

Methods: We analysed the success rate and time to confirmation of donor availability for CT requests initiated by transplant centers (TCs) to donors registered with DKMS Germany, comparing two time periods. The sex- and age-stratified analysis included all first CT requests in 2019 (n=27,530) and 2024 (n=39,995). CT availability was defined as donors' expressed willingness to donate and medically eligibility, excluding requests that were cancelled by the TC. CT duration was defined as the days between CT request and the results of the health assessment, including review of Health History Questionnaire and infectious diseases markers.
The success rates were analysed using logistic regression, and the CT duration was evaluated using cumulative incidence functions.

Results: Median age of requested donors was 27 years in both, 2019 and 2024 (p=0.5). In 2019, male donors were requested in 63% of searches, compared to 59% in 2024 (p<0.001). CT availability of DKMS donors decreased from 78.2% in 2019 to 72.6% in 2024. This decline was primarily due to donors' unwillingness to donate (4.0% in 2019 vs. 8.7% in 2024). The largest decrease of success rates was observed among female donors aged 17 to 25, with CT availability dropping from 80.9% in 2019 to 74.0% in 2024. The highest CT availability was seen among men aged 26 to 40, with 83.3% in 2019 and 78.3% in 2024. Women in the same age group, by contrast, showed the lowest CT availability, with 64.0% in 2019 and 59.6% in 2024. The main reason is the exclusion of donor searches during pregnancy and up to six months after childbirth. Further, medical ineligibility increases with age, affecting 12.7% of men and 14.5% of women over the age of 40 compared to 2.2% of men and 3.3% of women under 26 years in 2024.
The median CT duration was 11 days in 2019 and 14 days in 2024 (p<0.001). Search time analysis showed that if a donor had not been reported as available by day 14, the likelihood of a positive reply by day 28 ranged between 27% (female donors aged 26-40 years) and 43% (male donors aged 26-40 years).



Conclusions: Differences in donor availability by donor age and sex should be considered during donor search. Strengthening communication between donor registries and TCs could facilitate the timely initiation of additional donor requests at CT level.
The observed decline in donor availability between 2019 and 2024 suggests a need for more personalized and targeted donor communication strategies. Donation behaviour is influenced by a complex combination of individual motivations, socioeconomic factors, and situational circumstances. Further analyses will be required.

PAROUS FEMALE DONOR REDUCES RELAPSE RISK IN HIGH-RISK AML/MDS AFTER HAPLOIDENTICAL PBSCT WITH ATG/PTCY COMBINATION FOR GVHD PROPHYLAXIS

Huiying Qiu[1], *Xingying Li*[1], *Wenjuan Zhang*[2], *Jian Zhou*[3], *Lijing Shen*[4], *Yu Cai*[1], *Jun Yang*[1], *Chongmei Huang*[1], *Xiaowei Xu*[1], *Jiahua Niu*[1], *Kun Zhou*[1], *Ying Zhang*[1], *Xinxin Xia*[1], *Chang Shen*[1], *Yin Tong*[1], *Baoxia Dong*[1], *Liping Wan*[1], *Hao Zhang*[2], *Xianmin Song*[1]
[1]*Department of Hematology, Shanghai General Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China,* [2]*Department of Hematology, Affiliated Hospital of Jining Medical University, Jining, China,* [3]*Department of Hematology, Affiliated Cancer Hospital of Zhengzhou University and Henan Cancer Hospital, Zhengzhou, China,* [4]*Department of Hematology, Renji Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China*

Background: Haploidentical donors (HIDs) have gained viability with improved graft-versus-host disease (GVHD) prophylaxis. While young male donors are typically preferred, parous female donors have been regarded as suboptimal. However, the combination of low-dose anti-thymocyte globulin (ATG) and post-transplant cyclophosphamide (PTCy) has shown promising efficacy in preventing GVHD following haploidentical peripheral blood stem cell transplantation (haplo-PBSCT).

Methods: From May 2017 to November 2023, we conducted a multicenter retrospective study of 106 patients with acute myeloid leukemia or myelodysplastic syndrome to compare outcomes between parous female donors (n=47) and young male donors under 30 years old (n=59). Adult patients (≥18 years) with myeloid malignancies undergoing haplo-PBSCT with ATG/PTCy combination-based GVHD prophylaxis regimens. The graft source was peripheral blood stem cells (PBSCs) mobilized with granulocyte colony-stimulating factor. All patients received the GVHD prophylaxis regimen combining ATG and PTCy for transplantation. The low-dose ATG/PTCy regimen consisted of ATG (2.5 mg/kg/day on days -2 to -1), PTCy (50.0 mg/kg/day on day +3), cyclosporine A (CsA), and mycophenolate mofetil (MMF) (initiated on day +4).

Results: The parous female donor group exhibited a significantly lower 2-year cumulative incidence of relapse (CIR: 6.50% vs. 24.68%), which was confirmed on multivariate analysis as an independent factor associated with reduced CIR (P=0.033). Non-relapse mortality (NRM) was comparable between the groups (P=0.110). Although differences in overall survival, relapse-free survival, and GVHD-free/relapse-free survival did not reach statistical significance, consistent trends toward improved survival were observed in the parous female donor group, particularly among high/very-high-risk refined disease risk index patients, who exhibited an approximate 20% improvement in survival.

Conclusions: These findings suggest that the parous female donor may provide enhanced relapse protection without increasing NRM in AML/MDS patients receiving ATG/PTCy-based haplo-PBSCT.

OLDER DONOR AGE IS NOT ASSOCIATED WITH INFERIOR SURVIVAL IN CONTEMPORARY HAPLOIDENTICAL TRANSPLANTATION

Yosra Aljawai[1], *Denái Milton*[1], *George Chen*[1], *David Marin*[1], *Uday Popat*[1], *Betul Oran*[1], *Partow Kebriaei*[1], *Richard Champlin*[1], *Elizabeth Shpall*[1], *Rohtesh Mehta*[1], *Portia Smallbone*[1]
[1]*MD Anderson Cancer Center, Houston, United States of America (the)*

Background: Data regarding the association of donor age with haploidentical (haplo) hematopoietic stem cell transplant (HCT) outcomes has been inconsistent, particularly concerning a specific age cutoff. Most published studies on donor age in the haplo setting predated the advancement in cytomegalovirus (CMV) prophylaxis, improved graft-versus-

host disease (GVHD) treatments, maintenance therapy post-HCT.
Objective: Examine the role of donor age in a recent cohort of patients, from 2018-2024.

Methods: We included consecutive adult patients with hematologic malignancies who underwent their first haplo HCT (n=364) at MD Anderson Cancer Center. All patients received post-transplant cyclophosphamide (PTCy)-based GVHD prophylaxis. To determine the optimal donor age cutoff associated with overall survival (OS) and progression-free survival (PFS), we explored a series of donor age dichotomizations as well as categorization by 5-year intervals.

Results: Our analysis, using dichotomization of donor age, did not reveal a clear donor age cut-off to be associated with either OS or PFS. In the absence of a statistically significant age cutoff for OS or PFS, we categorized donor age into three groups (≤30 [n=155], 31-44 [n=139], and ≥45 years [n=70]) for all subsequent analyses based on cohort distribution and clinical relevance. Compared to donor age ≤30 years, the hazards of overall mortality were 0.92 (95% CI 0.62-1.37, *P* = 0.69) for donor age 31-44 years and 1.19 (95% CI 0.78-1.81, *P* = 0.43) for donor age ≥45 years in multivariable analysis (MVA). Similar patterns emerged for PFS. Older donor age was associated with increased hazards of non-relapse mortality (NRM) in MVA: (31-44 years: hazard ratio [95% CI] 1.44 [0.84-2.45], *P*= 0.18) and (≥45 years: 1.52 [0.87-2.66], *P* = 0.14). Consequently, relapse rates were lower in these groups (31-44 years: 0.55 [0.33-0.93], *P* = 0.025) and (≥45 years: 0.70 [0.36-1.36], *P* = 0.29) compared to donors ≤30 years.
Older donors were associated with a significantly increased risk of grade III-IV acute GVHD (31-44 years: 3.77 [1.69-8.39], *P*=0.001; ≥45 years: 3.83 [1.64-8.98], *P*= 0.002) compared to donors ≤30 years. The risk of chronic GVHD was also higher with older donors (31-44 years: 1.44 [0.84-2.45], *P*=0.18; ≥45 years: 1.52 [0.87-2.66], *P* = 0.14) compared to younger donors.
We noted patient and disease-related factors significantly associated with OS in MVA; older patient age (≥ 65 years vs. < 50 years: 1.90 [1.22-2.98], *P*= 0.005) and a high/very high disease risk index (DRI) (1.89 [1.38-2.60], *P*< 0.001). DRI also influenced relapse rates with a 2.5-fold increased risk observed in patients with high/very high DRI (95% CI 1.63-3.90, *P*< 0.001).

Conclusions: Our study suggested that dichotomization of donor age did not reveal it to be a major selection factor. However, it remains to be assessed whether HLA factors play a more dominant role, if improved post-HCT strategies have altered the adverse effect of donor age in this population, or if dichotomization may present a limited methodology of modeling donor age and novel approaches need to be adopted in this contemporary era. Despite the lack of survival differences, older donor age remains a significant predictor of severe acute GVHD risk.

THE IMPACT OF INDIRECT ALLORECOGNITION IN TRANSPLANT OUTCOMES AFTER UNRELATED DONOR TRANSPLANTATION FOR NONMALIGNANT DISEASES

Nágila Brotto[1,2], Joselito Getz[3], Rafaella Muratori[4], Margareth Kleina Feitosa[3], Luciana Dornelles[3], Gisele Loth[4,5], Cilmara Kuwahara[5], Carolina de Almeida Peixoto[5], Polliany Pelegrina[5], Vaneuza Funke[4], Samir Kanaan Nabhan[4], Ricardo Pasquini[4], ***Carmem Bonfim***[6,1]*, Alberto Lima[3]*
[1]Faculdades Pequeno Príncipe, Curitiba, Brazil, [2]Universidade Federal do Paraná, Curitiba, Brazil, [3]Histocompatibility Laboratory, CHC/UFPR, Curitiba, Brazil, [4]HCT Unit, CHC/UFPR, Curitiba, Brazil, [5]HCT, Hospital Pequeno Príncipe, Curitiba, Brazil, [6]Duke University, Durham, United States of America (the)

Background: Recent studies show that indirect allorecognition, analyzed by the *in silico* PIRCHE (Predicted Indirectly Recognizable HLA Epitopes) model, predicts a higher incidence of acute graft-versus-host disease (GVHD) and worse survival in patients with malignant diseases undergoing hematopoietic stem cell transplantation with unrelated donors (URD-HSCT). However, the impact of PIRCHE on URD-HSCT for non-malignant diseases is currently unknown.

This study aimed to evaluate the effect of indirect allorecognition of HLA-DPB1 mismatches, measured by the PIRCHE-I and -II scores, on the outcomes of URD-HSCT for non-malignant diseases.

Methods: We retrospectively analyzed 181 transplants for non-malignant diseases performed between 2007 and 2024. High-resolution HLA typing was performed by Sanger or next-generation sequencing (NGS). PIRCHE-I and -II scores in the Host-versus-Graft (HvG) and Graft-versus-Host (GvH) pathways were calculated using the pirche.com website. The primary outcomes were overall survival (OS) and graft-free, rejection-free survival (GRFS). The secondary outcomes were neutrophil (NE) and platelet (PE) recovery, graft failure (GF), GVHD II-IV, GVHD III-IV, cGVHD, and extensive cGVHD. Univariate analyses of primary outcomes were estimated using the Kaplan-Meier method and compared between groups using the log-rank test, while secondary outcomes were calculated using cumulative incidence curves considering competing risks and compared using Gray's test. $P < 0.01$ was considered significant. Multivariate analyses were performed using Cox regression, adjusted for competing risks. All statistical analyses were performed using EZR v1.68 software.

Results: The median age of the patients was nine years (range: 0-51). The main indications for URD-HSCT were congenital bone marrow failure (n = 82; 45.3%) and severe aplastic anemia (n = 51; 28.2%). All patients received bone marrow as a source of HSCs, and 96.7% received in vivo T-cell depletion with ATG. Among the 181 donor/recipient pairs, 42 (23.2%) were fully compatible for the HLA-A, -B, -C, -DRB1, -DQB1, and -DPB1 loci, and 139 (76.8%) were HLA-DPB1 mismatch. The presence or absence of PIRCHE-I and -II in the HvG and GvH pathways did not impact the outcomes of hematological recovery, rejection, GVHD, and OS (p>0.01). In the adjusted analyses, the absence and presence of PIRCHE-I and PIRCHE-II, in either the HvG or GvH direction, were significantly associated with poorer GRFS compared with the 12/12 control group (p<0.01; Table 1). However, the groups with HLA-DPB1 mismatches, regardless of the presence or absence of PIRCHE-I and -II, had a lower cumulative incidence of GRFS before 2 years (51.7%; 95% CI: 42.8-59.9%) compared to the fully compatible control group (77.7%; 95% CI: 59.8-88.3%), which was statistically significant in the analysis adjusted for competing risks (HR= 3.66; 95% CI: 1.75–7.69; p<0.001; Figure 1).

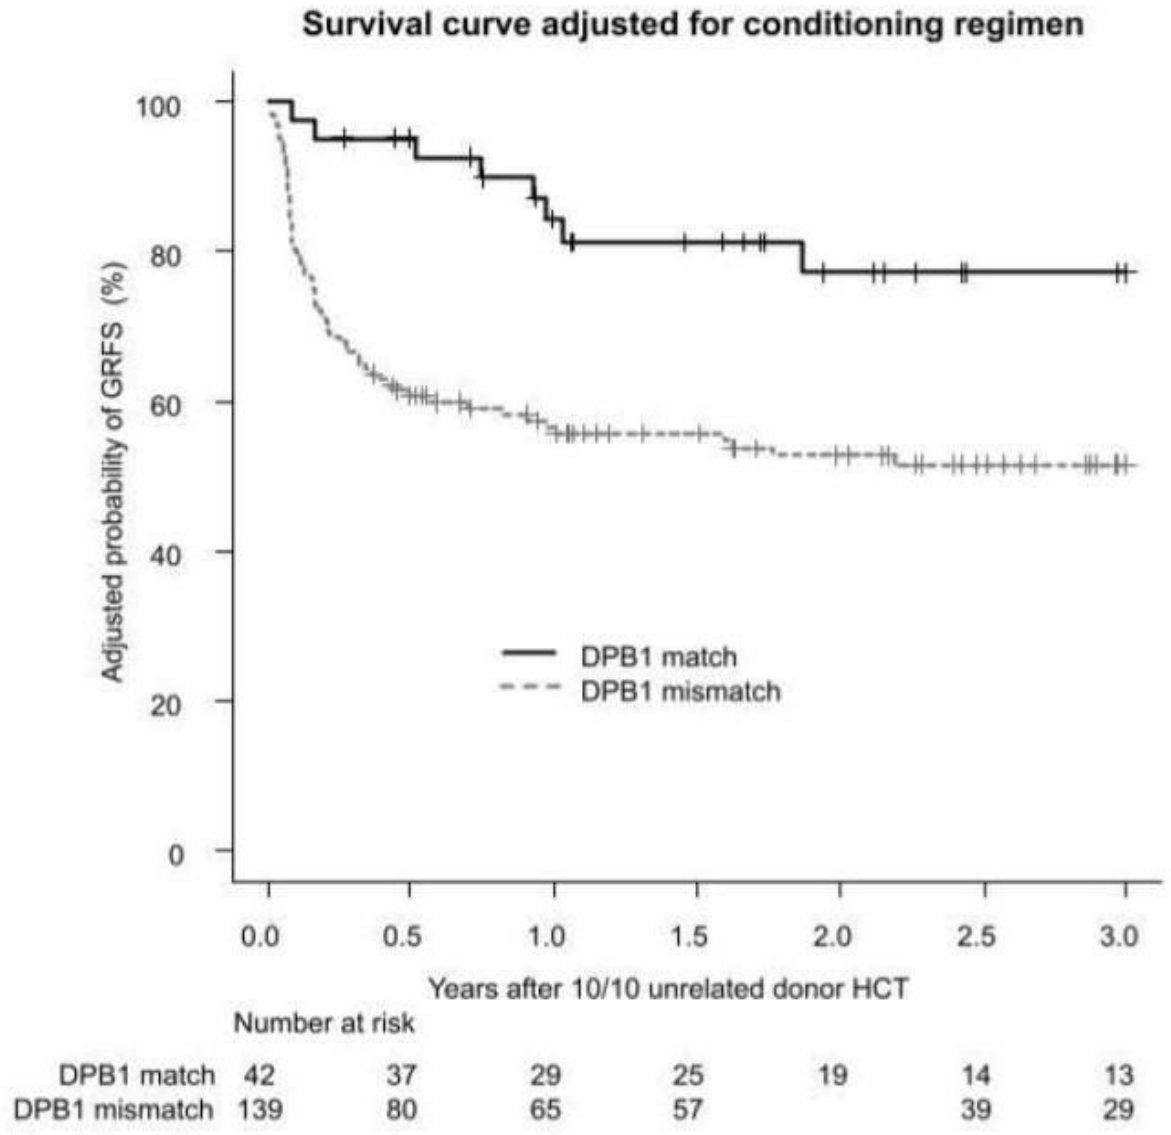
TABLE 1. MULTIVARIABLE ANALYSES FOR GRFS

GRFS[†Ω]	HR (95% CI)	P-value	Overall P-value[€]
Model 1: PIRCHE-I HvG			0.0025
Control 12/12	1 (Reference)	-	
PIRCHE- I HvG Absent	3.39 (1.49-7.70)	0.0036	
PIRCHE-I HvG Present	3.82 (1.78-8.20)	<0.001	
Model 2: PIRCHE-II HvG			0.0027
12/12 Control	1 (Reference)	-	
PIRCHE-II HvG Absent	3.78 (1.65-8.67)	0.0017	
PIRCHE-II HvG Present	3.61 (1.68-7.75)	<0.001	
Model 3: PIRCHE-I GvH			<0.001
Control 12/12	1 (Reference)	-	
PIRCHE- I GvH Absent	4.85 (2.14-10.98)	<0.001	
PIRCHE-I GvH Present	3.25 (1.52-6.96)	0.0025	
Model 4: PIRCHE-II GvH			0.0018
Control 12/12	1 (Reference)	-	
PIRCHE-II GvH Absent	4.55 (1.89-10.93)	<0.001	
PIRCHE-II GvH Present	3.47 (1.64-7.38)	0.0012	

[†]Final models adjusted for conditioning regimen.

[Ω]Cox model considering GRFS for less than 2 years due to violation of the Cox proportional hazards assumption. The Cox model was not performed for GRFS greater than 2 years, as there were no events in the 12/12 control group after 2 years; only censoring occurred.

[€]Overall p value for the Wald test.



Conclusions: Our findings suggest that the PIRCHE model is not a predictor of more permissible DPB1 mismatches. Thus, we conclude that, for non-malignant diseases, a fully compatible donor is always the best strategy to optimize GRFS after URD-HSCT.

Disclosure: Nothing to declare.

A324

EVALUATION OF RECOVERY AND ADVERSE EVENTS IN 1,638 HEALTHY ANTHONY NOLAN DONORS

Tania Dexter[1], *Angharad Pryce*[1], *Lucie De Cock*[1], *Emily Chan*[1], *Ellouise Bishop*[1], *Chloe Anthias*[1]
[1]*Anthony Nolan, London, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Anthony Nolan (AN) is a UK donor registry facilitating donations from healthy related and unrelated donors for allogeneic transplants worldwide. Peripheral blood stem cell (PBSC) donors receive 4-5 days of granulocyte-colony stimulating factor injections, standard 12L processing via apheresis on day 5 and repeat on day 6 if required. Bone marrow (BM) donors collect a maximum 20mls/kg under general anaesthetic. The registry performs short term donor follow-up at day 2-3, day 7, day 30 and long-term donor follow-up annually. Adverse reactions (ARs) are recorded internally and reported to the World Marrow Donor Association (WMDA) via the SPEAR reporting system if required. An AR is any unexpected response in the donor which requires further follow-up, monitoring or reporting to WMDA. These are identified from follow up questionnaire responses or following direct donor contact. The aim of this study was to determine the rate of ARs in donors and assess donor recovery time.

Methods: We retrospectively analysed follow-up questionnaires and ARs from 1,638 healthy donors donating 1st April 2022 - 31st March 2025. Day 2/3 questionnaires were administered via phone call and recorded on the AN CORAL database. Day 7 and 30 questionnaires were administered electronically. Follow-up questionnaires are non-compulsory, and not all questions require responses. Day 2/3 and day 7 questions are a 5-point Likert scale, day 30 a 0-10 scale.

Results: We reviewed responses from 1,486 (90.7% response rate) day 2/3 calls, 1,155 (70.5% response rate) day 7 questionnaires and 659 (40.2% response rate) day 30. Donors had a median age of 27 years. 1,053 (64.3%) males and 585 (34.8%) females.There were 105 (6.4%) BM donors, 238 (14.5%) donor lymphocyte collections (DLC) and 1,294 (79.0%) PBSC.
Self-reported donor recovery data are presented in Table 1 and Figure 1.

Question	**Answer**	**Day 2/3**			**Day 7**		
		BM	DLC	PBSC	BM	DLC	PBSC
In relation to your donation how are you	Much better than usual / Excellent	2 (3.2%)	0 (0.0%)	10 (1.3%)	8 (10.3%)	8 (29.6%)	107 (11.2%)

feeling emotionally?	Better than usual / Very good	8 (12.9%)	9 (8.9%)	122 (16.1%)	15 (19.2%)	7 (26.0%)	204 (21.4%)
	Normal / Good	50 (80.6%)	92 (91.1%)	600 (79.2%)	48 (61.5%)	12 (44.4%)	606 (63.5%)
	Worse than usual / Fair	2 (3.2%)	0 (0.0%)	25 (3.3%)	6 (7.7%)	0 (0%)	35 (3.7%)
	Much worse than usual / Poor	0 (0.0%)	0 (0%)	1 (0.1%)	1 (1.3%)	0 (0%)	2 (0.2%)
	Total	62	101	758	78	27	954
In relation to your donation how are you feeling physically?	Much better than usual /Excellent	0 (0%)	0 (0%)	0 (0%)	2 (2.6%)	6 (22.2%)	62 (6.5%)
	Better than usual /Very Good	1 (1.6%)	0 (0%)	4 (0.5%)	5 (6.4%)	5 (18.5%)	91 (9.5%)
	Normal /Good	28 (44.4%)	120 (90.1%)	543 (70.2%)	38 (58.7%)	13 (48.1%)	726 (75.9%)
	Worse than usual /Fair	33 (52.4%)	12 (9.1%)	212 (27.4%)	32 (41.0%)	2 (7.4%)	72 (7.5%)
	Much worse than usual /Poor	1 (1.6%)	0 (0%)	5 (0.6%)	1 (1.3%)	1 (3.7%)	6 (0.6%)

	Total	63	132	773	78	27	957
Are you able to participate in normal activities?	Yes	25 (25.8%)	192 (92.3%)	859 (72.7%)	56 (71.8%)	25 (92.6%)	946 (97.7%)
	No	72 (74.2%)	16 (7.8%)	322 (27.3%)	22 (28.2%)	2 (7.4%)	22 (2.3%)
Have you recovered from the donation?	Yes	21 (21.6%)	177 (85.0%)	766 (64.9%)	45 (57.7%)	25 (92.6%)	907 (93.5%)
	No	76 (78.4%)	31 (14.9%)	415 (35.1%)	33 (42.3%)	2 (7.4%)	63 (6.5%)
Table 1.							

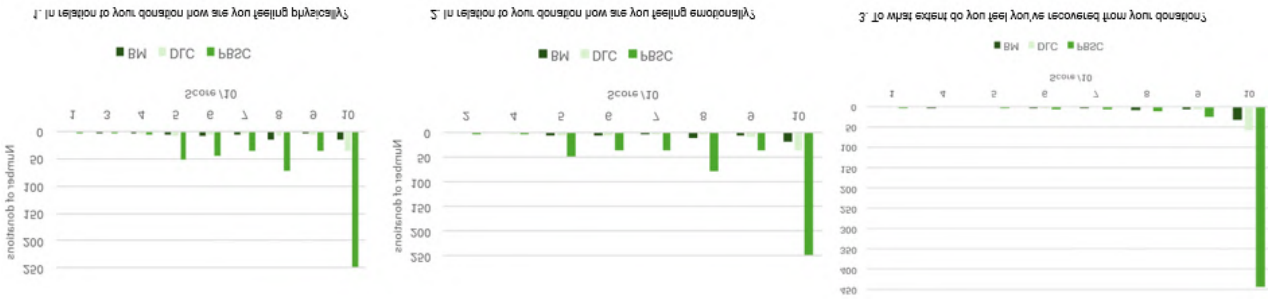


Figure 1. Donor recovery at 30 days

Most PBSC and DLC donors have recovered by 7 days (93.5% / 92.6% respectively) whereas 57.7% BM donors have recovered ($p<0.05$). At 30 days, 97.5% PBSC donors score their recovery >/= 8/10 compared to 91.5% BM donors ($p<0.05$).
96.1% PBSC donors feel emotionally normal or better than normal by day 7 and physically 91.8% are normal or better than normal. Comparatively, 91.0% BM donors feel emotionally normal or better than normal by day 7, only 57.7% physically.
38 ARs were raised relating to potential unexpected or prolonged donor side effects requiring further investigation or management. 12.4% BM donors experience an AR compared to 1.9% of PBSC donations ($p<0.05$). Only one AR was "Common Terminology Criteria for Adverse Events" grade 3 (<1% of BM donations), the remaining ARs were grades 1-2. The median age of donors experiencing an AR is higher (29 years) than in the follow up data (27 years) ($p=< 0.05$). 1.7% of males experience an AR compared to 3.4% females ($p<0.05$).

Conclusions: This data demonstrates excellent recovery for healthy donors to allogeneic transplantation with very low rates of unexpected complications. The recovery from a BM donation is more physically demanding and BM donors are more likely to experience an AR however these remain mild or moderate.

Disclosure: Nothing to declare.

A325

INTEGRATING NGS-BASED GERMLINE MUTATION DETECTION INTO DONOR EVALUATION ENHANCES MYELOID NEOPLASM RISK STRATIFICATION

Apostolia Papalexaxndri[1], Georgia-Maria Koutra[1], Tasoula Touloumenidou[1], Grigorios Salvaras[1], Eirini Dadaki[1], Angeliki Paleta[1], Aikaterini-Georgia Konstantinidou[1], Lamprini Vachtsetzi[1], Fotini Kika[1], Alkistis-Kira Panteliadou[1], Anna Vardi[1], Christos Demosthenous[1], Panagiotis Dolgyras[1], Giorgos Karavalakis[1], Nikos Spyridis[1], Ioanna Sakellari[1], ***Eleni Gavriilaki***[2]
[1]*General Hospital G. Papanikolaou, Thessaloniki, Greece,* [2]*2nd Propedeutic Department of Internal Medicine AUTH, Thessaloniki, Greece*

Background: Expanding recognition of germline predisposition in myeloid neoplasms has underscored the importance of systematic genetic evaluation into the donor selection process. Recent evidence indicates that germline variants and donor-derived clonal hematopoiesis (CH) can influence transplant outcomes. Our study evaluates an NGS-based strategy for detecting clinically relevant germline mutations in donor–recipient pairs to improve risk stratification in the allo-HCT setting.

Methods: Consecutive sibling donor-recipient pairs in AML patients undergoing allo-HCT in CR1 (17) or >CR1 (13) were retrospectively analyzed. Targeted NGS panel was applied to assess germline-predisposing variants, copy number variations (CNVs) and CH in bone marrow samples. Variants were classified according to American College of Medical Genetics and Genomics (ACMG) criteria. Variant Allele Frequency (VAF) patterns were used to infer germline origin. CH was identified based on VAF ≥2%.

Results: Thirty donor-recipient pairs were analyzed. Donor-derived variants included**:** i) CNVs**:** Six donors carried eight CNVs absent in recipients affecting *CEBPA* (n=2), *HRAS*, *TP53*, *ANKRD26*, *DNMT3A*, *KMT2A*, and *GNB1*. ii) VUS: 10 out of 30 donors (33%) harbored 13 VUS in key myeloid genes, including: *CSF3R(2), ANKRD26(2), GATA2(2), ZRSR2(1), TET2(1), PPM1D(1), CALR(1), KMT2A(1), RAD21(1), PRPF8(1).* iii) CH: Three recipients carried CH-associated mutations in *DNMT3A* and *KMT2A*. Of note, 11 low-VAF *BCORL1* variants (2–5.7%) were interpreted either as CH or as experimental artifacts due to background noise and were excluded from further analysis.
Recipient-side analysis included NGS at diagnosis. Five underwent confirmatory buccal/remission testing for the presence of potential germline variants. One donor–recipient pair shared a *CSF3R* variant. Seventeen recipients carried variants with VAF suggestive of germline origin, including four with possible germline *CEBPA* variants requiring further validation.
The median follow-up post allo-HCT was 17 months (range 5-35) and 1-year actuarial OS was 80%. Advanced disease resulted in a relapse rate of 37%(11/30). No cases of donor-derived leukemia were identified. Relapse was less frequent among patients receiving grafts from donors carrying germline VUS (2/11, 18%) compared with patients with donors not

carrying VUS mutations (8/19, 42%). Two relapses occurred after receiving grafts from donors with CNVs and 2 from donors with CH.
Chronic GVHD developed in 15/30 patients and was enriched among recipients of grafts from donors harboring germline VUS (8/15 vs 2/15 without cGVHD), suggesting increased donor–recipient allo-reactivity. No significant associations were identified between donor CNVs, CH and transplant outcomes at this stage.

Conclusions: NGS-based evaluation of donors reveals a substantial burden of VUS and CNVs in genes implicated in myeloid neoplasms. Less frequent relapse and increased GVHD was documented in patients receiving grafts with VUS donor variants not shared with the recipients, supporting a role of donor–recipient genetic disparity in shaping post-transplant immune responses. Although numbers are small, our observations raise the hypothesis that donor-derived germline variation may influence immune dynamics favoring allo-reactivity. Limited follow-up data prevent a comprehensive assessment of post-transplant complications. Further analyses will focus on expanding the cohort and monitoring long-term outcomes. Our data support the consideration of routine NGS screening of sibling donors in line with emerging international recommendations.

Disclosure: This work was in part supported by an investigator-driven grant from Novartis Hellas.

A326

HAPLOIDENTICAL SCT INDUCES LONG-TERM REMISSION IN PATIENTS WITH BPDCN

FengRong Wang[1], *LanPing Xu*[1], *Yu Wang*[1], *YuQian Sun*[1], *ShenMiao Yang*[1], *Pan Suo*[1], *Yang Liu*[1], *XiaoHui Zhang*[1], *XiaoJun Huang*[1]
[1]*Peking University Institue of Hematology, People's Hospital, Beijing, China*

Background: Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is a rare and highly aggressive disorder with dismal survival outcomes of 8-16months. Long-term disease control was only observed after alloSCT. Haplo-donors allows alloSCT in almost every patient and show stronger graft versus tumor(GVT) effect in most haematopoietic disorders. To confirm the benefit, we performed this single center,retrospective study in BPDCN patients who underwent HID-SCT.

Methods: From 2012 to 2025, 50 BPDCN patients received alloSCT in our institute, including 42 HID-SCT, 5 MSD and 3 URD. We analyzed the HID-SCT patients in this study. Diagnosis was confirmed by institute review according to the 2008 World Health Organization classification. All patients received myeloablative conditioning regimen(Bu/Cy-based in 41 and 8Gy TBI-based in 1). GvHD prophylaxis comprised cyclosporine A, MMF and short-term MTX, plus ATG (2.5mg/kg, days -5 to -2).

Results: The median age at SCT was 21(4-67)yrs with male predominantly(69%). Involvement of the skin, bone marrow (BM) and lymph node at diagnosis was observed in 50% of patients, of note there was a higher incidence of extra nodal lesions including sinus

(n=7), bone (n=6), the central nervous system(CNS, n=4), and testis in two boys(see table). 38 patients had chemotherapy(NHL-like in 7,leukemia-like in 31) as 1st line treatment resulting in a high CR rate of 86.8%, the other 4 progressed post surgery with a median interval of 4m. All but one received intrathecal chemotherapy (ITC, median=2) prophylaxis, 4 patients with documented CNS involvement had additional high dose MTX (or variant) before SCT. Thirty-four patients were in CR,4 in PR and 4 not remission at SCT. All patients achieved CR at D30 with full donor engraftment. The median time of neutrophil and platelet recovery were 11(range 10-21) and 13(range 9-33)days. The incidences of acute and chronic graft versus host disease (GvHD) were 44.5% and 55% respectively.
Until Nov 30,2025, the median follow up was 872(60-4947) days post SCT. Three-year overall survival (OS) and progression-free survival (PFS) were both 94.7%. Two patients died of infection and TMA each, resulting the D100 and 1y transplant-related mortality (TRM) of 3% and 6%, respectively. No relapse occurred, and donor stem cell infusion(DSI) proceeded prophylactically on D60 in patients with PD at SCT.
To the best of our knowledge, this is the first report to demonstrate long-term outcomes of HID-SCT for BPDCN with a reasonably large number of patients. The promising results indicated that BPDCN patients can achieve a durable remission with HID-SCT even those with poor disease status beyond CR1, and deserves further evaluation in the setting of prospective trials.

Table Patients characteristics and treatment outcomes

Characteristics	n (range)
Age，Median（range），y	21（4-67）
M:F	29:13
Localization：skin/BM/LN (%)	85.7 / 71.4 /78.6
Skin+BM+LN Skin+BM other：bone/sinus/CNS /testis	21例 （50%） 24例 （57.1%） 6/7/4/2例
BM blast, Median（range）	23（0-95%）
Chemo before SCT， Median（range）	4 (3-13)
ITC Median（range）	2（0-9）
Status @ AlloSCT :CR/PR/PD	34/4/4
Diagnosis to SCT(d) Median(range）	160 (89-495)
HLA Mismatch 1-2 loci/ 3 loci	4 /39
D-R relation sib/parents/children/other	5/23/12/2

Conditioning: Bu/Cy/ATG TBI/CY/ATG BU/FLU/CY/ATG	37 1 4
Graft BM+PBSC/ PBSC	13/29
MNC Median,10^8/kg	8.58 (5.3-17.3)
CD34+Median, 10^6/kg	3.30 (0.74-10.1)
Engraftment, Median (d) ANC BPC	 11 (10-21) 13 (9-33)
F.U	872 (60-4947)

Conclusions: HID-SCT was feasible and with low TRM resulting in excellent survival in BPDCN patients, even in no-remission patients. No one relapsed in this cohort, and this demonstrated the stronger GVT effect and long-term diseased control of HID-SCT in BPDCN patients.

PROBABLE DONOR – RECIPIENT TRANSMISSION OF HEPATITIS E VIRUS WITH A HAEMATOPOIETIC STEM CELL TRANSPLANT. WMDA RECOMMENDATIONS ON HEV ASSESSMENT IN DONORS AND RECIPIENTS

Tigran Torosian[1], *Eefke van Eerden*[2], *David Allan*[3], *Meghann Cody*[4], *Mirjam Fechter*[5,2], *Diane Fournier*[6], *Grzegorz Hensler*[2,1], *Catherine Latour*[7], *Gabriela Marti*[8], *Gayathri Nair*[8], *Jason Oakes*[4], *Lotte Saes*[5], *Hung Yang*[9]
[1]*Fundacja DKMS, Warsaw, Poland,* [2]*World Marrow Donor Association, Leiden, Netherlands (the),* [3]*Canadian Blood Services, Ottawa, Canada,* [4]*NMDP, Minneapolis, United States of America (the),* [5]*Matchis Foundation, Leiden, Netherlands (the),* [6]*Hema-Quebec, Quebec City, Canada,* [7]*Hema-Quebec, Montreal, Canada,* [8]*Blutspende SRK Schweiz, Köniz, Switzerland,* [9]*Stem Cell Donors Australia, Sydney, Australia*

Background: Haematopoietic Stem Cell (HPC) Donors are tested for numerous infection disease markers (IDM) to prevent infection transmission from donor to recipient, according to local and international standards both on verification typing (VT) and physical examination (PE). Some Donor Registries and Donor Centres additionally perform IDM testing on collection day. Hepatitis E Virus nucleic acid (HEV NAT) testing is not a standard in HPC donors but is included in IDM panels in some countries.
Objectives: To evaluate the number of serious adverse (product) events and reactions

(SPEARs) reported to WMDA (World Marrow Donor Association) on collection day donor positive HEV NAT results. To propose recommendations for donor registries, collection and transplant centres on the assessment of donor related risk of HEV transmission based on data revied by WMDA SPEAR Committee.

Methods: In 2025 WMDA was informed through the SPEAR Reporting Tool of a probable case of donor–recipient HEV transmission via a Peripheral Blood Stem Cell (PBSC) product. Reports submitted to the WMDA between JAN 2019 and DEC 2025 were analysed to identify all similar cases. The SPEAR Committee prepared a communication to share details on the case and considerations for HEV testing of donors.

Results: Among 2661 reports, 16 incidents concerned positive HEV PCR on collection day. In 12 cases the products were infused before the results were available with only one case of probable transmission described below.
The donor was asymptomatic during work up and collection, with normal liver function tests and negative for HEV NAT at PE. Routinely performed collection day IDMs were available 3 days post donation and revealed HEV NAT positivity. The TC was informed immediately and initiated serial recipient testing. Recipient became HEV NAT positive approximately 4 weeks post transplantation, apparently caused by HEV transmission with HPC product. To WMDA knowledge the patient remained asymptomatic.
High HEV seroprevalence is defined as >25–30% of the population anti-HEV IgG positive and is seen in many European countries (France, Germany, the Netherlands, Poland) where it is contracted zoonotically as a result of consumption of uncooked or undercooked meat (mostly pork), and in many Asian countries (mostly contracted with contaminated water). There are numerous cases of transfusion-transmitted HEV, which can be dangerous for immunocompromised patients. This has led to the implementation of HEV screening strategies among blood and HPC donors in some countries.

Conclusions: **WMDA SPEAR Committee communication and recommendations:**

- Transplant centres should be aware of the risk of HEV transmission with cellular products.
- Consider HEV testing at PE and day of collection, when donor is from high prevalence area.
- Transplant centres should be aware of collection day IDMs being performed and what IDMs are tested, if results are pending – usually available post product infusion.
- Collection day IDMs should be acquired promptly and in case of positive findings should be communicated to transplant centres immediately.
- Serial HEV NAT should be taken into consideration in case of unexplainable post-transplant liver complications.
- All cases of collection day HEV NAT positive findings should be reported as SPEAR depending on outcome.

CLINICAL PERSPECTIVES ON GERMLINE VARIANTS IN HEMATOPOIETIC STEM CELL TRANSPLANTATION: A NATIONWIDE SURVEY IN JAPAN

Mizuki Watanabe[1], *Junya Kanda*[2], *Yasuhito Nannya*[3], *Takahiro Maeda*[4], *Motohiro Kato*[5], *Takahiro Fukuda*[1]
[1]*National Cancer Center Hospital, Tokyo, Japan,* [2]*Kyoto University Hospital, Kyoto, Japan,* [3]*Institute of Medical Science, The University of Tokyo, Tokyo, Japan,* [4]*Kyushu University Graduate School of Medical Sciences, Fukuoka, Japan,* [5]*The University of Tokyo, Tokyo, Japan*

Background: Hereditary hematologic disorders have increasingly attracted attention and represent a critical consideration in the management of hematologic malignancies, particularly in the context of hematopoietic stem cell transplantation (HSCT). In Japan, insurance-covered panel sequencing for hematologic diseases was launched in 2025, enabling broader identification of germline variants in clinical practice. However, the integration of genetic findings into transplant decision-making remains challenging, and awareness and consensus among transplant physicians have not been systematically evaluated. This study aimed to assess transplant physicians' perspectives, experiences, and perceived challenges regarding the issue.

Methods: A nationwide, web-based questionnaire survey was conducted targeting transplant physicians at Japan Society for Transplantation and Cellular Therapy–certified transplant centers from March to April 2025. Personal invitations were sent to eligible physicians. The survey included questions on awareness of germline predisposition, understanding of clinical genetics terminology, experience with HSCT for inherited hematologic disorders, institutional genetic support systems, and unresolved issues related to donor coordination and confirmatory genetic testing. Responses were analyzed descriptively.

Results: A total of 257 physicians responded (response rate, 30%), including 183 adult hematologists, 70 pediatricians, and 4 from other or mixed specialties. Overall, 79% of respondents worked at institutions providing genomic medicine services. Awareness of germline involvement in inherited hematologic disorders was high (95%), as was recognition of germline contributions to solid tumors (87%). Understanding declined with increasing complexity of genetic concepts, particularly regarding variant pathogenicity classification, interpretation of variants of uncertain significance, and confirmatory testing strategies. Differences were observed between pediatricians and adult hematologists, with pediatricians reporting higher familiarity with inherited hematologic disorders and greater experience incorporating genetic information into clinical decision-making, including HSCT for inherited hematologic disorders than adult hematologists (63% vs. 31%, $p<0.001$). The latter more frequently reported uncertainty regarding genetic interpretation and donor-related genetic evaluation, likely reflecting differences in disease spectrum and prior training or clinical experience.
Access to genetic counseling did not differ significantly between the institutions with established genomic medicine infrastructure and non-genomic centers (99% vs. 97%; $p=0.48$). In contrast, confidence in genetic terminology was significantly higher among physicians working at genomic centers than among those at non-genomic centers (59% vs.

25%, $p<0.001$). Although approximately 40% of physicians reported experience with HSCT for inherited hematologic disorders, no national consensus or standardized framework existed for donor coordination among related donor candidates. The necessity, timing, and scope of confirmatory genetic testing for related donors, as well as counseling strategies and subsequent genetic support for patients and family members, varied substantially by specialty and institutional background, and respondents reported persistent operational gaps in these areas.

Conclusions: As germline variants become an integral part of routine HSCT practice, this survey showed that increasing awareness has not yet translated into uniform clinical implementation in Japan, reflecting structural and educational gaps. While international societies have begun to establish shared principles for genetic risk assessment and donor screening, there remains a clear need in Japan to develop comprehensive frameworks for integrating genomic testing into HSCT, including evidence- or consensus-based guidelines, standardized clinical pathways, and cross-disciplinary education.

Disclosure: Nothing to disclose.

AGE-DEPENDENT CHANGES IN LYMPHOCYTE COMPOSITION OF PERIPHERAL BLOOD STEM CELL GRAFTS FOR ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

Daniel Munárriz[1], Juan Manuel Torres[1], Natalia Egri[1], María Suárez-LLedo[1], Paola Charry[1], Joan Cid[1], Miquel Lozano[1], Enric Carreras[1], Laura Rosiñol[1], Francesc Fernández-Avilés[1], Carmen Martínez[1], Montserrat Rovira[1], ***M Queralt Salas***[1]
[1]*Hospital Clínic Barcelona, Barcelona, Spain*

Background: Younger donor age is a major determinant of allogeneic hematopoietic cell transplantation (allo-HCT) outcomes, consistently associated with lower non-relapse mortality, improved overall survival, and reduced graft-versus-host disease (GVHD). However, the immunological mechanisms underlying this advantage remain insufficiently defined.

The lymphocyte composition of younger donors may influence graft composition and post-transplant immune recovery, but systematic comparisons of these populations in stem cell products remain limited. This study characterizes age-associated differences in lymphocyte subsets in peripheral blood stem cell (PBSC) grafts to identify immunological features that may contribute to the superior outcomes observed with younger donors.

Methods: We conducted a retrospective single-centre analysis of samples collected from consecutive PBSC grafts from healthy related and unrelated donors between 2024 and 2025. All PBSC products were collected after granulocyte colony-stimulating factor (G-CSF) mobilization, and the study samples were cryopreserved immediately after collection. Lymphocyte subsets were quantified using multiparametric flow cytometry. Donor age was

analyzed as a continuous variable and by predefined cut-offs (30, 40, and 50 years). Statistical comparisons were performed using Pearson/Spearman correlations and Mann–Whitney or t-tests, as appropriate.

Results: Thirty-four consecutive PBSC grafts were analyzed. Median donor age was 36 years (range 15–69), 11 (32%) were ≥40 years and 11 (32%) were female.
As described in Table 1, donor age was associated with a clear shift from a naïve-dominant to a more differentiated lymphocyte graft profile. More specifically, increasing donor age correlated with a significant decline in naive CD4+ T cells (r = -0.36, p = 0.037), total CD8+ T cells (r = -0.379, p = 0.027), and naive CD8 T cells (r = -0.526, p = 0.0014). Moreover, double-negative T cells (CD3+CD4-CD8-), also decreased with age (-0.384, p = 0.025). In contrast, no significant age-related differences were observed in NK cells, $CD19^{+}$ B cells, or γδ T-cell populations.

Table 1. Pearson's correlation according to age.

Subpopulation	Correlation	Confidence interval	*p* value
CD3	-0.226	-0.524 - 0.121	0.198

NK56 NK56.dim	0.111 0.077	-0.236-0.433 -0.268-0.405	0.532 0.664
LTreg CD12low TCRalfabeta TCRgammadelta Treg mem Treg naïve Treg Th1 Treg Th17 Treg Th2 Treg Th17	0.0064 -0.265 0.178 0.268 -0.0055 0.0906 0.171 0.393 0.351	-0.349-0.36 -0.554-0.0801 -0.17-0.487 -0.0958-0.568 -0.402-0.305 -0.292-0.449 -0.215-0.512 0.023-0.668 -0.0259-0.64	0.973 0.13 0.313 0.146 0.766 0.646 0.383 0.0387 0.0674

Complementary age-stratified analyses confirmed these findings: donors ≥30 or ≥40 years showed significantly lower levels of naïve CD4⁺ and naïve CD8⁺ subsets compared with younger donors (Figure 1). Effector CD4⁺ and CD8⁺ T-cell populations, as well as total regulatory T cells, did not show significant differences across age groups. However, aging was associated with expansion of more differentiated lymphocyte populations, including Th2-polarized regulatory T-cells (r = 0.393, p = 0.0387) and higher CD4⁺ central memory T-cell frequencies in donors ≥40 years (19.18% vs. 26.93%, p = 0.0317).

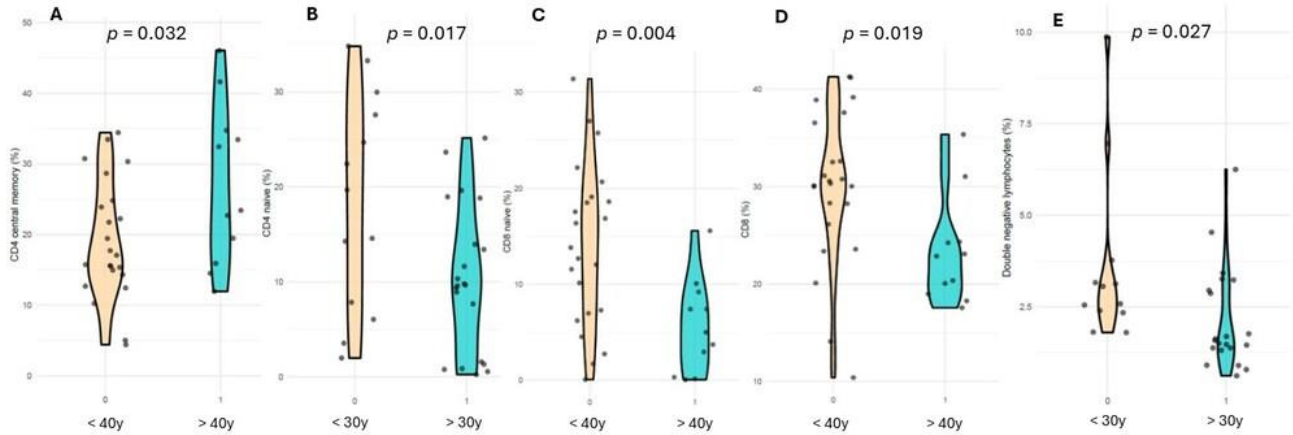

Figure 1. Differences in lymphocyte subsets between donors according to age. A: CD4 central memory; B: CD4 naïve; C CD8 naïve; D: CD8; E: double-negative lymphocytes.

Conclusions: Donor age markedly influenced the immunological composition of PBSC grafts. Younger healthy donors showed a graft profile enriched in naïve CD4⁺ and CD8⁺ T cells and double-negative T cells, consistent with a more plastic and less differentiated immune repertoire that may support robust peripheral expansion during the early post-transplant period and favor more efficient and balanced immune reconstitution. These results offer a biological explanation for the enhanced immune reconstitution, lower immunogenicity, and reduced GVHD risk consistently observed in recipients of younger donors.

Disclosure: Nothing to declare.

A331

CLINICAL VALUE OF ROUTINE BONE MARROW EXAMINATION IN RELATED STEM CELL DONORS

Anders Lillemoen Drivenes[1], *Ingerid Weum Abrahamsen*[1], *Tor Henrik Anderson Tvedt*[1], *Camilla Dao Vo*[1], *Tobias Gedde-Dahl*[1], *Anders Eivind Myhre*[1]
[1]*Oslo University Hospital, Oslo, Norway*

Background: At some transplant centres, bone marrow aspiration is part of the evaluation of potential related allogeneic haematopoietic stem cell transplant (HSCT) donors. We aimed to determine how often morphological bone marrow examination – performed irrespective of blood counts, peripheral smear findings, or known predisposing germline mutations - influenced donor eligibility and whether abnormal findings led to a haematological diagnosis.

Methods: Retrospective audit of medical records of 208 individuals evaluated as potential related donors for adult patients receiving HSCT at Oslo University Hospital between January 2018 and June 2025.

Results: A total of 902 adult transplants were performed during the audit period; haematological malignancies accounted for 94.8% (n=856). Related donors were used in 15.3% (n=138) of procedures.
Of the 208 potential donors assessed, 207 (99.5%) underwent bone marrow aspiration. The cohort included 140 males (67.3%) and 68 females (32.7%). The familial relationship was as follows: 55% siblings, 12% parents, 26% sons or daughters, 1% half-siblings, and 6% unspecified. The median donor age was 37 (16-69) years.
Six (2.9%) of the evaluated individuals were excluded due to bone marrow abnormalities, of which four (1.9%) had abnormal peripheral counts and/or blood smear, and two (1.0%) had isolated bone marrow findings. Four (1.9%) were excluded due to abnormal peripheral counts and four (1.9%) because of non-hematological conditions.
Of the individuals with abnormal bone marrow smears, two were found to carry variants of uncertain significance (VUS), in PDGFRA (n=1and ATRX (n=1). As of August 2025, none of these have developed hematologic disease. One potential donor was later diagnosed with a hematologic malignancy; this individual had a normal bone marrow smear but abnormal peripheral counts and a sibling with a predisposing germline ERCC6L2 mutation.
Out of 208 individuals 194 (93.3%) were cleared as donors while 14 (6.7%) were not cleared, and to date stem cells have been collected from 164 (79.0%).

Conclusions: Among potential related stem cell donors, isolated morphological bone marrow abnormalities led to donor exclusion in only 1% of cases – and no disease was detected in these. Based on these findings, routine bone marrow assessment has been removed from our related donor evaluation protocol. Ready access to unrelated donors means that related donors are typically evaluated only when there is little concern for family predisposition. Although these findings may not be fully applicable to settings with greater

reliance on family donors, morphological assessment alone appears both insufficient - and likely redundant - as a criterion for donor acceptance.

Disclosure: Nothing to declare.

A332

NOT ALL LOW PLATELET COUNTS ARE SPURIOUS: DUTY OF CARE IN CORD BLOOD BANKING

Rachel Pawson[1], *Sonia Kawa*[1], *Ying Li*[1], *Leona Crane*[1], *Anthony Meally*[1], *Bhaskar Rathod*[1], *Yvonne Caffrey*[1], *Abdul Hussain*[1], *Siju Kuriakose*[1], *Christina Coroyannakis*[2], *Alexandra Ross*[1], *Subarna Chakravorty*[3], *Ulrike Paulus*[1]
[1]*NHS Blood and Transplant Colindale Centre, London, United Kingdom of Great Britain and Northern Ireland (the),* [2]*St George's University Hospitals NHS Foundation Trust, London, United Kingdom of Great Britain and Northern Ireland (the),* [3]*King's College Hospital, London, United Kingdom of Great Britain and Northern Ireland (the)*

Background: FACT NetCord standards require cord blood banks to perform a full blood count (FBC) on collected cord blood units (CBUs) and to investigate abnormalities, with notification of the baby's physician when indicated. Low platelet counts in CB collections can arise from clotting within the placenta or cord, but, if ignored, genuine neonatal thrombocytopenia—including congenital thrombocytopenia or fetal/neonatal alloimmune thrombocytopenia (FNAIT)—could be missed. Following consultation with neonatal haematology and general neonatology experts in our collection hospitals, it was agreed that CB units (CBUs) with platelet counts <100 × 10^9/L should be reported to the baby's neonatal physician.

Methods: The NHS Cord Blood Bank (NHS CBB) established a clinical communication pathway whereby CBB staff notify hospital obstetric or neonatal teams when a platelet count of <100 × 10^9/L is identified in a CBU. Hospital teams decide whether the baby requires follow-up blood testing, and the CBB obtains results of any subsequent FBCs. Further clinical information may be requested to inform donor authorisation and the safety of the donation. This study summarises our findings and compares CBU platelet counts with those obtained directly from babies.

Results: Since July 2016, 15,567 CBUs have been collected. The median platelet count was 270 (mean +/- 2SD: 149-391) (Y. Li, personal communication). A total of 111 CBUs (0.7%) had platelet counts <100 × 10^9/L. Of these babies, 68 (61%) had an FBC performed within 48 hours of birth. Twelve babies (18% of those with follow-up) had confirmed thrombocytopenia. Only two of these twelve had been tested before contact by the CBB -one due to hypoglycaemia and one due to clinical illness of unclear cause. In the remaining ten cases, testing was initiated after CBB notification. One of these babies was anaemic, raising suspicion of congenital viral infection. The other nine were clinically well, but three mothers were found to be thrombocytopenic, with immune thrombocytopenia (ITP) suspected.

Conclusions: While clotting in the placenta or cord often explains low platelet counts in CBUs, identifying true neonatal thrombocytopenia is clinically important. Our findings indicate that 18% of CBUs (12/68) with platelet counts <100 × 10^9/L corresponded to genuine thrombocytopenia in the baby. Although common causes of neonatal thrombocytopenia may be clinically evident, rarer conditions such as FNAIT may not be. Because FNAIT has significant implications for future pregnancies, timely notification of low CBU platelet counts represents an important duty of care. Additionally, maternal immune thrombocytopenic purpura was identified in one-third of cases with confirmed neonatal thrombocytopenia, underscoring the value of this communication pathway for both infant and maternal health.

Disclosure: Nothing to declare.

Background: In allogeneic hematopoietic stem cell transplantation (allo-HCT), recipients with high-risk diseases often require a strong graft-versus-leukemia (GVL) effect to prevent relapse. However, this benefit is accompanied by increased risks of graft-versus-host disease (GVHD) and non-relapse mortality (NRM). Therefore, the optimal donor and stem cell source for these patients remain unclear.
An HLA-matched related donor is generally considered the preferred option when available. Nevertheless, allo-HCT with female donor and male recipient (F-to-M) is associated with increased risks of chronic GVHD and NRM, even if an HLA-matched related donor is selected. These adverse effects are thought to result from allogeneic immune responses of female donor cells against Y-chromosome antigens in male recipients.
Taken together, recipients with high-risk diseases may potentially benefit from the enhanced allogeneic response in F-to-M allo-HCT through a stronger GVL effect, although this

advantage may come at the cost of a higher risk of chronic GVHD.
Thus, we evaluated whether the effect of sex-mismatched allo-HCT on clinical outcomes differs according to stem cell source among recipients with high-risk disease.

Methods: We analyzed recipients with high-risk diseases who had received their first allo-HCT from an HLA-matched related donor between 2007 and 2024 in Japan, using Japanese registry database. Their diseases included AML (>CR2 or on disease), ALL (>CR2 or on disease), or CML (>CP2 or on disease). Overall survival (OS) was estimated using the Kaplan–Meier method and compared by the log-rank test. Cumulative incidences of relapse and NRM were compared using Gray's test, treating each event as a competing risk. Multivariable analyses used the Cox proportional hazard model for OS and the Fine–Gray model for cumulative incidences. Hazard ratio (HR) of F-to-M allo-HCT was adjusted for recipient age, donor age, disease type, performance status (PS), HCT-CI, conditioning intensity, year of transplantation, and GVHD prophylaxis.

Results: Focusing on male recipients undergoing bone marrow transplantation (BMT), the 2-year OS was significantly higher in the F-to-M group than that in the M-to-M group (54.4% vs. 35.1%, P= 0.025). Multivariable analysis confirmed that F-to-M allo-HCT was associated with improved OS (HR 0.70; 95% CI 0.51–0.96, P= 0.028). Specifically, NRM did not differ significantly between the F-to-M and M-to-M groups (HR 1.03; 95% CI 0.55–1.96, P= 0.92). However, the relapse risk was significantly reduced in F-to-M allo-HCT (HR 0.66; 95% CI 0.47–0.93, P= 0.018), leading to superior survival.
Among male recipients undergoing peripheral blood transplantation (PBSCT), the 2-year OS did not differ between the F-to-M and M-to-M groups (36.2% vs. 35.2%, P= 0.51). Multivariable analyses revealed that F-to-M allo-HCT was not associated with survival outcomes in the PBSCT cohort (HR 1.15; 95% CI 0.95-1.39, P= 0.16). Although the mild reduction in relapse risk might exist (HR 0.86; 95% CI 0.70–1.07, P= 0.18), this benefit was offset by an increased risk of NRM (HR 1.55; 95% CI 1.10–2.19, P= 0.013).

Conclusions: Male recipients with high-risk diseases might benefit from selecting a female donor through increasing GVL effect when BMT was selected as a cell source, but not when PBSCT was selected.

A335

TRANSIENT ACUTE MYOCARDIAL INJURY DURING G-CSF MOBILIZATION IN HEALTHY PERIPHERAL STEM CELL DONORS: A CASE SERIES

*Francesca Pavanello[1], **Anna Colpo**[1], Andrea Silvio Giordani[1], Ilaria Rigato[1], Claudia Santarossa[1], Anca Irina Leahu[1], Alida Linda Patrizia Caforio[1], Alessandro Lanti[1]*
[1]Padova University Hospital, Padova, Italy

Background: Peripheral blood stem cell (PBSC) donation for allogeneic transplantation is widely used thanks to its established efficacy, safety, and lower procedural burden compared to bone marrow donation. The most frequent G-CSF (*Granulocyte-Colony Stimulating Factor*)

– related adverse events are mild musculoskeletal pain and headache, while severe complications are rarely reported. Cardiovascular effects of G-CSF remain controversial, with sporadic reports of vasculitis, myocarditis and myocardial infarction.We report three cases of acute myocardial injury in otherwise healthy donors.

Methods: We retrospectively collected data of 3 healthy donors (2 related and 1 unrelated) who developed acute myocardial injury during PBSC mobilization with biosimilar filgrastim (10 µg/kg/day for 5 consecutive days), observed at our Department between January 2024 and December 2025. Two donors were aged 21 (one male, one female) and had no cardiovascular risk factors, while the third 54 year-old female donor had hypertension and was overweight. In the same period 67 healthy donors were collected in our institution.

Results: All donors presented to the Emergency Room (ER) because of persistent precordial chest pain starting during mobilization and worsening during and after stem cell collection. In two cases hospital admission was required, while the latter case was discharged by the ER and managed as an outpatient. Laboratory testing showed elevated troponin I levels with "raise-and-fall" kinetics (range 21–237 ng/L, normal value < 12 ng/L in females and < 20 ng/L in males) in all donors, with subsequent normalization. In all cases, ECG was normal at admission and discharge. In the 21-year-old male donor, transthoracic echocardiography (TTE) revealed moderate left ventricular (LV) dilatation with preserved ejection fraction (EF); cardiac MRI confirmed the mild LV dilatation with 46% EF in absence of myocardial/pericardial tissue characterization abnormalities. Holter ECG monitoring, coronary angio-CT and anti-myocardial antibodies were negative. He was discharged without specific therapy; at follow-up LV EF normalized. In the 21-year-old female donor TTE showed preserved biventricular function and mild pericardial effusion that was treated with a short ibuprofen therapy. At follow-up she was asymptomatic and pericardial effusion resolved. The 54-year-old female donor had normal TTE and coronary angio-CT; no arrhythmias were detected at continuous monitoring and troponin levels rapidly decreased. She was discharged with indication to perform cardiac MRI, which is planned.

Conclusions: This is among the first reports of transient myocardial injury in healthy PBSC donors after receiving G-CSF, suggesting a possible association. Cardiovascular adverse events should be considered in the differential diagnosis of donors reporting chest pain during HSCs mobilization, leading to prompt cardiological evaluation. Careful clinical monitoring and multidisciplinary management are crucial. Larger datasets are needed to better define the cardiovascular safety profile, long-term cardiac prognosis and possible mechanisms of myocardial injury of G-CSF in healthy donors.

Disclosure: Nothing to declare

A336

EVALUATION OF RELATED HEMATOPOIETIC STEM CELL DONORS IN THE CONTEXT OF FACT-JACIE STANDARDS IMPLEMENTATION

Leandro Castellanos[1,2], *Marina Mariani*[1], *Milagros Lopez Orozco*[1,2], *Maria Victoria Suen*[1], *Paola Fernandez*[1], *Maria Teresa Oliva*[1], *Cristian Rodriguez*[1], *Martin Milanesio*[1,2], *Virginia Damonte*[1,2], *Maria Emilia Mas*[1,2], *Mercedes de Jesús García*[1,2], *Ana Gabriela Sturich*[1,2], *Juan Carlos Damonte*[1,2], *Evelin Pirazzini*[1,2], *Ana Lisa Basquiera*[1,2]
[1]*Hospital Privado Universitario de Córdoba, Córdoba, Argentina,* [2]*Instituto Universitario de Ciencias Biomédicas de Córdoba (IUCBC), Córdoba, Argentina*

Background: The appropriate evaluation of donors aims for donor safety, product quality, and recipient safety. Our objective was to describe the results of these evaluations in a setting of FACT-JACIE standards implementation.

Methods: Data from related allogeneic hematopoietic stem cell donors between 2019 and 2025 were retrospectively analyzed. Donors were evaluated in the Bone Marrow Transplant and Cellular Therapy Program at Hospital Privado Universitario de Córdoba, Argentina. Data were collected on laboratory studies, type of donation, and associated complications. Both pediatric and adult donors were included.

Results: Between 2019 and 2025, 252 potential related donors were evaluated (median age 36 years; range 3 to 70 years; males 135, 53.6%).
Among mandatory infectious disease screening tests in Argentina, positivity was as follows: syphilis serology, 7 cases (2.8%); Chagas serology, 6 cases (2.4%); HTLV-I/II, 1 case (0.4%); and hepatitis B core antibody (anti-HBc), 1 case (0.4%). No positive cases were detected for HIV (serology and NAT), HCV (antibodies and NAT), HBV (surface antigen and NAT), or brucellosis. All donors with positive results were considered ineligible.
Other relevant test results were as follows: CMV IgG positivity in 222 cases (88.1%), EBV IgG positivity in 241 cases (95.6%), and toxoplasmosis positivity in 61 cases (24.4%).
Of all hemoglobin electrophoresis performed, only one case (1.5%) was heterozygous for sickle cell disease (SCD) and was excluded. This subject presented mild anemia on the blood count.
In total, 15 donors were considered ineligible (5.9%), of which 12 were later deemed suitable to donate after further evaluation and/or treatment of the cause of ineligibility and donated without evidence of recipient-related complications. The remaining three patients were considered not suitable for the following reasons: SCD (also with Chagas positivity), dysfibrinogenemia (also with syphilis positivity), and HTLV-I/II positivity.
Additionally, five donors who were eligible were not suitable for donation due to the following reasons: breast cancer diagnosed during the evaluation, uncontrolled comorbidities, Wolff-Parkinson-White diagnosed during evaluation, positive pregnancy test, and history of antiphospholipid syndrome with pulmonary thromboembolism.
A total of 244 subjects donated for a relative (96.8%): 205 cases by peripheral blood (apheresis; 84.0%), 37 cases by bone marrow (harvest; 15.2%), and 2 cases by both methods (0.8%). Among apheresis donors (median age 38.5 years; range 3–70; 100 females), 22 required more than one apheresis (10.7%), 30 (14.6%) required catheter placement, and 18 (8.8%) received plerixafor in addition to filgrastim. Catheter placement

was more frequent in female donors (26.0% vs 3.7%; p < 0.001).
Overall, significant adverse events occurred in only three cases (1.2%): thrombosis in one patient and bleeding in another, both related to the apheresis catheter and resolved completely without hospitalization; and one donor who required hospitalization for G-CSF–associated bone pain.

Conclusions: Stem cell donation, whether from peripheral blood or bone marrow, is a safe procedure in the context of implementing FACT-JACIE quality standards. The most frequent positive tests in our setting are syphilis and Chagas disease, which did not contraindicate donations. Conversely, detection of SCD was a rare event in our series and among patients with normal hemoglobin levels.

Disclosure: Nothing to declare.

A337

SERIOUS ADVERSE REACTIONS AND EVENTS IN RELATED HAEMATOPOIETIC CELLS DONORS – WMDA COMMUNICATION AND RECOMMENDATIONS ON RELATED DONORS FOLLOW UP AND REPORTING OF SAE

Grzegorz Hensler[1,2], *Eefke van Eerden*[1], *Gayathri Nair*[3], *Tigran Torosian*[2], *Meghann Cody*[4], *David Allan*[5], *Mirjam Fechter*[6], *Diane Fournier*[7], *Catherine Latour*[8], *Gabriela Marti*[3], *Jason Oakes*[4], *Lotte Saes*[6], *Hung Yang*[9]
[1]*World Marrow Donor Association, Leiden, Netherlands (the),* [2]*Fundacja DKMS, Warsaw, Poland,* [3]*Blutspende SRK Schweiz, Köniz, Switzerland,* [4]*NMDP, Minneapolis, United States of America (the),* [5]*Canadian Blood Services, Ottawa, Canada,* [6]*Matchis Foundation, Leiden, Netherlands (the),* [7]*Hema-Quebec, Quebec, Canada,* [8]*Hema-Quebec, Montreal, Canada,* [9]*Stem Cell Donors Australia, Sydney, Australia*

Background: WMDA (World Marrow Donor Association) governs a global biovigilance system for serious (product) events and reactions (SPEAR) reporting that allows submission of SPEARs for unrelated and related haematopoietic cells (HPC) donors. We present data on SPEARs concerning related donors submitted to WMDA.

Methods: SPEAR reports submitted between 31.12.2018 and 28.11.2025 were grouped to show number of reports in related (RD) and unrelated donors (UD), difference in number of reporting organizations, report types, HPC collection methods in the reported incidents, median age of RD and UD that were subject to harm.

Results: Overall, 88 RD reports were submitted by 17 organizations. Number of reports per organisation varied from 1 to 56, with most reporting single incidents. By law, some registries are required to conduct UD and RD follow-up (FU) starting 6 months post donation. All the reports were accepted, but 4 did not fulfil the SPEAR definition. There were 78 Harm to Donor (HtD) reports, 5 Risk of Harm (RoH) and 1 Harm to Recipient (HtR) report. One minor RD was lost to FU until six years when reported chronic and persistent pain and a lump

at the collection site which proved clinically relevant.
Table 1 summarises details on reports.
There were 31 Short Term HtD reports (occurred within 6 months post donation). Two solid tumours diagnosed within the first 6 months of donation were probably present at the time of donation (59-year-old male with kidney cancer and 67-year-old male with a prostate cancer). Two donor deaths – none deemed related to the donation procedure. Among the 47 Long Term HtD reports (>6 months post donation), 32 malignancies were reported (5 haematological and 27 non-haematological). Median age of RD was 47 years.
The number of SPEARs reported for UD was 2402 with 1929 HtD, 340 HtR and 133 RoH reports. There were 917 short term HtD reports, with the most frequent report types presented in table 1. Long term HtD (974) were predominantly malignancies and autoimmune diseases reported per WBMT Minimal Data Set, not related to donation. Median age of UD was 30 years.

Table 1. Summary of incidents reported on related versus unrelated donors	**Related Donors**		**Unrelated Donors**	
Number of reports accepted as SPEAR	84		2402	
PBSC	67 (80%)		1962 (82%)	
BM	10 (12%)		355 (15%)	
MNC	7 (8%)		41 (2%)	
Harm to Donor	78		1902	
Short Term Harm	31		917	
The most frequent types of donor harm	Thrombotic/embolic	6	Infections	192
	Infections (COVID-19)	5	Acute systemic toxicity during mobilization or collection	111
	Cardiovascular	4	Autoimmune disease	82
	Bleeding complications	3	Unnecessary Donor Burden	72

Table 1. Summary of incidents reported on related versus unrelated donors	Related Donors		Unrelated Donors	
	Allergic reaction	3	Allergic reaction	68
	Unnecessary Donor Burden	3	Cardiovascular	42
	Autoimmune disease	2	Mechanical damage	41
	Non-haematological malignancy	2	Non- haematological malignancy	26
	Other	3	Thrombotic/embolic	25
Long Term Harm	47		974	
Autoimmune diseases	12		378	
Malignancies	32		560	
Other	3		36	

Conclusions:

- Reporting of RD SPEAR is considerably smaller than in UD, rather caused by underreporting, especially considering that per WBMT data even up to 53% of transplants are performed using related donors.
- The reports originate mostly from one organisation legally obliged to conduct RD FU and from organisations that facilitate coordination of HPC collection from RD.
- Median age of RD, whose harm was reported, is higher than of UD (47 versus 30 years).

WMDA communication and recommendations on related donor follow up:

- It is essential to conduct follow-ups for all donors, including related, and report all SPEARs.
- Clear protocols of FU should reach minor donors through their guardians, with sensitivity to privacy and consent.

- Follow-up should be age-appropriate, with tools and communication tailored to minors and their families.
- Consider extending the standard 10-year follow-up period until the minor donor reaches the age of majority to ensure the independence of the information collected.

Disclosure: Nothing to declare.

A338

EVOLUTION OF UNRELATED DONOR ACTIVITY IN CHILE: RETROSPECTIVE ANALYSIS OF DKMS DONOR SEARCHES FROM 2018 - 2024

Lorena Cerda[1,2], *Sandra Giovanna Salamanca Pinzon*[1], *Nithya Babu Rajendran*[1], *Cristian Sotomayor*[3], *Angélica Wietstruck*[3], *Paula Catalan*[4], *Nicolás Rojas*[5], *Julia Pingel*[1,6], *Francisco Barriga*[2]
[1]*DKMS Registry gGmbH, Tuebingen, Germany,* [2]*Fundación de Beneficencia DKMS Chile, Santiago, Chile,* [3]*Red Salud UC Christus, Santiago, Chile,* [4]*Hospital Luis Calvo Mackenna, Santiago, Chile,* [5]*Clínica Davila, Santiago, Chile,* [6]*DKMS Group gGmbH, Tuebingen, Germany*

Background: Unrelated donors (URDs) remain essential for stem cell transplantation (SCT) in patients lacking matched sibling donors (MSDs). Despite global growth in donor registries, individuals from ethnically diverse and admixed populations—such as those in South America—remain underrepresented, resulting in reduced match probabilities. DKMS Chile was established in 2018 and has since recruited over 302,000 URDs and facilitated the shipment of 650 stem cell products, including 243 for Chilean patients. The DKMS Registry, active in Chile since 2016, supports nationwide URD searches in collaboration with public and private transplant centers. Beginning in July 2024, all WMDA donors were included in the searches. The main objective is to demonstrate the impact on patients in Chile by analyzing donor activity within the country.

Methods: We performed a retrospective analysis of all DKMS Registry searches for Chilean patients from July 2018– June 2024. High-resolution typing was available for HLA-A, -B, -C, -DQB1, and -DRB1. For each search, the number of 10/10 matched unrelated donors (MUDs) and 9/10 mismatched unrelated donors (MMUDs) was recorded. Searches were categorized by whether they yielded 0, 1, or ≥5 donors. URD SCT activity reported to the WMDA from 2018–2024 was analyzed, comparing use of DKMS Chile versus international donors. Donor utilization trends were also assessed for pediatric SCT in three major Chilean transplant centers (Luis Calvo Mackenna Hospital, Davila Clinica and UC Christus).

Results: During the analyzed period, 586 URD searches were conducted. The proportion of patients without any available MUD or MMUD donors decreased from 21% (July 2018–June 2019) to 17% (July 2023–June 2024). At the same time, searches resulting in at least one available MUD donor increased from 42% to 46%. The number of bone marrow (BM) and peripheral blood stem cell (PBSC) URD products shipped to Chile and reported to the WMDA increased from 5 to 75. In 2024, products shipped by DKMS Chile represented 64% of the

total. Three pediatric transplant centers reported a total of 510 SCT during this period. Utilization of URDs rose from 7% to 56%, while the use of cord blood units (CBUs) declined from 50% to 3% ($p < 0.001$). The proportion of URDs used was evenly distributed between MUD and MMUD.

Conclusions: The establishment of the DKMS Chile donor center and its integration into national transplant programs have contributed to significant improvements in unrelated donor (URD) matching and have supported the expansion of allogeneic stem cell transplantation within the country. The continued growth of a large, locally recruited donor registry—now comprising over 302,000 fully HLA-typed individuals—has led to a steady reduction in the proportion of patients without suitable matches.
While these outcomes are promising, it is crucial to pursue further analysis using larger datasets or more granular methodologies. Nevertheless, considering the persistent underrepresentation of HLA types and the high degree of genetic admixture in South American populations, the Chilean experience provides a scalable model that could inform the development of comparable initiatives throughout the region.

Disclosure: Nothing to declare

A339

EXPANDING DONOR ACCESS IN DEVELOPING COUNTRIES: EXPERIENCE WITH PEDIATRIC HAPLOIDENTICAL STEM CELL TRANSPLANTATION AT A PRIVATE CENTER IN JORDAN

Ayad Ahmed Hussein[1], *Bayan Majed Alaaraj*[1], *Dyala M. Alfryjat*[1], *Ahmed Mahmoud Rawashdeh*[1], *Bayan Amer Habeeb*[1], *Tariq ahmed Abdelghani*[1], *Ala' Al Qhaiwi*[1]
[1]*Bone Marrow and Stem Cell Transplantation Center, Istishari Hospital, Amman, Jordan*

Background: Hematopoietic stem cell transplantation (HSCT) is an established therapeutic modality for a broad range of malignant and non-malignant conditions. Matched sibling donors (MSD) are not frequently available, and access to large unrelated donor registries remains limited in the Eastern Mediterranean region. Haploidentical HSCT (haplo-HSCT) has emerged as an increasingly important alternative, offering rapid donor identification and wider applicability. The introduction of post-transplant cyclophosphamide (PTCy) has significantly enhanced the safety and feasibility of haplo-HSCT. Despite its expanding global use, published data from our region remains limited.

Methods: A retrospective medical file review of all pediatric patients who received haplo-HSCT at the Bone Marrow and Stem Cell Transplantation Center, Istishari Hospital, Jordan, from June 2016 till, June 2025.

Results: Twenty-seven patients underwent 29 T-replete haplo-HSCT with PTCy. The median age was 7.6 (range, 0.6–21) years and 20 (74%) were males. Thirteen patients had acute leukemia, including 6 with acute lymphoblastic leukemia (ALL) and 7 with acute myeloid leukemia (AML). Fourteen patients had non-malignant disorders, including severe aplastic

anemia (SAA; n = 9), hemoglobinopathies (n = 3), and inborn errors of metabolism (n = 2). A parent served as the donor in 80% of transplants. Peripheral blood stem cells (PBCs) were the graft source in 20 transplants (69%). Donor-recipient ABO incompatibility was documented in 8 (28%) and gender mismatch in 19 (66%) transplants. The median infused CD34+ and CD3+ cell doses were 8.4 $\times 10^6$/kg (range1.4–19) and 21.7 $\times 10^7$/kg (range 3.4–48), respectively. Total body irradiation (TBI) was incorporated in the conditioning regimen in majority of the transplants (n=26, 90%), with single fraction TBI of 300 cGy was used in 16/29 transplants (mostly for non-malignant disorders). Engraftment was documented in 26/27 patients with a median of 15 (11–32) days for neutrophil and 21 (13–75) days for platelets engraftment. One patient with SAA had primary graft failure and subsequently engrafted following a second haplo-HSCT.
Post-transplant complications included CMV reactivation (n=12, 41%), EBV reactivation (n=2, 6%), BK virus cystitis (n=2, 6%), adenovirus colitis (n=1, 3%), HHV-6 reactivation (n=1, 3%), mucor mycosis sinusitis (n=1, 3%), central venous line-associated bloodstream infection (n=4, 13%), idiopathic pneumonitis (n=1, 3%), posterior reversible encephalopathy syndrome (n=3, 10%), and pneumatosis intestinalis (n=1, 3%). Only one patient required ICU admission for sepsis and subsequently recovered.
At a median follow-up of 49 months (range 6–109), 20 patients are alive with overall survival of 75%. Notably, survival among patients with non-malignant disorders was excellent (93%). We lost 7 patients, 4 of them due to leukemia relapse. One patient with infantile ALL is still alive and disease-free following an second haplo-HSCT due to disease relapse.

Conclusions: Haplo-HSCT offers a reasonable and effective option for patients lacking MSD, specially in regions with scanty unrelated donors registries. We documented favorable outcome and excellent survival that compares to international data, particularly for patients with non-malignant hematological diseases, highlighting its feasibility and effectiveness in a resource-limited settings.

Disclosure: Nothing to declare.

A340

IDENTIFYING REASONS FOR LOCAL VS INTERNATIONAL UNRELATED DONOR SELECTION IN HEMATOPOIETIC CELL TRANSPLANT IN CANADA

Matthew Seftel[1,2], *Tanvir Hassan*[3], *Hari Maganti*[3], *Patti Wright*[3], *Emma Chartrand*[3], *Debra Bastien*[3], *Yiming Guo*[3], *Meagan Green*[3], *David Allan*[4,3]
[1]*Canadian Blood Services, Vancouver, Canada,* [2]*University of British Columbia, Vancouver, Canada,* [3]*Canadian Blood Services, Ottawa, Canada,* [4]*The Ottawa Hospital, Ottawa, Canada*

Background: Understanding factors impacting unrelated donor selection for allogeneic hematopoietic cell transplantation continues to evolve. An examination of donor usage in for Canadian patients was undertaken to understand what donor factors are prioritized, and why international donors may be chosen in preference to local Canadian donors. Our aim was to inform the optimal recruitment of registrants to the unrelated donor registry at Canadian Blood Services.

Methods: Retrospective cohort study of consecutive unrelated allogeneic donor transplants performed in Canada (excluding Quebec) in 2023.

Results: We identified a total of 500 patients (mean age 51.7 years; 8.2% < 18 years; 62% male) who underwent transplants involving HLA-matched (n=416, 83%) or mismatched unrelated (17%) donors. Indications for transplant were: Leukemias (59.8%), myelodysplasia (17.6%) and other malignant and non-malignant diseases (22.6%). Mean donor age was 28.7 years. Donor/recipient CMV concordance was present in 73% and ABO match or minor mismatch was present in 62%. Selection of Canadian (CDN) donors for CDN patients (n=50, 10% of all transplants) was characterized by a preference for 10/10 HLA-matched, young (≤ 30 years old), male registrants and was positively influenced by availability of donor CMV serostatus and ABO blood group typing at time of initial donor search. In cases where an international donor was used and where an HLA-matched CDN donor option was also present at search, transplant centres prioritized young (≤ 30 years), male, CMV matched donors. ABO matching and HLA-DP-matching appeared as lower priorities in donor selection.

Conclusions: This real world evidence study demonstrated that donor youth (<30), male donor sex, and baseline CMV and ABO serology are important variables associated with domestic donor selection. To best serve the Canadian patient population, HLA matched donors will benefit from CMV and ABO results available as these data will facilitate timely donor selection.

Disclosure: All authors are employees and/or paid consultants with Canadian Blood Services. The authors have no other disclosures.

A341

AN INTERSTING CASE OF DONOR DERIVED LEUKAEMIA POST CORD BLOOD TRANSPLANT

Ememobong Eno Usoro[1], *Robert Wynn*[1], *Ramya Nataraj*[1], *Omima Mustafa*[1], *Claire Horgan*[1], *Srividhya Senthil*[1]
[1]*Manchester Foundation Trust, Manchester, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Donor-derived leukemia and clonal haematopoiesis are rare, often hard-to-recognize complications of allogeneic HSCT with poor prognosis. We report a case of donor-derived JMML with a PTPN11 variant occurring eight months after cord blood transplant for high-risk AML.

Methods: A 13-year-old boy underwent a T-cell–replete 6/8 mismatched cord blood transplant (CBT) with treosulfan-based myeloablative conditioning for high-risk post-transplant relapse of KMT2A-mutated, therapy-related AML in molecular remission. Third-party granulocytes were administered peri-transplant under the GRANS trial to enhance CD8 cytotoxic T-cell expansion and augment the graft-versus-leukaemia effect from the engrafting cord blood. His previous medical history included pre-B acute lymphoblastic

leukaemia (ALL) treated successfully according to UKALL 2019 guidelines, following which he unfortunately developed therapy-related AML with a KMT2A::MLLT3 rearrangement. After achieving molecular remission with debulking chemotherapy, he underwent a matched unrelated donor HSCT with busulfan-based conditioning. He remained in molecular remission with full donor chimerism until a molecular relapse occurred 14 months post-transplant. Following venetoclax-based therapy and renewed remission, he proceeded to a second HSCT as described above.
He engrafted promptly with full donor chimerism. His post-transplant course was complicated by grade 4 biopsy-proven gut graft-versus-host disease requiring multiple therapeutic agents. Secondary to the GVHD process, he developed transplant-associated thrombotic microangiopathy (TA-TMA) and received eculizumab with partial response. Six months post-transplant, he developed progressive leucocytosis characterised by neutrophilia and left-shifted myeloid precursors. Baseline monocytosis gradually increased without circulating blasts. Persistent nucleated red cells were initially thought to reflect consumptive processes in the context of active TMA. Over the following months, his white cell count rose above 100×10^6/L, with chimerism consistently donor in all lineages, unremarkable bone marrow assessments, and persistently negative KMT2A::MLLT3 transcripts. Myeloid NGS identified a PTPN11 missense variant (VAF 46%), establishing a diagnosis of donor-derived JMML. He deteriorated and died shortly thereafter. The DDL event was reported to the cord blood registry for donor follow-up.

Results: Donor-derived leukaemia (DDL) after umbilical cord transplantation is rare but clinically important. Reported prevalence is 80.5 cases per 100,000 transplants, with cumulative incidences of 0.067%, 0.132% and 0.363% at 5, 10 and 25 years after HSCT. Both patient and donor factors appear contributory. Inconsistent genetic screening during donor selection, significant donor germline variants, and acquired donor clonal haematopoiesis within a heavily treated recipient marrow microenvironment all increase risk. MDS and AML are the most frequent DDL subtypes, whereas donor-derived ALL, CML and multiple myeloma are rarely described. This represents the first documented case of donor-derived JMML. Data regarding donor outcomes in DDL are limited and especially difficult to obtain for cord blood donors. Notably, in an EBMT survey, only a modest proportion of donors (8–20%) subsequently developed haematological malignancy on follow-up. These observations highlight the need for systematic long-term monitoring of both recipients and donors to better characterise risks overall.

Conclusions: We document the first donor-derived JMML with a PTPN11 mutation after cord blood transplant. This case underscores diagnostic challenges, the need for awareness of DDL, and the importance of standardised donor genetic screening despite ethical and logistical barriers.

Disclosure: Nothing to declare

P109

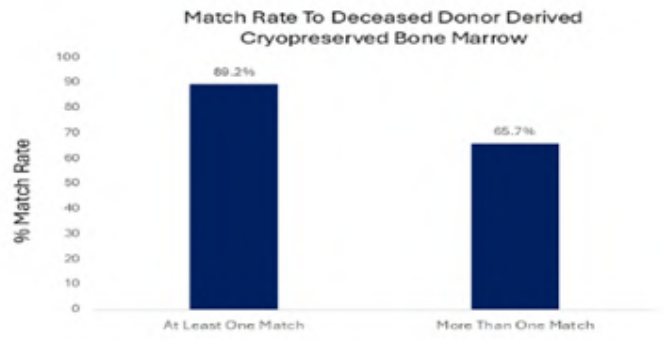
ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION USING DECEASED DONOR DERIVED CRYOPRESERVED BONE MARROW: A POTENTIAL ALTERNATIVE GRAFT SOURCE FOR PATIENTS WITH UNMET NEED

Sagar Munjal[1], *Termeh Shamloo*[1], *Preethi Prasad*[1], *Brian Johnstone*[1], *Erik Woods*[1]
[1]*Ossium Health, San Fransisco, United States of America (the)*

Background: It's been reported that expanding access to allogenic hematopoietic cell transplant (HCT), for patients is feasible as the outcomes of using mismatch unrelated donors (MMUD) along with post-transplant cyclophosphamide are similar to those obtained using a related haploidentical donor. A significant unmet need remains in the timely provision of suitable unrelated donor grafts. An alternative hematopoietic progenitor cell (HPC) graft source obtained from the vertebral bodies (VBs) of deceased organ donors could alleviate many of the obstacles for patients that lack a suitable HLA-matched donor and for high risk patients who require faster HLA-mismatched donor options.
We have developed a GMP compliant process to recover and cryogenically bank HPCs from deceased organ donors (OD). Here we present the results from 988 deceased donors to quantify if unmet needs in patients who require allogeneic transplants can be addressed by an on demand cryopreserved bone marrow product.

Methods: Nineteen clinical sites involved in recruitment of acute leukemia patients who are eligible for allogenic transplant were evaluated to determine the potential for matching to an OD-HPC, Marrow (Cryopreserved) product if a suitable living donor was not available in a timely fashion. Patients who could not find more than three fully HLA matched living donors were evaluated for availability of an OD-HPC product from the bank. The sites participating in PRESERVE I and the HOPE program were evaluated. PRESERVE I is a clinical trial studying safety and efficacy of 4-8/8 HLA-matched HPC, Marrow (Cryopreserved) recovered by organ procurement organizations (OPOs) and shipped to our manufacturing facility for processing. The HOPE program is an expanded access program offered to patients who do not qualify for PRESERVE.

Results: Two hundred and thirty-two patients with hematological malignancies eligible for allogenic HCT treatment were matched to Ossium's cryopreserved HPC, marrow inventory. The match rate was 89.2% (n=207/232). 65.7% of patients matched to more than one cryopreserved product. Donor age ranged from 7 to 55 years old (mean age=36) and average dose available was 5.9M CD34 cells/kg for a 70kg patient.



Conclusions: Since 2024, through our combined efforts, Eleven patients received life-saving bone marrow transplants for whom a suitable living donor was not available. We are partnering with key OPOs to increase the bank size, which will increase access to life saving bone marrow transplants for patients with unmet needs. Timely availability of a HPC, Marrow (Cryopreserved) product obtained from deceased donors can serve as another important option for expanding access to HCT for patients with hematological malignancies and non-hematological conditions. Ongoing clinical studies are evaluating efficacy and safety of this novel, OD-HPC, Marrow (Cryopreserved) product.

FIRST REPORT OF SUCCESSFUL, LIFESAVING AND TIMELY GRAFT RESCUE USING AN OFF-THE-SHELF CRYOPRESERVED, CADAVERIC

MARROW IN TRANSPLANT FOLLOWING UNAVAILABILITY OF A LIVING MATCHED UNRELATED DONOR

*Sumithira Vasu[1], Sarah A. Wall[1], Karilyn Larkin Larkin[1], **Sagar Munjal**[2], Marcos J de Lima[1], Gabriela Sanchez Petitto[1]*
[1]The Ohio State University, Columbus, United States of America (the), [2]Ossium Health, San Fransisco, United States of America (the)

Background: Allogeneic hematopoietic cell transplantation (alloHCT) remains a curative therapy for patients with acute myeloid leukemia (AML) and relies on timely donor availability. When a donor becomes unavailable after conditioning, outcomes can be catastrophic, especially following myeloablative regimens. This case report describes the timely and successful use of cryopreserved, off-the-shelf, hematopoietic progenitor cells (HPC) derived from cadaveric bone marrow (BM), after an unexpected living donor unavailability.

Methods: A 34-year-old male with AML in first complete remission (CR1) began myeloablative fludarabine/busulfan conditioning in preparation for a 10/10 HLA-matched unrelated donor peripheral blood stem cell transplant. On Day -3 of conditioning, the donor experienced a severe allergic reaction to filgrastim, rendering the donor ineligible. Conditioning was interrupted after receiving 3 of 4 planned doses of fludarabine 40 mg/m^2/d and busulfan 131 mg/m^2/d To facilitate faster receipt of an allograft, an emergency request for a cryopreserved HPC-BM product from a deceased donor was submitted. Within 24 hours of request, a 6/8 HLA-matched, bidirectional ABO mismatched marrow graft was chosen among six allograft options and within 72 hours, the product was shipped to the treating institution.
The deceased donor was a 41-year-old White female and 6/8 HLA matched to the recipient. The BM was available as an off-the-shelf product, obtained by harvest from vertebral bodies and processed and cryopreserved via proprietary methods. The product contained 5.57 × 10^6 CD34$^+$ cells/kg.
A fourth fludarabine 40 mg/m2 dose was given and the HPC-BM infusion was infused 48 hours after the planned day 0 and was well tolerated. GVHD prophylaxis consisted of tacrolimus, mycophenolate mofetil, and post-transplant cyclophosphamide.

Results: Neutrophil engraftment was achieved on Day +14 (ANC: D+14 = 1.17 K/µL; D+15 = 5.61 K/µL; D+16 = 10.36 K/µL) with robust platelet engraftment reported by Day +16 (D+16 = 108 K/µL; D+17 = 115 K/µL; D+18 = 138 K/µLDay +30, donor chimerism increased to 61% for CD3$^+$ cells and remained 100% donor in the CD33$^+$ lineage. By day 100, CD3 chimerism increased to 87% and CD33 chimerism remained at 100%. Day 30 and 100 marrow biopsy confirms molecular and morphologic remission with donor-derived hematopoiesis.
The patient developed steroid-responsive grade II acute upper GI GVHD (stage 1) on Day

+27, and Grade 1 skin GVHD responsive to topical therapy.

Fig 1: Patient safety journey

Conclusions: Timely access to an off-the-shelf marrow product prevented catastrophic graft failure or debilitating opportunistic infections. Day 0 was delayed by only 48 hours and the product was identified within 24 hours of request. A clinical trial using cryopreserved, off-the-shelf marrow grafts as primary graft option is underway (NCT #05589896).

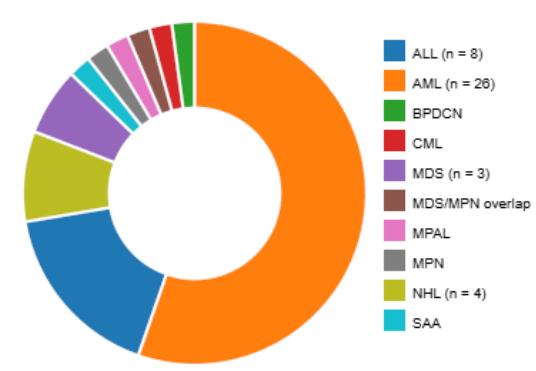
OUTCOMES AFTER HAPLOIDENTICAL STEM CELL TRANSPLANTATION WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE: A RETROSPECTIVE SINGLE-CENTER COHORT STUDY

Jean Gabriel Caurette[1], *Giang Lam Vuong*[1], *Joerg Westermann*[1], *Julia Jesse*[1], *Lukas Anton Schaefer*[1], *Olga Blau*[2], *Lars Bullinger*[1], *Igor-Wolfgang Blau*[1], *Adriane Halik*[1]
[1]*Charité - Universitätsmedizin Berlin, Corporate Member of Freie Universität Berlin, Humboldt Universität zu Berlin, and Berlin Institute of Health, Berlin, Germany,* [2]*Labor Berlin, Charité Vivantes Ltd, Berlin, Germany*

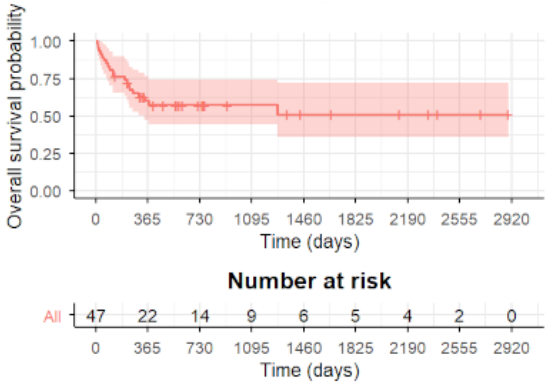
Background: Haploidentical stem cell transplantation (haploSCT) with post-transplant cyclophosphamide (PT-Cy) has broadened donor availability and is increasingly used when a matched unrelated donor (MUD) is unavailable or when urgent transplantation is required. Several studies have shown comparable outcomes between haploSCT and MUD transplantation when PT-Cy-based graft-versus-host disease (GvHD) prophylaxis is used. We report outcomes of all consecutive patients who underwent haploSCT with PT-Cy at a single center in Germany.

Methods: We retrospectively analyzed 47 adult patients undergoing alloSCT from a haploidentical donor at the Charité, Universitätsmedizin Berlin (Germany) between January 2016 and May 2024. Statistical analysis was performed in R version 4.5.2.

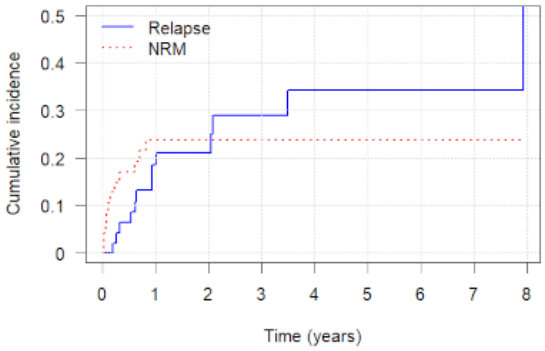
Results:



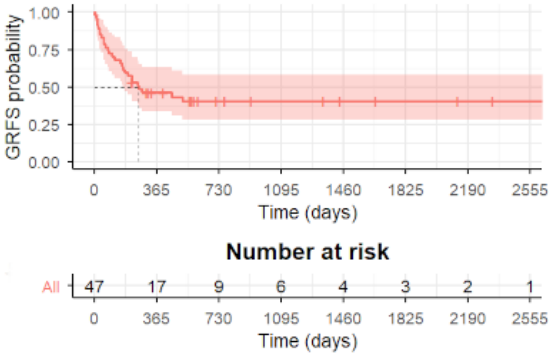
a. Underlying diseases in patients undergoing haploSCT



b. Probablility of Overall Survival



c. Cumulative incidence of relapse and non relapse mortality (NRM)



d. Probability of GvHD-free, relapse-free survival (GRFS)

Median time of follow-up was 25 months (range, 9 days-95 months). The median age at transplant was 41 years (range, 21-67). Donors had a median age of 36 years (range 14-72). AML was the most frequent indication for transplantation (51%), followed by ALL (17%). Patient characteristics are summarized in Table 1, and underlying diseases are displayed in Figure 1a. At the time of transplant, 57% of patients were in complete remission (CR1 or CR2), while 28% presented with relapsed or refractory disease; 19% had previously undergone an alloSCT. High HCT-CI (≥3) was present in 30% of patients, and 23% had a Karnofsky score ≤70%, reflecting a relevant proportion of high-risk candidates. The day 100 cumulative incidence of CMV reactivation was 21%. Acute GvHD (aGvHD) grade II-IV occurred in 27% (95% CI: 13-39%) and grade III-IV in 4% (95% CI: 0-10%) of patients. The 1- and 3-year Cumulative Incidence of Relapse (CIR, Figure 1c) was 19% (95% CI: 7-31%) and 30% (95% CI: 14-46%), respectively. Non-Relapse Mortality (NRM, Figure 1c) at day 100, 6 months, and 1 year was 14% (95% CI: 5-25%), 17% (95% CI: 6-28%), and 23% (95% CI: 11-35%). Overall Survival (OS, Figure 1b) at 1 year and 3 years was 60% (95% CI: 47-77%) and 57% (95% CI: 44-74%), respectively.

Variable	Level	n	%	median	range
HaploSCT Timepoint	2016-2018 2019-2021 2022-2024	13 9 25	28 19 53	-	-
Patient Sex	Male Female	33 14	70 30	-	-
Patient Age (years)	-	-	-	41	21-67
Donor Age (years)	-	-	-	36	14-72
Disease Status before HaploSCT	CR1/CR2 Refractory/relapsed PR n/a	27 13 2 5	57 28 4 11	-	-
CMV Serostatus Match, Donor/Recipient	Negative/Negative Positive/Negative Negative/Positive Positive/Positive n/a	8 4 13 21 1	17 9 28 45 2	-	-
Table 1.	**Patient and Donor Characteristics**				

Conclusions: Outcomes in our cohort were consistent with contemporary reports of PT-Cy-based haploSCT. The relatively low CIR alongside notable early NRM suggests a pronounced graft-versus-leukemia effect, achieved despite a low incidence of severe aGVHD. Importantly, these results were observed in a high-risk patient population with a substantial proportion of relapsed/refractory disease, prior alloSCT, high comorbidity burden (HCT-CI ≥3), and impaired performance status, supporting the feasibility and effectiveness of haploSCT even in this challenging setting. While early NRM remains a key limitation, long-term survival was achievable in patients surviving beyond the early post-transplant period. HaploSCT therefore represents a robust option for patients lacking a suitable MUD or requiring urgent transplantation. Prospective comparative studies are warranted to determine optimal donor choice and refine patient selection for haploSCT.

MANAGEMENT OF GROUP B STREPTOCOCCUS IDENTIFIED DURING STERILITY TESTING OF CORD BLOOD UNITS

Sonia Kawa (Thevarajan)[1], Emma Watkins[2], Kennedy Davies[3], Benjamin Cash[3], Pasco Hearn[1], Christina Kortsalioudaki[4], Alexandra Ross[3], Rachel Pawson[5], ***Ulrike Paulus***[3]
[1]NHS Blood and Transplant, London/Colindale, United Kingdom of Great Britain and Northern Ireland (the), [2]NHS Blood and Transplant, Birmingham, United Kingdom of Great Britain and Northern Ireland (the), [3]NHS Blood and Transplant, Bristol/Filton, United Kingdom of Great Britain and Northern Ireland (the), [4]University College Hospital, London, United Kingdom of Great Britain and Northern Ireland (the), [5]NHS Blood and Transplant, Oxford, United Kingdom of Great Britain and Northern Ireland (the)

Background: All cord blood units (CBUs) collected by the NHS Cord Blood Bank (CBB) undergo sterility testing. Very infrequently, the NHS CBB identifies contamination of CBUs with Group B Streptococcus (GBS).
GBS infection *(Streptococcus agalactiae)* is the most frequent cause of severe early-onset infection in newborn infants. There is no national screening programme for GBS in the UK but, when GBS is identified in pregnancy, UK guidelines require specific follow-up in subsequent pregnancies, to minimise the risk of neonatal GBS infection. The clinical significance of GBS identified on CBU sterility testing is less clear.

Methods: Subject matter experts and stakeholders (microbiologists, neonatologists, NHS CBB medical and laboratory staff) agreed that it was clinically appropriate to share GBS positive results with donor mothers and healthcare staff, retrospectively and prospectively. A communication process had to be developed, considering that the retrospective follow-up period spanned a decade. The donor's current general practitioner (GP) was identified and contacted by NHS CBB medical staff, to provide rationale for contact and explore the most appropriate approach to the donor mother. Where appropriate, medical staff then contacted the mother directly, explained the result and provided patient information. The GP was then updated on outcome of communication and asked to record the results in the mother's record.

Results: From December 2014 to September 2025, 8751 CBUs underwent sterility testing, 259 were bacterially contaminated and of those, 11/8751 (0.13%) were reported positive for GBS (3 month period in 2016 excluded - data unavailable).
8 GPs were contacted for retrospective follow-up. In one case, the GP strictly advised not to contact the mother due to unrelated reasons. For the remaining seven cases, the GP deemed it appropriate to contact the donor mother and this was done as per process described above.
It was possible to communicate with all 7 mothers. They were satisfied with the information provided. No neonatal complications attributed to GBS were reported for the index or subsequent pregnancies.
For two cases, no retrospective follow-up was undertaken: due to a combination of donor not being registered with a GP, together with length of time since donation (9 years) and current maternal age (49 years) (one case). In another case, donation was over 10 years prior to case identification and current maternal age 52 years.

One case was identified prospectively and the mother contacted directly on day 13 post donation

Conclusions: Retrospective identification of relevant cases and communication between GP practices, donors and the NHS CBB were logistically challenging and required a careful step-by-step process. Experience has highlighted the importance of engaging with the GP to avoid potentially inappropriate contact with the donor. Feedback from GPs and mothers has been very positive, and the process has minimised impact on GP workload.
Although risk and impact are low, the NHS CBB has a duty of care to communicate test results that may have clinical significance. Future prospectively identified cases are expected to be managed and donor mothers notified within 6 weeks post cord blood donation.

TP53 VARIANT ALLELE FREQUENCY AS A GENETIC MRD MARKER PREDICTS RELAPSE AND GUIDES SUBTYPE-SPECIFIC THERAPY IN TP53-MUTATED AML/MDS UNDERGOING ALLOGENEIC STEM CELL TRANSPLANTATION

*Yeqian Zhao[1,2,3], Weijie Cao[4], Jimin Shi[1,2,3], Yi Luo[1,2,3], Jian Yu[1,2,3], Lizhen Liu[1,2,3], Xiaoyu Lai[1,2,3], Huarui Fu[1,2,3], Congxiao Zhang[1,2,3], Yi Yu[1,2,3], Yishan Ye[1,2,3], Jiehan Liang[1,2,3], Xin Huang[5], Wei Shi[6], Yang Cao[6], Xiaoxia Hu[7], He Huang[1,2,3], **Yanmin Zhao**[1,2,3]*
[1]Bone Marrow Transplantation Center of the First Affiliated Hospital & Liangzhu Laboratory, Zhejiang University School of Medicine, Hangzhou, China, [2]Institute of Hematology, Zhejiang University, Hangzhou, China, [3]Zhejiang Engineering Laboratory for Stem Cell and Immunotherapy, Hangzhou, China, [4]Department of Hematology, The First Affiliated Hospital of Zhengzhou University, Zhengzhou, China, [5]Department of Hematology, the First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China, [6]Institute of Hematology, Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China, [7]Shanghai Institute of Hematology, State Key Laboratory of Medical Genomics, National Research Center for Translational Medicine at Shanghai, Ruijin Hospital affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China

Background: TP53 mutations occur in up to 20% of acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS) patients, defining a high-risk disease with poor outcomes. Allogeneic stem cell transplantation (HCT) remains the only potential curative option, but relapse due to measurable residual disease (MRD) remains a major challenge. Despite the established prognostic value of genetic MRD in specific AML subtypes (e.g., those with NPM1

or FLT3-ITD mutations), the predictive significance of pre- and post-transplant genetic MRD across TP53-mutated AML/MDS subtypes remains unclear in patients undergoing HCT.

Methods: This multicenter cohort study enrolled 139 adult patients with TP53-mutated AML, MDS, or MDS/AML who underwent their first HCT between September 2016 and April 2024. TP53 variant allele frequency (VAF), as genetic MRD, is assessed using digital droplet PCR. Multiparametric flow cytometry (MFC) is also employed for MRD evaluation. Key endpoints included overall survival (OS), event-free survival (EFS), and cumulative incidence of relapse (CIR). Patients were stratified by disease subtypes (AML and MDS/AML with blasts ≥10% vs. MDS with blasts <10%) and pre-transplant genetic MRD thresholds. The impact of conditioning regimens, including decitabine-based protocols, was analyzed based on MRD status.

Results: When stratified by pre-HCT genetic MRD into three groups (VAF≤0.01%, 0.01–0.1%, and >0.1%), patients with VAF >0.1% had significantly inferior outcomes compared to the other two groups (2-year OS: 55.4% vs. 76.7%/75.0%, p=0.240;2-year EFS: 40.3% vs. 69.7%/75.0%, p=0.028; 2-year CIR: 52.0% vs. 13.3%/0%, p=0.001). After adjustment for confounding variables, pre-HCT TP53 VAF >0.1% remained an independent predictor of worse outcomes (EFS: aHR 3.3, 95%CI 1.5-7.2; CIR: aHR 8.2, 95%CI 2.6-26.2; OS: aHR 2.5, 95%CI 1.0-6.1). Post-HCT VAF >0.01% also independently predicted inferior OS (aHR 2.7, 95%CI 1.2-6.0), EFS (aHR 2.7, 95%CI 1.4-5.0), and CIR (aHR 4.1, 95%CI 2.1-8.2). Dynamic peri-transplant MRD monitoring showed superior prognostic discrimination. Combining genetic MRD with MFC enhanced risk stratification pre-HCT, with dual-positive patients having the worst survival (EFS: aHR 7.0, 95%CI 2.6-18.9; CIR: aHR 30.3, 95%CI 4.5-205.0; OS: aHR 4.5, 95%CI 1.5-13.6).
Clearance of TP53-mutated clones pre-transplant improved survival in AML and MDS/AML (2-year OS: 77.2% vs. 47.2%, p=0.025; 2-year CIR: 12.8% vs. 62.3%, p<0.001) but had no significant impact in MDS. Regarding conditioning regimens, myeloablative conditioning and reduced-intensity conditioning regimens showed no significant survival differences regardless of MRD status. For patients with pre-HCT VAF >0.1%, decitabine- incorporated conditioning reduced 2-year CIR (23.8% vs. 63.4%, p=0.016) with trends toward better EFS (58.9% vs. 32.5%, p=0.072), while no benefit was observed in those with VAF≤0.1%. Melphalan-based conditioning and donor type (haploidentical vs. matched sibling/unrelated) had no significant impact on outcomes across MRD strata.

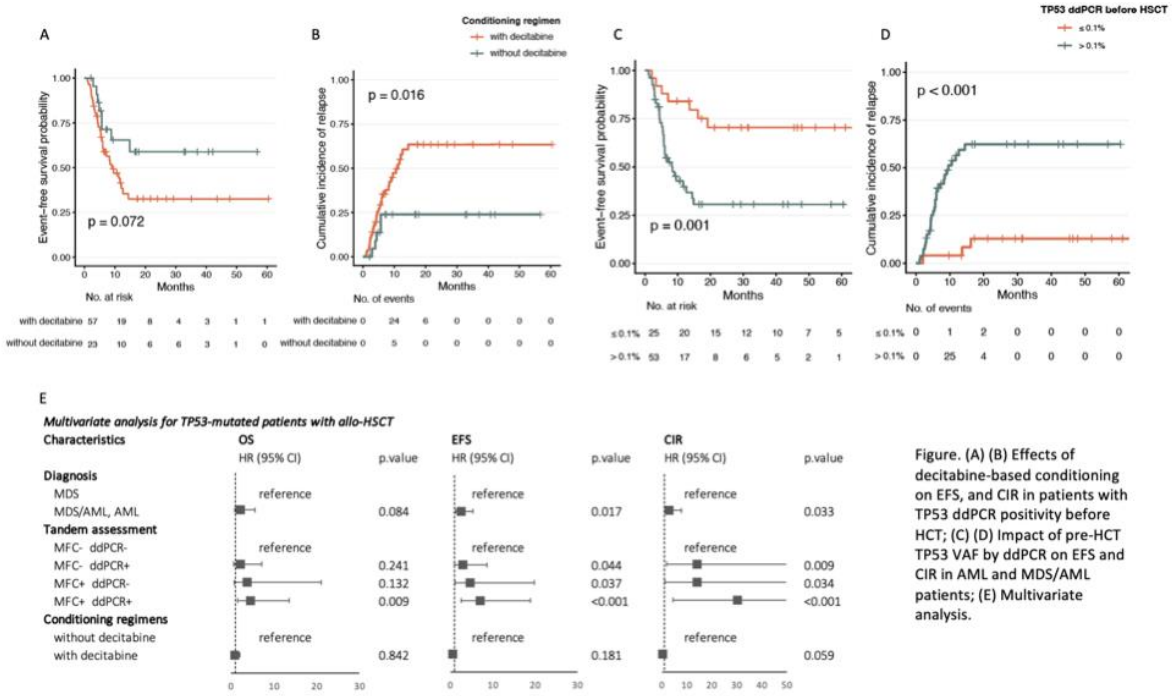

Figure. (A) (B) Effects of decitabine-based conditioning on EFS, and CIR in patients with TP53 ddPCR positivity before HCT; (C) (D) Impact of pre-HCT TP53 VAF by ddPCR on EFS and CIR in AML and MDS/AML patients; (E) Multivariate analysis.

Table. Baseline data of TP53-mutated AML/MDS patients	
Characteristics	**%, median (N = 139)**
Gender Female Male	 42% (58/139) 58% (81/139)
Age at transplantation	52 (Range 15,69)
Diagnosis MDS MDS/AML AML	 27% (38/139) 29% (41/139) 43% (60/139)
Complex/monosomal karyotype	54% (67/123)

Table. Baseline data of TP53-mutated AML/MDS patients	
Characteristics	**%, median (N = 139)**
MFC-MRD	
negative	44% (61/139)
positive	56% (78/139)
TP53-ddPCR before HCT	
≤0.1%	26% (29/110)
>0.1%	74% (81/110)
Conditioning regimen	
MAC	66% (92/139)
RIC	34% (47/139)
with decitabine	26% (36/139)
without decitabine	74% (103/139)
with melphalan	26% (36/139)
without melphalan	74% (103/139)
Donor Type	
MSD	8% (11/139)
HID	84% (117/139)
URD	8% (11/139)
TP53-ddPCR after HCT	
≤0.01%	66% (66/100)
>0.01%	34% (34/100)

Conclusions: Pre-transplant genetic MRD monitoring effectively refines risk stratification in TP53-mutated AML/MDS. Intensive pre-transplant therapy to achieve MRD clearance benefits AML and MDS/AML patients, while early HCT may suffice for MDS regardless of deep MRD clearance. Decitabine- incorporated conditioning reduces relapse risk in patients with high pre-HCT MRD, highlighting the value of MRD-guided regimen selection. Eradicating TP53-mutated clones post-transplant is paramount to improving survival in this high-risk population.

Disclosure: There is nothing to disclose.

Background: Allogeneic hematopoietic cell transplantation (HCT) is an effective treatment option for acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS). Still, relapse of the primary disease remains the leading cause of post-HCT mortality. Current peripheral blood-based standard-of-care surveillance methods, such as CD3 and CD33 lineage-specific chimerism by short tandem repeat–PCR (STR-PCR), have poor sensitivity and lack standardization. Measurable residual disease (MRD) testing, either by multi-flow cytometry (MFC) or molecular methods, provides higher specificity but often requires bone marrow sampling. Thus, both STR-PCR and MRD tests are limited in post-HCT relapse monitoring. AlloHeme (CareDx, Brisbane, CA), a next-generation sequencing (NGS)-based test coupled with a proprietary algorithm, has been developed to predict the likelihood of a relapse.

Methods: ACROBAT study (NCT04635384) prospectively enrolled 162 AML and 65 MDS subjects (total 227) in 11 US sites. Testing was performed at 14 post-HCT time points over 2 years. NGS chimerism was tested in unsorted whole blood, and CD3+ and CD33+ fractions with a limit of detection of 0.02%. The AlloHeme Algorithm utilizes multi-analyte longitudinal chimerism data to determine relapse risk. 32 subjects were excluded due to the occurrence of early post-transplant events (non-relapse mortality (NRM), and relapse), non-compliance with testing regimen or consent withdrawal before the algorithm could be applied (<49 days), resulting in an analytical cohort of 195 subjects. Relapse was determined by the treating physicians per CIBMTR criteria. Here, we present interim 18-month results from the study on the performance of the AlloHeme test for relapse prediction, with the intention of a complete study readout at EBMT 2026.

Results: At the data cut-off date, the median follow-up in the AML and MDS group was 23.4 months (IQR, 10-24). Among the cohort of 195 AML and MDS subjects, 37 (19%) experienced relapse, and 26 (13%) had NRM. The cumulative incidence of relapse was significantly higher in patients who were AlloHeme positive compared to AlloHeme Negatives following 3-, and 6-month landmark time points (Figure 1A). Overall, the AlloHeme test demonstrated high sensitivity (91%) and specificity (92%) for relapse prediction, with a positive predictive value (PPV) of 74% and a negative predictive value (NPV) of 98%. The median lead time from a positive test to clinical relapse was 45 days (IQR: 22-108 days),

with 40% identified at least 60 days before clinical relapse (Figure 1B). Compared with modeling NGS-chimerism at the best STR-PCR sensitivity threshold of 1% increased mixed chimerism or the site-reported multi-flow cytometry-measurable residual disease (MFC-MRD), AlloHeme demonstrated superior test performance in predicting relapse (Table 1).

Figure 1: Landmark analysis at 3 and 6 months shows that the subjects positive for AlloHeme are at increased risk for post-HCT relapse (Panel A). Lead time from AlloHeme positive results to relapse in relapsed AML and MDS patients (Panel B).

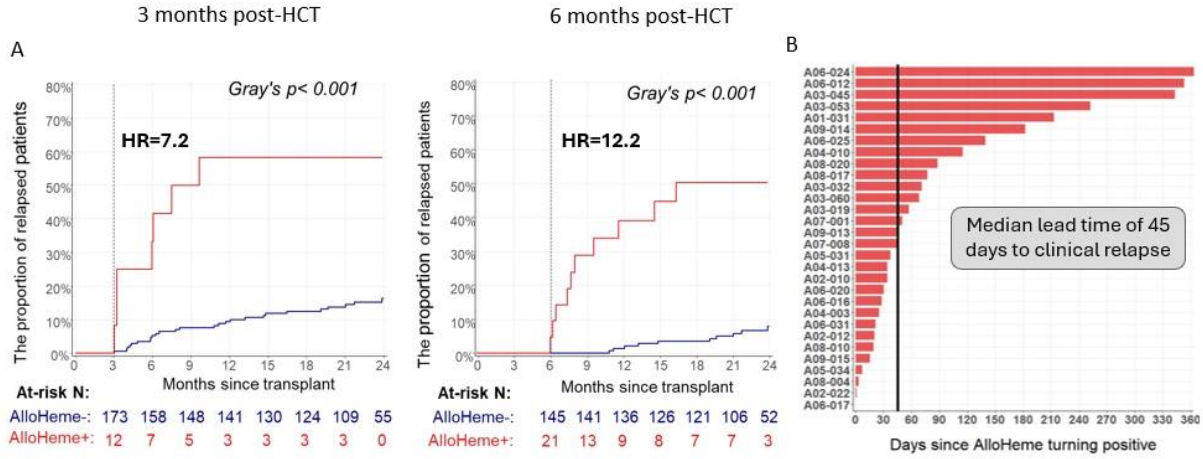

Table 1: AlloHeme test performance compared to other testing modalities

Test	Sensitivity	Specificity	PPV	NPV	AUC	N Relapse	N Total	Lead time to Relapse (Median [IQR] in days) ~	
AlloHeme	0.91	0.92	0.74	0.98	0.88	32	160	45 [22 - 108]	
STR-PCR*	0.50	0.93	0.64	0.88	0.71	32	160	20 [1 - 38]	
BM MFC-MRD**	0.50	0.94	0.72	0.85	0.72	26	104	0 [0 - 11]	
*STR-PCR is an NGS-chimerism modelled at 1% threshold (STR-PCR equivalent).									
**MFC-MRD is based on site-reported bone marrow testing; thus, the analysis set has different N relapse and N total.									

Table 1: AlloHeme test performance compared to other testing modalities

~Lead time to relapse is calculated from the first positive AlloHeme test, the first increasing mixed chimerism of >1% (STR-PCR), or the first positive MFC-MRD test reported at the site.	

Conclusions: ACROBAT interim results demonstrate that AlloHeme monitoring in post-HCT AML and MDS patients can accurately predict relapse with a significant lead time over current relapse-defining criteria, potentially reducing unnecessary bone marrow testing for relapse-free patients while enabling timely interventions by accurately predicting early relapse.

OS17-04

PROGNOSTIC VALUE OF PERI-TRANSPLANT MOLECULAR MRD MONITORING BY TARGETED NGS FOR ALLO-HCT RECIPIENTS WITH FLT3-ITD MUTATED ACUTE MYELOID LEUKEMIA: A MULTICENTER STUDY OF TROPHY GROUP

Background: Relapse remains the primary cause of treatment failure after allogeneic hematopoietic stem cell transplantation (allo-HCT) in patients with FLT3-ITD–mutated acute myeloid leukemia (AML). Dynamic monitoring of measurable residual disease (MRD) offers an early predictor of post-transplant relapse. While PCR–next-generation sequencing (PCR-NGS) is sensitive for FLT3-ITD MRD detection, data in Asian populations are scarce, and its utility to guide conditioning regimens or post-transplant tyrosine kinase inhibitor (TKI) maintenance remains unclear.

Methods: We conducted a multicenter cohort study across three TROPHY group sites in China, enrolling 219 adult FLT3-ITD AML patients in morphologic complete remission undergoing allo-HCT between November 2016 and June 2024. Peri-transplant MRD was systematically assessed using multiparameter flow cytometry (MFC), capillary electrophoresis (CE), and PCR-NGS. The prognostic value of pre- and post-transplant MRD and its utility in guiding conditioning intensity and post-HCT TKI maintenance were evaluated.

Results: Pre-transplant MRD positivity (>0.001%) by PCR-NGS was associated with significantly inferior outcomes compared with MRD-negative patients (2-year RFS: 56.8% vs. 86.5%; CIR: 30.0% vs. 6.9%; OS: 65.9% vs. 88.4%; all $p < 0.001$). Notably, low-level FLT3-ITD (0.001%-0.1%) molecular MRD (M), below the detection threshold of CE, conferred a substantial risk of post-transplant relapses (CE-/M- vs. CE-/M+: 8% vs. 25%, $p < 0.001$). Dynamic peri-transplant assessment incorporating both pre- and post-HCT MRD status provided superior risk stratification compared with static measurements at either time point alone (C-index: 0.76 vs. 0.66 vs. 0.67 for RFS; 0.73 vs. 0.64 vs. 0.67 for OS). Given the dynamic behavior of FLT3-ITD clones, tandem MRD using both PCR-NGS and MFC was assessed. The most favorable outcomes were observed in the MFC-MRD-negative/molecular MRD-positive (F-/M+) group (2-year CIR: 6.4%; RFS: 92.9%; OS: 92.9%), whereas the

poorest outcomes were seen in the double-positive (F+/M+) group (CIR: 45.0%; RFS: 34.3%; OS: 43.1%; all p < 0.001). Among flow MRD-negative patients, molecular MRD further stratified risk (F-/M- vs. F-/M+: CIR 6.4% vs. 23.0%, p=0.024; RFS 88.3% vs. 66.0%, p=0.003; OS 89.8% vs. 73.6%, p=0.024), whereas among molecular-negative patients, flow MRD had no significant prognostic impact. Combined assessment increased negative predictive value (PPV 0.48; NPV 0.89), enhancing relapse exclusion with modest increase in false positives. Among pre-transplant molecular MRD-positive patients, myeloablative conditioning conferred significantly better outcomes than reduced-intensity regimens (2-year RFS: 61.3% vs. 20.0%, p = 0.002; OS: 72.1% vs. 40.0%, p = 0.002). Post-transplant TKI maintenance independently improved survival in pre-transplant molecular MRD-negative patients (OS: aHR 0.3, p = 0.029; RFS: aHR 0.3, p = 0.019), whereas for the molecular MRD-positive cohort, gilteritinib shows a slight trend toward improved RFS compared to sorafenib (no maintenance vs. sorafenib vs. gilteritinib: 38.5% vs. 58.1% vs. 72.7% p=0.065).

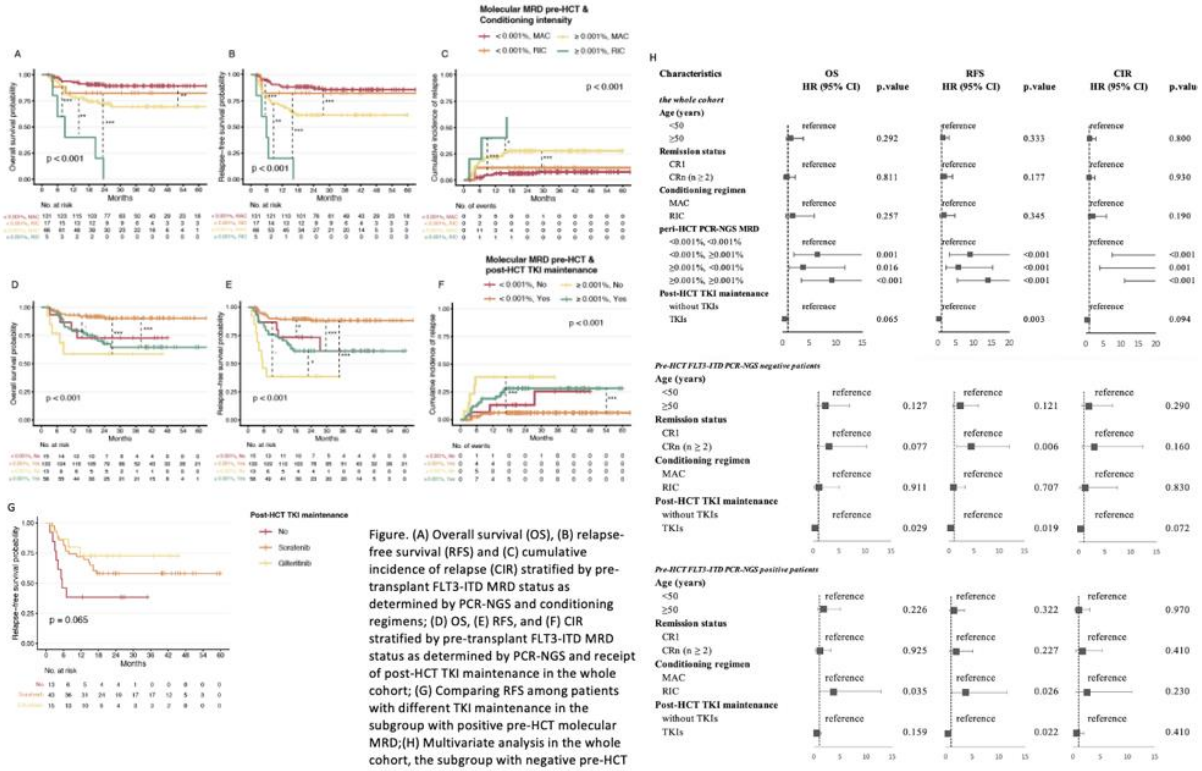

Figure. (A) Overall survival (OS), (B) relapse-free survival (RFS) and (C) cumulative incidence of relapse (CIR) stratified by pre-transplant FLT3-ITD MRD status as determined by PCR-NGS and conditioning regimens; (D) OS, (E) RFS, and (F) CIR stratified by pre-transplant FLT3-ITD MRD status as determined by PCR-NGS and receipt of post-HCT TKI maintenance in the whole cohort; (G) Comparing RFS among patients with different TKI maintenance in the subgroup with positive pre-HCT molecular MRD;(H) Multivariate analysis in the whole cohort, the subgroup with negative pre-HCT molecular MRD, and the subgroup with positive pre-HCT molecular MRD.

Table. Baseline characteristics of FLT3-ITD patients with allo-HCT

Characteristics	all patients (N = 219)	pre-HCT molecular MRD- (N = 148)	pre-HCT molecular MRD+ (N = 71)	p.value
Age (years)	44 (Range 16-67)	44 (Range 16-66)	43 (Range 17-67)	0.700
Gender Female Male	 51% (111/219) 49% (108/219)	 49% (73/148) 51% (75/148)	 54% (38/71) 46% (33/71)	0.800
Remission status CR1 CRn(n≥2)	 87% (191/219) 13% (28/219)	 89% (131/148) 11% (17/148)	 85% (60/71) 15% (11/71)	0.400
MFC-MRD before HCT <0.01% ≥0.01%	 81% (177/219) 19% (42/219)	 86% (128/148) 14% (20/148)	 69% (49/71) 31% (22/71)	0.002
CE-MRD before HCT <0.1% ≥0.1%	 92% (177/192) 8% (15/192)	 100% (123/123) 0% (0/123)	 69% (49/71) 31% (22/72)	<0.001
Conditioning regimen MAC RIC	 90% (197/219) 10% (22/219)	 89% (131/148) 11% (17/148)	 93% (66/71) 7% (5/71)	0.300
Post-HCT TKI maintenance sorafenib gilteritinib without TKIs	 73% (159/219) 14% (31/219) 13% (29/219)	 78% (116/148) 11% (16/148) 11% (16/148)	 61% (43/71) 21% (15/71) 18% (14/71)	0.021

Conclusions: PCR-NGS–based molecular MRD monitoring enables dynamic risk stratification and can inform personalized transplant strategies, including choice of conditioning intensity and post-HCT TKI maintenance, to improve outcomes in patients with *FLT3*-ITD AML.

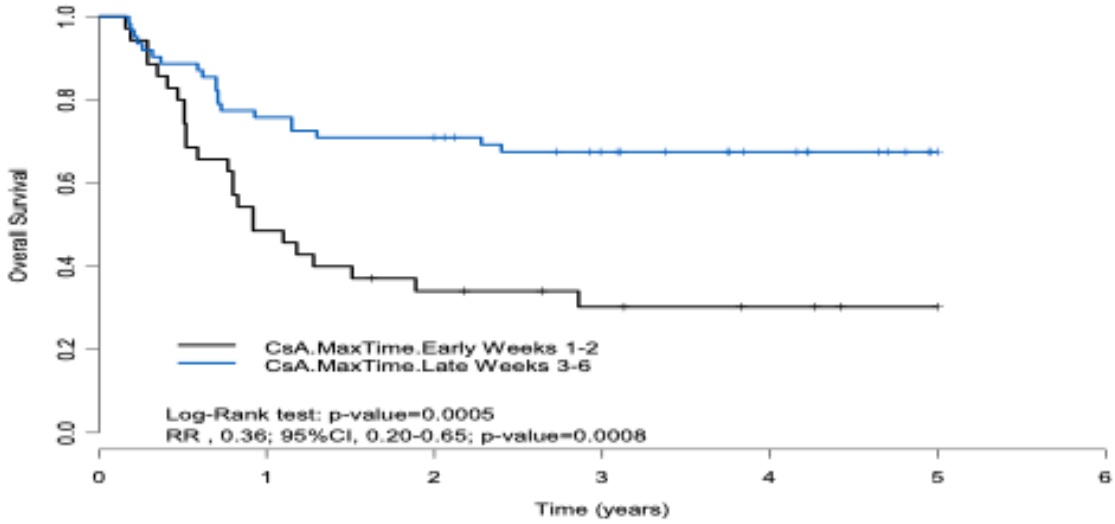
Background:

Ciclosporin is the principal GVHD prophylaxis in allogeneic HSCT, but its use may attenuate the graft-versus-leukaemia (GVL) effect. Although higher ciclosporin exposure has been linked to increased relapse risk, inadequate immunosuppression raises the risk of severe GVHD and associated morbidity and mortality. Target trough levels and treatment duration vary widely between centres due to limited evidence. T-cell–replete cord blood transplantation (TRCBT) offers superior GVHD-free, relapse-free survival (RFS) in AML. We report a multicentre analysis evaluating the association between ciclosporin exposure and relapse in a large, homogeneous paediatric AML cohort undergoing TRCBT. The analysis adjusted for pre-transplant minimal residual disease (MRD) and GVHD, providing guidance for optimal ciclosporin dosing to maximise RFS.

Methods: This retrospective study included all UK paediatric transplant centres and examined patients who received TRCBT for high-risk AML from 2013–2023. Case records provided patient, donor and transplant characteristics; GVHD prophylaxis; ciclosporin trough levels in the first 8 weeks; and outcomes including GVHD, relapse and transplant-related mortality (TRM). The primary endpoint was time to relapse. Associations between relapse and ciclosporin exposure, duration and serum levels at defined post-transplant intervals were assessed using multivariate Cox regression.

Results: The cohort comprised 172 patients, including 82 who were MRD-positive pre-transplant, with a median follow-up of 737 days (range 24–3540). All received ciclosporin and MMF as GVHD prophylaxis; Overall mortality was 40.7%, with nearly three-quarters of deaths occurring in MRD-positive patients. Relapse was the leading cause of death, accounting for 68.7% of deaths in the MRD-positive group and 41.6% in the MRD-negative

group. Median time to relapse was 180 days (range 32–949), with one-third occurring within 6 months. TRM was 13% and represented the main cause of death in MRD-negative patients.



Target ciclosporin trough levels varied substantially across centres (100–350 ng/mL). Patients were grouped by when their peak median levels occurred: early (weeks 1–2) or later (weeks 3–6). Overall survival was significantly better (p=0.0008) in those maintaining higher levels (>150 ng/mL) during the later post-engraftment period (weeks 3–6) and lower levels (<150 ng/mL) earlier. This supports the importance of preserving the early T-cell response to reduce relapse risk, while intensified immunosuppression in weeks 3–6 may reduce GVHD-related mortality without compromising disease control.
On a patient hierarchical clustering heat map, patients with lower ciclosporin levels in the first 2 weeks followed by higher levels thereafter (Cluster 4) showed a trend towards improved overall survival (p=0.05) compared with clusters showing the opposite pattern, underscoring the impact of temporal immunosuppression on outcome.

Conclusions: Lower pre-engraftment ciclosporin levels (<150 ng/mL) were associated with improved OS and RFS, likely reflecting enhanced early cord blood–derived T-cell responses in AML HSCT. Recent work demonstrates that very early T-cell responses during double CBT (DCBT) and granulocyte infusions occur and can control relapse; high ciclosporin exposure during this period suppresses these critical responses. This study shows that a structured, temporally tailored ciclosporin regimen can effectively balance GVHD control with GVL preservation, optimising RFS and OS in high-risk paediatric AML.

MUTATIONAL LANDSCAPE CHANGES OF AML IN PATIENTS RELAPSING AFTER ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

Background: Relapse of acute myeloid leukemia (AML) after allogeneic hematopoietic cell transplantation (allo-HCT) remains a major clinical challenge with poor outcomes. Although relapse biology is influenced by AML molecular heterogeneity and the selective pressures of allo-HCT, the specific mutational and clonal dynamics at relapse and their prognostic significance are incompletely defined. Understanding these dynamics is critical for improving post-transplant surveillance and therapeutic strategies.

Methods: This retrospective, multicenter study analyzed 57 adult AML patients who received allo-HCT at centers in Freiburg (Germany), Toronto (Canada), and Patras (Greece) between April 2005 and March 2024 and subsequently experienced hematologic relapse by December 2024. Paired next-generation sequencing (NGS) myeloid panels (38–84 genes) were performed at diagnosis/pre-HCT and at relapse. Mutational trajectories were categorized as constant, linear, branching, or parallel evolution. Primary endpoints included overall survival (OS) and progression-free survival (PFS), assessed by Kaplan-Meier analysis. Multivariable logistic regression was used to identify predictors of early relapse (<6 months post-HCT).

Results: At relapse, 68% of patients showed genetic instability with acquisition or loss of mutations, predominantly affecting FLT3-ITD, NRAS, and KRAS. In contrast, founder mutations such as DNMT3A and TP53 commonly persisted. Clonal evolution patterns varied: 35% of cases displayed a constant profile, 29.8% linear, 22.8% branching, and 12.3% parallel evolution. Survival analysis revealed that these evolution categories were not significantly associated with OS or PFS. However, timing of relapse was highly prognostic. Patients who relapsed within six months after transplant had markedly reduced OS compared to those with later relapse (p=0.049), regardless of clonal evolution pattern. Increased mutation burden at diagnosis was an independent predictor for early relapse (OR 1.84, 95% CI 1.02–3.33, p=0.04), while branching evolution reduced the odds of early relapse. Low rates of acute and chronic GVHD were seen across the cohort, and salvage therapies were broadly utilized after relapse.

Conclusions: AML relapse after allo-HCT was characterized by substantial genetic and clonal instability. However, the specific mutational dynamics or clonal evolution pattern observed at relapse did not independently impact survival outcomes. The timing of relapse—especially early recurrence within six months post-transplant—was found to be the strongest predictor

of poor prognosis. Increased mutational complexity at diagnosis also elevated the risk for early relapse. These findings highlight the value of intensified molecular monitoring in the early post-transplantation phase and the preferable use of persistent mutations for measurable residual disease (MRD) assessment. Larger studies and integration of multi-omics data are needed to elucidate clonal-immune interactions driving relapse and to inform risk-adapted interventions.

A343

GRANULOCYTE TRANSFUSION DURING CORD-BLOOD TRANSPLANT PRODUCES EARLY, REPRODUCIBLE, EFFECTOR MEMORY CD8+ T-CELL EXPANSION WITH CLINICALLY SIGNIFICANT CLINICAL RESPONSES IN REFRACTORY AML

Nathan Jeffreys[1], *Roisin Borrill*[1], *Claire Horgan*[1], *Omima Mustafa*[1], *Ramya Hanasoge-Nataraj*[1], *Simon Stanworth*[2], *Suzy Morton*[3], *Kay Poulton*[4], *Srividhya Senthil*[1], *Robert Wynn*[1]
[1]*Bone Marrow Transplant Unit, Royal Manchester Children's Hospital, Manchester, United Kingdom of Great Britain and Northern Ireland (the),* [2]*NHS Blood and Transfusion, Oxford, United Kingdom of Great Britain and Northern Ireland (the),* [3]*NHS Blood and Transfusion, Birmingham, United Kingdom of Great Britain and Northern Ireland (the),* [4]*Transplantation Laboratory, Manchester University NHS Foundation Trust, Manchester, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Cord blood transplant (CBT) has been showed to have favourable outcomes in high-risk relapsed/refractory leukaemia compared to other cell sources. The use of CBT has declined, mainly as PTCy has enabled easier access to mismatched family and unrelated donors where there is no matched donor.
We have previously reported on our use of pooled granulocyte infusion to augment the graft vs leukaemia effect during CBT, by promoting an early and transient CD8+ T-cell expansion, associated with a cytokine release syndrome and improved outcomes. Here we extend our report on CD8 donor-derived T-cell expansion early after CBT, and its clinical significance.

Methods: In total, 29 patients with high-risk paediatric leukaemia have received pooled granulocyte infusion in combination with T-replete CBT at our centre (registration: NCT05425043). Lymphocyte subset evaluation was performed at regular timepoints during early post-transplant follow-up. Comparison was made to a cohort of 26 AML patients who received CBT without granulocyte infusion at our centre between 2015 to 2023 for markers

of initial cytokine release syndrome (CRS), engraftment kinetics and clinical outcomes including relapse rates and overall survival.

Results: Donor-derived lymphocyte expansion occurred early post-transplant (prior to day +14) in 22/29 patients, reaching a median peak absolute lymphocyte count of 1.6 (IQR 0.89 – 2.86) at day +9 post-transplant (IQR day +8 to +11). When stratified by lymphocyte subset, early CD3+ and CD8+ expansion was significantly higher than CD4+ expansion. CRS was universally provoked by granulocyte infusion in all patients, with grade 1 CRS in 64% and grade 2 CRS in 28%, however no admission to intensive care was required.
Post expansion, CD8+ contraction was noted with sustained detectable CD8+ levels in all. CD8+ count recovery to within normal range was noted by 3 months in 4/15 (27%), 6 months in 5/13 (38%), 9 months in 5/10 (50%) and 12 months in 7/9 (78%). CD8+ recovery to normal range was associated with improved survival. Graft failure occurred in 5/29 patients, all who did not experience lymphocyte expansion. For the 24/29 patients who achieved engraftment, the 1-year overall survival was 74.8% and the 1-year event free survival was 58.3%. OS in those who did not have early lymphocyte expansion was poor.

Conclusions: The administration of granulocytes during CBT induces a CD8+ biased T cell expansion and clinical CRS in most patients. Following early expansion, CD8+ counts contracted but remain detectable until count recovery, with levels within the normal range for by 1 year in most patients surviving to this time point. The presence of CD8+ response is associated with induction of remission, as has been described by Milano et al. in Seattle where granulocyte infusion has been replaced by pooled, expanded CB units with reports of a similar excellent disease response.
The phenotype switch of these cells, from naïve to memory, suggests that this is antigen-specific T-cell response. This CB derived T cell response might therefore be redirected against tumour antigens, for example by vaccination, and form the basis of a new transplant technology to reduce disease relapse.

Clinical Trial Registry: NCT05425043

Barcelona, Barcelona, Spain, [3]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Spain, [4]Universitat de Barcelona, Barcelona, Spain, [5]Fundació i Institut de Reserca Josep Carreras Contra la Leucèmia, Barcelona, Spain

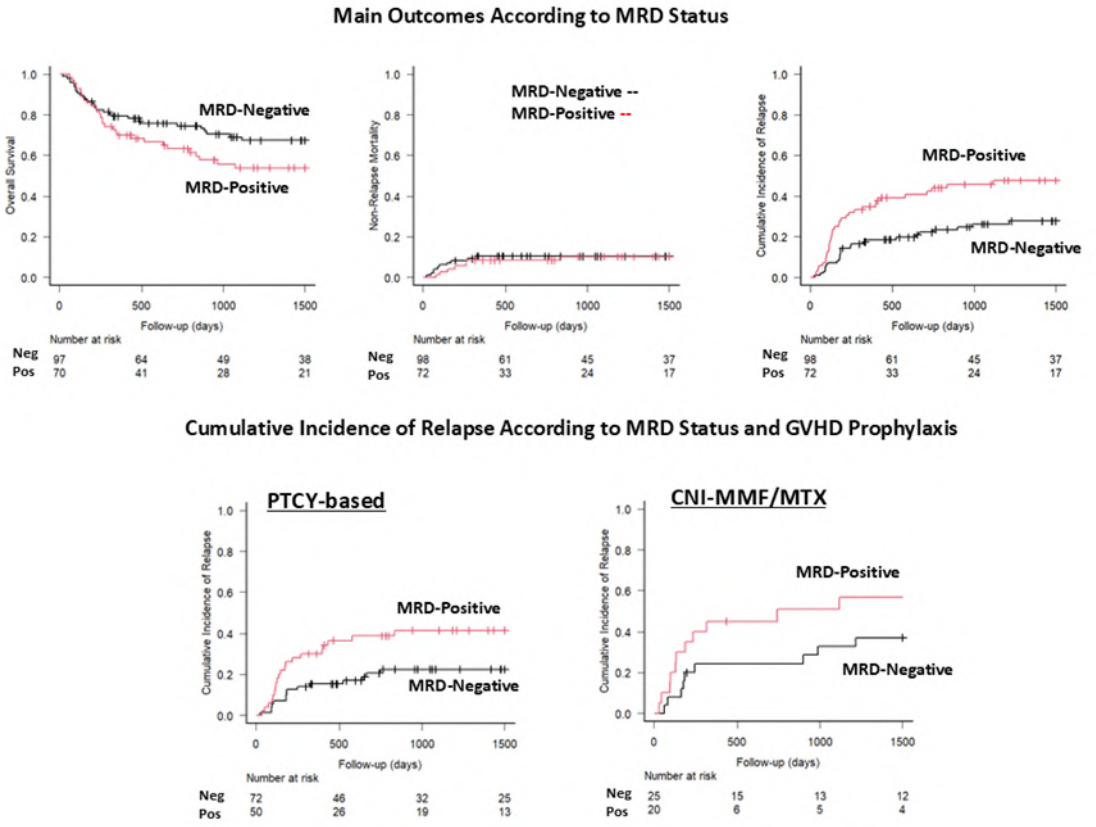
Background: Allogeneic hematopoietic cell transplantation (allo-HCT) remains a curative treatment for patients with acute myeloid leukemia (AML), with substantial expansion of its use secondary to reductions in transplant-related toxicity and advances in supportive care. Measurable residual disease (MRD) before transplantation is considered a key prognostic factor, but lack of standardized assessment limits its consistent application. In parallel, post-transplant cyclophosphamide (PTCy) is being widely used for graft-versus-host disease (GVHD) prevention by substantially reducing chronic GVHD, although concerns persist about potential effects on relapse. This study evaluates the prognostic impact of pre-transplant MRD in AML patients undergoing allo-HCT in complete remission (CR) and explores whether PTCy use impacts on relapse risk.

Methods: The 167 consecutive adults with CR AML with available pre-transplant MRD data who underwent their first allo-HCT between 2014 and 2024 at our center were included. MRD assessment was performed by multiparameter flow cytometry and, when applicable, molecular techniques. MRD positivity was defined as any detectable residual disease. Disease relapse was defined as any morphologic or molecular recurrence of disease after allo-HCT in patients who had previously achieved CR. This definition was adopted due to its direct implications for clinical practice in the allo-HCT setting.

Results: Median age was 53 years, and 70 (41.9%) patients were MRD-positive at transplant. Baseline characteristics were largely balanced except for a higher proportion of HCT-CI >3 among MRD-positive patients. Most patients (n=122, 73.1%) received PTCy-based GVHD prophylaxis, and 89 (53.3%) underwent reduced-intensity conditioning.
Rates of acute and chronic GVHD were similar between MRD groups. Overall, 55 patients (32.9%) experienced relapse (48 morphological and 7 molecular), occurring more frequently among MRD-positive individuals (44.3% vs. 24.7%, p=0.008). As shown in **Figure 1,** , cumulative incidence of relapse (CIR) at 3 years was higher in MRD-positive patients (45.7% vs. 26.1%, p=0.006), while non-relapse mortality remained comparable (10.1% vs. 10.2%, P=0.884). Three-year overall survival (OS) was inferior in MRD-positive compared with MRD-negative recipients (53.8% vs 69.0%, p=0.044).
In multivariate analyses (**Table 1),** MRD positivity independently predicted increased relapse risk (HR 2.27, p=0.005) and inferior OS (HR 1.83, p=0.023). High/very-high Disease Risk Index also conferred adverse outcomes, whereas PTCy remained independently associated with improved OS (HR 0.46, p=0.013). Conditioning intensity, donor type, and HCT-CI did not significantly influence relapse or survival.
Lastly, we further analyzed outcomes according to GVHD prophylaxis showing that the negative effect of MRD positivity on relapse risk persisted regardless of prophylactic strategy. Among patients receiving PTCy, the 3-year CIR was 41.4% in MRD-positive vs. 22.3% in MRD-negative patients. In those not receiving PTCy, rates were 50.8% and 32.7%, respectively **(Figure 1).**

Table 1. Impact of Pre-Transplant MRD Status on Outcomes

Univariate Analysis	**OS HR (95% CI)**	**P value**	**CIR HR (95% CI)**	**P value**
MRD Detection Positive (vs. Negative)	1.65 (1.01-2.71)	0.046	2.01 (1.19-3.40)	0.008
Diagnosis of mod-sev cGVHD Time-Dependent	0.67 (0.25-1.80)	0.433	0.54 (0.17-1.68)	0.290
Multivariate Analysis	**OS HR (95% CI)**	**P value**	**CIR HR (95% CI)**	**P value**
MRD Detection Positive (vs. Negative)	1.83 (1.08-3.10)	0.023	2.27 (1.27-4.03)	0.005
GVHD Prophylaxis PTCy-based (vs. others)	0.46 (0.25-0.85)	0.013	0.59 (0.31-1.17)	0.110
Age Continuous (Range)	1.01 (0.97-1.03)	0.856	0.99 (0.96-1.02)	0.630
HCT-CI > 3 (vs. 0-3)	1.32 (0.75-2.30)	0.330	1.28 (0.72-2.29)	0.390
Disease Rik Index High-Very High (Low-Intermediate)	4.54 (2.56-8.04)	<0.001	3.85 (2.01-7.45)	<0.001
Conditioning Regimen RIC (vs. MAC)	1.62 (0.74-3.55)	0.222	2.01 (0.85-4.71)	0.11
Donor type MMUD/Haplo vs. HLA-matched	1.05 (0.55-2.03)	0.866	0.60 (0.29-1.24)	0.17



Conclusions: Pre-transplant MRD positivity remained a strong and independent predictor of relapse and mortality after allo-HCT in AML. The prognostic relevance of MRD was consistent across GVHD prophylaxis regimens, and PTCy did not increase relapse risk while providing a survival advantage. These findings support systematic MRD assessment before transplantation and reinforce the use of PTCy for GVHD prevention without compromising disease control.

AZACITIDINE MAINTENANCE AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION IN HIGH-RISK AML: A SINGLE-CENTER RETROSPECTIVE STUDY

*Federica Ardizzoia[1,2], Francesco Iannotta[1], Francesco De Felice[1,2], Francesco Barbato[1,2], Marcello Roberto[1,2], Margherita Ursi[1,2], Gabriele Fontana[1,2], Michele Loffredo[1], Enrica Tomassini[1], Gianluca Storci[1], Serena De Matteis[1], Barbara Sinigaglia[1], Luca Zazzeroni[1], Elisa Dan[1], Elena Campanini[1], **Sadia Falcioni**[1], Enrico Maffini[1], Massimiliano Bonafè[1,2], Francesca*

Bonifazi[1]
[1]IRCCS Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy, [2]University of Bologna, Bologna, Italy

Background: Disease relapse remains the main cause of allogeneic hematopoietic stem cell transplantation (allo-HSCT) failure in high-risk acute myeloid leukemia (AML). Maintenance strategies with hypomethylating agents are under investigation, with heterogeneous results.

Methods: This single-center retrospective matched case-control study enrolled adult patients (≥18 years) with high-risk AML undergoing allo-HSCT between 2018 and 2025. All patients in the AZA cohort received post-transplant azacitidine maintenance (37.5–75 mg/m²/day subcutaneously, days 1–5 every 28 days) for 24–36 cycles, starting between 35- and 120-day after allo-HSCT. High-risk AML was defined as adverse-risk disease according to ELN2017 or ELN2022 criteria; primary refractory disease; ≥5% blasts or ≥1% measurable residual disease by multiparameter flow cytometry (MFC-MRD) and/or droplet digital polymerase chain reaction (PCR-MRD) at the start of conditioning; second or subsequent allo-HSCT; ≥0.1% MFC-MRD and/or PCR-MRD within 120-day after allo-HSCT. Hematologic engraftment, complete remission (CR), ECOG score 0-2, no uncontrolled infection, and no active grade 2-4 acute Graft versus Host Disease (aGvHD) were required. FLT3-ITD mutated AML was excluded. Outcomes of the AZA cohort were compared with those of a matched historical control group that did not receive maintenance therapy (NO AZA cohort). Primary endpoints were overall survival (OS) and relapse-free survival (RFS).

Results: The AZA cohort included 29 patients as reported in Table 1. With a median follow-up of 18 months (95%CI, 12–25), 2-year OS, RFS, cumulative incidence of relapse (CIR) and non-relapse mortality (NRM) were 69% (95%CI, 48–98), 60% (95%CI, 40–88), 40% (95%CI, 16–65), and 0%, respectively. Patients received a median of 12 cycles (2–25) of azacitidine, with discontinuation in 13 patients, mainly due to relapse (28%). Treatment was well tolerated; the most common adverse events were constipation (62%), nausea (55%), neutropenia (grade 3–4, 41%) and thrombocytopenia (grade 3–4, 14%). Infections occurred in 52% of patients (grade 3–4, 21%). The median time to relapse was 13 months (95%CI, 4–22), and predominantly involved (67%) TP53 mutated and/or complex/monosomic karyotype AML. During maintenance, 14% of patients received additional therapy due to MRD relapse/persistency: azacitidine ± donor lymphocyte infusion ± venetoclax. The comparison between the AZA cohort and the NO AZA cohort (n=21), with similar characteristics at baseline except for a higher frequency of MFC-MRD ≥ 1% in the AZA cohort (p=0.026) (Table 1), showed no significant differences in OS (p=0.72) nor RFS (p=0.95). Similarly, CIR (p=0.50), NRM (p=0.16), grade 2-4 (p=0.96) and grade 3-4 (p=0.69) aGVHD, any grade (p=0.97) and moderate-severe (p=0.69) cGvHD, were comparable. In the overall study population (n=50), multivariable Cox regression analysis identified advanced disease (AD) and TP53 mutation associated with worse OS (AD: HR=2.91, p=0.06; TP53mut: HR=6.68, p=0.004) and RFS (AD: HR=3.41, p=0.01; TP53mut: HR=4.61, p=0.01). Subgroup analysis showed no benefit from azacitidine maintenance in any high-risk category (TP53mut, CMK, AD, reduced-intensity conditioning).

CLINICAL OUTCOMES OF AZACITIDINE–VENETOCLAX IN RELAPSED AML AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION: A RETROSPECTIVE STUDY OF THE ASOVASNA CELLULAR THERAPY GROUP

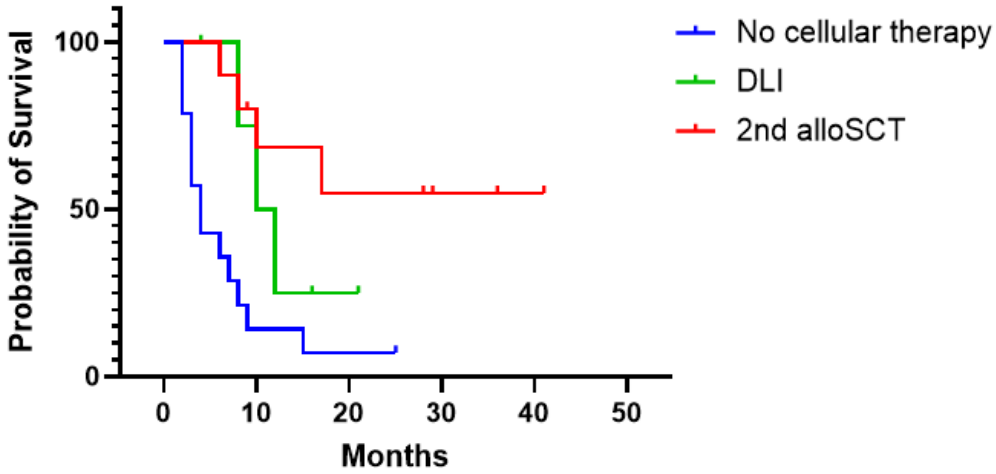
Candela Ceballos[1], Nerea Arratibel[1], Guillermo Martín Sánchez[2], José Antonio Flores Garcia[2], Juan Manuel Cerezo Martin[2], Mercedes Colorado[2], Sara Villar[3], Maria Panizo[3], Jose Rifón[3], Itziar Oiartzabal[1], Hodei Arrizabalaga[1], Carlos Panizo[1], ***Maria de la Cruz Viguria***[1]
[1]Hospital Universitario de Donostia, San Sebastián, Spain, [2]Hospital Universitario Marqués de Valdecilla, Santander, Spain, [3]Clínica Universitaria de Navarra, Pamplona, Spain*

Background: Azacitidine plus venetoclax (Aza/Ven) is a standard frontline therapy for newly diagnosed AML in unfit patients; however, its role in relapsed AML after allogeneic hematopoietic stem cell transplantation (alloHSCT) remains unclear. Outcomes in this setting are poor, and therapeutic options are limited. We evaluated the efficacy and safety of Aza/Ven, alone or combined with cellular therapies, in patients with relapsed AML after alloHSCT.

Methods: We conducted a retrospective multicenter study including patients with first relapse of AML after alloHSCT treated with Aza/Ven ± cellular therapy between October 2021 and December 2025. Overall response rate (ORR; CR/CRi per ELN 2022) and overall survival (OS) were assessed. Safety and factors affecting treatment tolerability were analyzed.

Results: Thirty-three patients received Aza/Ven as first-line therapy for post-transplant relapse. Donor types included matched related (30%), matched unrelated (24%), mismatched unrelated (42%), and haploidentical donors (4%). Patients exhibited a high-risk genetic profile, predominantly with myelodysplasia-related mutations involving SRSF2, ASXL1, RUNX1, IDH1/2, DNMT3A, TET2, STAG2, and BCOR. TP53 mutations and complex or monosomic karyotypes were mainly observed in therapy-related and secondary AML. The median time to relapse was 7 months (range, 1–190), with 48.5% occurring within 6 months post-transplant. Clonal evolution was detected in 51% of cases. The mean bone marrow blast percentage at relapse was 14.3%. One patient presented with extramedullary relapse (sarcoma).Full-dose azacitidine was administered in 94% of patients, while venetoclax dosing was adjusted according to antifungal prophylaxis and cytopenias or patient frailty. The median number of treatment cycles was 3 (range, 1–13). Cellular consolidation included second alloHSCT (30%) or donor lymphocyte infusion (DLI, 36%); 34% did not receive cellular therapy, mainly due to active GVHD or rapid disease progression.
The ORR was 57.6%, and the median OS was 9.4 months. Median OS differed significantly by treatment strategy (p=0.001), reaching 17.3 months after second alloHSCT, 10 months with DLI, and 4 months without cellular therapy. In the adjusted Cox regression model, consolidation with 2nd alloHSCT was associated with a significantly reduced risk of death (HR 0.20; 95% CI, 0.06–0.63; p=0.006), while DLI demonstrated a trend toward benefit (HR 0.37; p=0.059).

Cytopenias and infections were the most common adverse events, frequently requiring treatment modifications, including dose adjustments, delays, or interruptions. Severe infections occasionally led to treatment interruption. GVHD was observed in 2 of 11 patients receiving DLI.



Conclusions: This analysis suggests that Aza/Ven may serve as an effective therapeutic backbone for patients with relapsed AML after alloHSCT, particularly when used as a bridge to cellular consolidation. Consolidation with cellular therapies, especially second alloHSCT, was associated with improved survival outcomes. Prospective studies are warranted to define optimal patient selection and consolidation strategies.
Although Aza/Ven is generally well tolerated, the high incidence of infections and cytopenias frequently requires dose adjustments and close monitoring to optimize treatment adherence and clinical outcomes.

OUTCOMES OF SECOND ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION USING POST-TRANSPLANT CYCLOPHOSPHAMIDE AND A DIFFERENT DONOR AFTER RELAPSE FOLLOWING A FIRST ALLOGRAFT: A SINGLE-CENTER RETROSPECTIVE STUDY

Lucía Castilla García[1], *Rebeca Bailen Almorox*[1], *Ignacio Alberto Gomez Centurion Luna*[1], *Maria José Llácer Ferrandis*[1], *Íñigo Gastaminza Láinez*[1], *Javier Bañón Soria*[1], *Julia Parra Serrano*[1], *Paula Berigüete Mora*[1], *Santiago Álvarez López*[1], *Cristina Muñoz Martínez*[1], *Santiago Sabell Stewart-Howie*[1], *Javier Anguita Velasco*[1], *Carolina Martínez Laperche*[1], *Ramón García Sanz*[1], *Mi Kwon*[1]
[1]*Hospital General Universitario Gregorio Marañón, Madrid, Spain*

Background: Relapse after allogeneic hematopoietic stem cell transplantation (allo-HSCT) remains the leading cause of treatment failure in patients with hematologic malignancies. A second allo-HSCT represents a potentially curative option for selected patients; however, it is associated with substantial toxicity, non-relapse mortality, and a persistent risk of disease recurrence. Real-world data on long-term outcomes after second allo-HSCT remain limited, particularly in the PT-CY era. We report our single-center experience with second allo-HSCT performed after relapse following a first allograft.

Methods: A unicentric retrospective study was conducted including adult patients who underwent a second allo-HSCT due to hematologic malignancy between 2012 and June 2025 after relapse following a first allograft. Data were collected from institutional databases and medical records. The choice of conditioning intensity for the second allo-HSCT was based on disease status, prior transplant-related toxicity, and comorbidity burden. In all cases, a donor distinct from the one used for the first allo-HSCT was selected. In patients who had previously received a haploidentical transplant, a different haploidentical donor was selected based on the results of HLA loss studies in the relapsed underlying disease. PBSC were used as stem cell source and GVHD prophylaxis consisted on PT-CY administered on days +3 and +4, followed by a calcineurin inhibitor (CNI) and mycophenolate mofetil (MMF) in all cases.

Results:

N	34
Age, median (range)	42 (22–67)
Male sex, n (%)	18 (53%)
Diagnosis/status before HSCT2, n (%)	Acute leukemia (AML/ALL): 22 (65%) CR MRD− 9 | CR MRD+ 6 | Active 7 MDS: 3 (9%) – Active MPN (MF/CML): 6 (17%) CR MRD− 4 | CR MRD+ 2 LPD: 3 (9%) – CR 1 | Active 2
HSCT1 donor type, n (%)	MUD 12 (35%) | Haplo 10 (30%) MRD 7 (21%) | MMUD 3 (9%)
Conditioning HSCT1	MAC 27 (80%) | RIC 7 (20%)

HCT-CI ≥3, n (%)	17 (50%)
DRI, n (%)	Intermediate 9 (26%) | High/Very high 25 (74%)
HSCT2 donor type, n (%)	MUD 12 (35%) | Haplo 12 (35%) MRD 7 (21%) | MMUD 3 (9%)
Conditioning HSCT2, n (%)	Intermediate TCI 24 (70%) | High TCI 10 (30%)
Time 1st–2nd HSCT, months	13.2 (5.6–320.2)
Early complications HSCT2, n (%)	Mucositis ≥G2 47% | Hepatotoxicity ≥G2 41% Cystitis 26% | CMV 35% | VOD 18% Endothelial injury 12% | Sepsis 24%

A total of 34 second allogeneic HSCTs were performed during the study period. Patient baseline characteristics and transplant-related complications are summarized in Table 1. The study population represented a very high-risk cohort: 50% of patients had an HCT-CI ≥3, and the majority were classified as high or very high Disease Risk Index (DRI) at the time of the second transplant. In addition, more than half of the patients underwent transplantation with suboptimal disease control, including active disease or measurable residual disease (MRD) positivity. With a median follow-up of 48.6 months, the estimated 4-year OS was 38% and 36% for 4-year EFS. The[K.1] [LCG2] cumulative incidence of NRM was 23% at 4 years. Relapse remained the main cause of treatment failure, with a cumulative incidence of 41% at 2 years and 46% at 4 years. Overall survival was superior in patients transplanted in remission, particularly those with MRD-negative disease, who achieved a median OS of 27.0 months (IQR 16.9–66.8) compared with 7.0 months (IQR 4.2–26.9) in the remaining patients.

Conclusions: In our experience, second allo-HSCT after relapse using PT-CY as GVHD prophylaxis and a different donor, provided meaningful long-term survival, with nearly 40% of patients alive at 4 years despite a highly adverse-risk profile. NRM was acceptable in this high-risk population, while relapse continued to be the main cause of failure. Optimization of pre-transplant response and post-transplant strategies, including maintenance approaches, may still lead to improved outcomes. These data support second allo-HSCT using PT-CY, as a valid therapeutic option in selected patients relapsing after a prior allograft.

DONOR DERIVED LEUKEMIA, SINGLE CENTRE EXPERIENCE

Markéta Šťastná Marková[1], *Veronika Válková*[1], *Jana Marková*[1], *Monika Beličková*[1], *Šárka Ransdorfová*[1], *Marie Valeriánová*[1], *Ludmila Nováková*[1], *Antonín Vítek*[1], *Mariana Koubová*[1], *Jan Vydra*[1]
[1]*Institute of Hematology and Blood Transfusion, Praha 2, Czechia*

Background: Donor-derived leukemia (DDL) is a rare complication following allogeneic hematopoietic stem cell transplantation (HSCT). Although it frequently mimics relapse of the original malignancy, it originates from donor hematopoietic cells that undergo leukemic transformation within the recipient's microenvironment. The incidence of DDL is estimated to be less than 1% of all HSCT cases, and its pathogenesis is very heterogenous and remains still poorly understood.

Methods: We retrospectively analyzed patients diagnosed with donor-derived hematologic malignancy. When feasible, donor origin was confirmed using chimerism analysis, and molecular genetic testing and cytogenetic changes were evaluated alongside demographic data and primary disease characteristics. Structured case reports were compiled.

Results: Over a 15-year period,1,308 allogeneic transplants were performed at our center. Six cases of donor-derived hematologic malignancy were identified (0.46%). In half of these,

transmission from donors with germline mutations was suspected; the remaining donors showed no similar changes. Notably, one patient with primary CBF leukemia (CBFβ/MYH11+) developed CBF DDL (AML1/ETO+), and another with initial chromosome 7 involvement exhibited recurrent chromosome 7 abnormalities with different breakpoints. Two patients with donor-derived polycythemia vera acquired germline JAK2 R1063H mutations, considered to have limited impact on the JAK/STAT pathway. One donor harboring TP53 (VAF 2%), ZRSR2 (0.4%), and two PPM1D mutations (0.04% and 0.4%) remained clinically healthy ten years later, showing modest clonal expansion (TP53 3%, ZRSR2 12%, PPM1D 3% and 9%), while the recipient's DDL exhibited the same mutational profile with markedly increased VAFs (TP53 34%, ZRSR2 2%, PPM1D 0.08% and 1.8%) and AML diagnosis.

Conclusions: Donor-derived leukemia (DDL) represents an extremely rare complication of HSCT, with current knowledge largely based on individual case reports. Despite the heterogeneity of this condition, available evidence supports the hypothesis that the recipient's microenvironment plays a crucial role in leukemogenic processes. This environment may not only damage healthy donor hematopoiesis but also enable clonal expansion of cells carrying germline or somatic mutations that have not manifested as disease in the donor. A deeper understanding of these mechanisms could substantially advance our knowledge of the etiopathogenesis of DDL as well as de novo hematologic malignancies.

Disclosure: I have no conflict of interest.

EFFICACY AND TOXICITY OF DONOR LYMPHOCYTE INFUSION IN A FIXED-DOSE COHORT: CLINICAL OUTCOMES AND PATIENT-REPORTED BURDEN

Julian Greß[1], *Krischan Braitsch*[1], *Maike Hefter*[1], *Katharina Nickel*[2], *Katrin Koch*[1], *Katharina S. Götze*[1,3,4], *Florian Bassermann*[1,3,4], *Peter Herhaus*[1], *Mareike Verbeek*[1]
[1]*TUM University Hospital, Munich, Germany,* [2]*Klinikum Traunstein, Traunstein, Germany,* [3]*German Cancer Consortium (DKTK), Partner Site Munich, Heidelberg, Germany,* [4]*Bavarian Center for Cancer Research (BZKF), Munich, Germany*

Background: Patients with relapse after allogeneic hematopoietic stem cell transplantation (alloSCT) have poor outcomes regardless of the underlying disease. In this setting, donor lymphocyte infusion (DLI) constitutes an established cellular therapy but carries significant risks of inducing graft-versus-host disease (GvHD). No international standardized dosing protocols are established to optimally balance graft-versus-leukemia effects against GvHD. At our institution, we employ the commonly used four-step escalation regimen (1, 5, 10, 50 × 10^6 CD3+/kg) at 4-week intervals. Several episodes of severe GvHD after the fourth DLI dose were observed in our cohort, and in view of the expanding use of combination therapies, this dosing approach may warrant re-evaluation. This retrospective analysis was performed to characterize the outcomes associated with this dosing regimen.

Methods: We analyzed 60 patients receiving DLI post-alloSCT at our tertiary care center (2014-2025). Indications were preemptive (measurable residual disease (MRD)/mixed chimerism) or therapeutic (hematological/extramedullary relapse). Overall survival (OS) and event-free survival (EFS) were estimated using the Kaplan-Meier method. Cumulative incidences of relapse, non-relapse mortality (NRM), and GvHD were calculated using competing risks. Prognostic factors were identified using Cox regression models. Response was defined as morphological remission, MRD negativity, or improved donor chimerism. Additionally, patient-reported outcomes (PROs) were assessed cross-sectionally in a survivorship sub-cohort (≥ 3 months post-last dose) using the NCI PRO-CTCAE.

Results:

Parameter	**Value (n (%))**
Sex (Male / Female)	32 (53%) / 28 (47%)
Diagnosis (AML / MDS+MPN / Other*)	29 (48%) / 14 (23%) / 17 (28%)
HCT-CI Score (0 / ≥1)	35 (58%) / 25 (42%)
Conditioning (MAC / RIC or RTC)	22 (37%) / 38 (63%)
Donor (MUD / MRD / Mismatch)	32 (53%) / 17 (28%) / 11 (18%)
History of aGvHD (prior to DLI)	40 (67%)
Time alloSCT to DLI, months (median)	8.2 [3.0–62.1]
Indication (Preemptive / Therapeutic)	38 (63%) / 21 (35%)**
DLI Strategy (Mono / +Hypomethylating agents / +Other***) **Other: ALL, CLL, MM ***Other: Venetoclax, TKI, IMiDs etc.*	13 (22%) / 29 (48%) / 18 (30%) ***1 Patient not assessed*

Median age was 58 years (range 24-74); acute myeloid leukemia (AML) (48%) and myelodysplastic syndromes/myeloproliferative neoplasms (23%) were the most common underlying diseases. DLIs were administered preemptively in 63% and therapeutically in 35%. Thirty-four patients (57%) received the maximum DLI dose (≥ 4). Response was observed in 34 patients (57%). Median OS and EFS were 17.3 and 5.4 months, respectively. The cumulative incidence of acute GvHD (aGvHD) was 58% (grade III-IV: 18%), while chronic GvHD (cGvHD) occurred in 38% (moderate/severe: 15%). Notably, 51% of aGvHD events occurred in patients receiving ≥ 4 doses, with 33% being grade III-IV. In univariate analysis, early treatment discontinuation (1-2 doses) was significantly associated with inferior EFS (HR 2.68, p=0.017) and OS (HR 2.15, p=0.045). In multivariate analysis, this lower dose level remained significantly associated with inferior EFS (HR 3.09, p=0.005), while cGvHD emerged as the strongest independent predictor for favorable outcomes in both EFS (HR 0.25, p<0.001) and OS (HR 0.42, p=0.022). Unexpected hospitalizations occurred in 63% (n=38; median 9 days), primarily triggered by infections (n=24) and GvHD (n=19).

NRM was 27%; primary causes of death included infections (n=12) and GvHD (n=3). PROs (median 36 months from first DLI; response rate 74%; n=17) identified cutaneous toxicity (Δ mean severity +1.36) and fatigue (Δ +1.00) as dominant stressors, while cognitive function remained stable. Despite high concordance between clinical GvHD status and PROs (rash severity 3.29 in GvHD vs. 0.00 in controls), global treatment satisfaction remained preserved in the GvHD cohort (mean 3.57).

Conclusions: Fixed-dose escalation is an effective treatment option, though the clustering of adverse events at the highest dose level indicates a narrow therapeutic window. Consequently, the optimal use of DLI regarding dynamic, response-adapted dosing strategies requires further investigation to better balance efficacy and safety.

Disclosure: Nothing to declare

A352

EFFECT OF MINIMAL RESIDUAL DISEASE GUIDED POSTTRANSPLANT 6-MERCAPTOPURINE AND METHOTREXATE MAINTENANCE ON PROGNOSIS OF HIGH-RISK PEDIATRIC ACUTE LYMPHOBLASTIC LEUKEMIA: A SINGLE-CENTER EXPERIENCE

Zühre Kaya[1], *Ahmet Bayramlı*[2], *Serap Kirkiz Kayalı*[2], *Emine Yılmaz Orulluoğlu*[2], *Ülker Koçak*[2]
[1]*Gazi University Faculty of Medicine, Department of Pediatric Hematology, Unit of Stem Cell Transplant, Ankara, Turkey,* [2]*Gazi University Faculty of Medicine, Department of Pediatric Hematology, Ankara, Turkey*

Background: The role of preemptive 6-mercaptopurine (6-MP)/methotrexate (MTX) maintenance after allogeneic stem cell transplantation (allo-SCT) in children with high-risk acute lymphoblastic leukemia (ALL) is not well-established. For years, leukemia physicians have used 6-MP and MTX maintenance with excellent results for ALL. However, only two consecutive studies from the Minnesota transplant group revealed no consensus on the efficacy of posttransplant maintenance therapy with 6-MP/MTX in a small mixed-age cohort of high-risk ALL patients. This study aimed to investigate the effect of flow cytometric minimal residual disease (Flow-MRD)-guided posttransplant maintenance with 6-MP/MTX on the prognosis of high-risk pediatric ALL.

Methods: Forty high-risk ALL children were divided into two groups: Group 1 (n=16) received posttransplant 6-MP/MTX maintenance, and Group 2 (n=24) did not. The detection of Flow-MRD positive (≥0.1%) results was assessed monthly for the first 100 days, then every three months for the next 365 days. All patients' transplant data were retrospectively reviewed.

Results: After allo-SCT, six patients (35%) in Group 1 and eleven (65%) in Group 2 had overt relapse. In Group 1, Flow-MRD-directed maintenance was initiated after the detection of positive MRD in 11 patients within the first three months of transplantation and 5 patients six months later. Overt relapse occurred in two (20%) of eleven individuals and in four

(80%) of five patients on maintenance. Reversible grade 1-2 hematological and liver toxicity were detected in twelve (75%) of the 16 subjects in Group 1. In group 2, seven patients died from refractory leukemia within six months of transplantation, while the other four survived. Patients on maintenance had a significantly higher cumulative survival (82%) compared to those without maintenance (38%) ($p<0.05$). Older recipient age (>6 years) [Hazard Ratio (HR): 2.4], TBI-based conditioning [HR: 3.1], acute GVHD complications [HR: 2.6], short relapse time (<1 year after allo-SCT) [HR: 3.2], and lack of maintenance therapy [HR: 4.1] were all risk factors for mortality.

Conclusions: To our knowledge, this is the first pediatric study to assess preemptive, flow-MRD-guided 6-MP/MTX maintenance after allo-SCT in high-risk ALL. This approach to relapse prevention in pediatric ALL may enhance survival with minimal toxicity and low cost; nevertheless, further research is needed for a full assessment of these potential approaches.

Clinical Trial Registry: No

CLINICAL COURSE AND SURVIVAL OF AML PATIENTS WITH CLONAL EVOLUTION AT RELAPSE AFTER ALLOGENEIC STEM CELL TRANSPLANTATION

Lukas Schaefer[1], *Adriane Halik*[1], *Giang Lam Vuong*[1], *Julia Jesse*[1], *Joerg Westermann*[1,2], *Igor-Wolfgang Blau*[1], *Lars Bullinger*[1,2], *Olga Blau*[1,2]
[1]*Charité Universitätsmedizin Berlin, Berlin, Germany,* [2]*Labor Berlin - Charité Vivantes Ltd, Berlin, Germany*

Background: Acute myeloid leukemia (AML) exhibits substantial genetic diversity, which plays a key role in determining disease prognosis. Relapse following allogeneic stem cell transplantation (alloSCT) is largely driven by residual leukemic subclones, their evolution under therapeutic selective pressure, and mechanisms of immune evasion. Despite advances in treatment, post-transplant relapse remains a major clinical challenge, particularly in patients harboring high-risk genetic alterations. This study aims to investigate patterns of clonal evolution in individuals with AML who experience relapse after alloSCT, and to correlate these molecular and genetic dynamics with the patients' subsequent clinical course in order to better understand factors that influence treatment response, disease progression, and overall outcomes.

Methods: NGS analysis using a 64-myeloid gene panel (Agilent Technologies) at diagnosis, during disease remission, and at relapse after alloSCT revealed clonal evolution in 24 patients with AML (10 women and 14 men). All patients had undergone alloSCT at our institution within the past 6 years. Age ranged from 29 to 71 years (median 58 years). 14 of the 24 patients (71%) had secondary AML after MDS. Most patients (84%) were transplanted from matched unrelated donors.

Results: At diagnosis, most patients carried distinct genetic alterations—most commonly in TP53, SF3B1, RUNX1, TET2, DNMT3A, ASXL1, and SRSF2. These mutations became undetectable in complete remission after therapy and alloSCT. At relapse, however, original clones re-emerged together with newly developed subclones, leading to a mutational profile that differed substantially from diagnosis. Relapse samples not only retained baseline mutations but frequently acquired additional alterations, particularly in RUNX1, NRAS, KRAS, NF1, and FLT3. Mutations observed exclusively during clonal evolution at relapse included NRAS, KRAS, PHF6, DDX41, STAG2, and WT1, underscoring dynamic clonal progression. Overall survival varied considerably within the cohort, with only a subset of patients achieving long-term remission. A complete loss of mutations or mutations such as DNMT3A, TET2, and ASXL1 were more commonly observed among longer-term survivors, whereas alterations including TP53, NRAS, and KRAS were predominantly associated with early relapse and inferior survival. The impact of donor lymphocyte infusion (DLI), graft-versus-host disease (GVHD) and relapse therapy on clonal evolution and outcome requires further analysis in this heterogenous cohort.

Conclusions: Allogeneic stem cell transplantation (alloSCT) is the treatment of choice for AML patients with poor prognosis, but relapse remains common. Relapsed AML with clonal evolution is associated with adverse outcomes. Original clones persisted, while new subclones with additional mutations emerged, resulting in a mutational profile distinct from diagnosis. A better understanding of these dynamics may aid in preventing relapse and tailoring targeted therapeutic approaches.

MONOCYTE-T CELLS CROSSTALK ORCHESTRATES EARLY GRAFT-VERSUS-LEUKEMIA IMMUNITY IN AML PATIENTS AFTER TRANSPLANTATION

Weiqian Dai[1], Linjie Wu[1], Xueying Zhao[1], Aiming Pang[1], Erlie Jiang[1], Tao Cheng[1,2], ***Sha Hao***[1,2]
[1]*Institute of Hematology and Blood Diseases Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Tianjin, China,* [2]*Tianjin Institutes of Health Science, Tianjin, China*

Background: Acute myeloid leukemia (AML) is the most common acute leukemia in adults, for which haploidentical hematopoietic stem cell transplantation (haplo-HSCT) is a key curative strategy. This study builds on prior research (Huo, et al., Sci Immunol. 2023) to investigate early immune reconstitution post-transplant and its association with graft-versus-leukemia effects in early relapse.

Methods: Firstly, we performed single-cell RNA sequencing on serially collected fresh peripheral blood (PB) and bone marrow (BM) samples from three AML patients and four aplastic anemia (AA) patients at 14, 30, and 60 days after haplo-HSCT. We next generated

single-cell transcriptomics and TCR repertoires using thawed BM samples from six additional AML patients - three maintaining continuous complete remission (CCR) and three experiencing ER within 6 months post-HSCT, at 30 days, 90 days (representing the pre-relapse phase), and at the time of relapse (for the ER group only) post-HSCT. Functional assays were conducted to assess the effect of galectin-9 (Gal-9) expression on monocytes on T cell exhaustion.

Results: AML patients exhibited fundamentally distinct post-HSCT expansion kinetics compared to AA patients, characterized by sequential monocyte (day 30) and T cell (day 60) activation phases. Monocytes from AML patients at 30 days post-transplant showed elevated expression of genes related to tumor immunity and T-cell proliferation, such as TNFSF10 and JAK2, along with their corresponding transcription factors. Concurrently, early post-transplant T cells underwent rapid activation, with significant upregulation of genes associated with antigen presentation and TCR signaling. Furthermore, we found that monocyte-T cell interactions in AML patients at 30 days post-transplant were substantially stronger than in AA patients, with heightened activity in tumor progression-related pathways such as Galectin, ADGRE, and LAIR1.
We further investigated GVL mechanisms through comparative analysis of monocyte and T cell dynamics in AML patients achieving CCR versus those experiencing ER following haplo-HSCT. CCR patients developed a distinct $CD8^+$ T cell subset characterized by high FCER1G expression at 30 days post-HSCT. In contrast, $CD8^+$ T cells in ER patients exhibited more exhausted phenotypes, with impaired signal-incoming capacity, while their monocytes remained hyperactivated and overexpressed Gal-9. Flow cytometry confirmed that monocytes from ER patients at 30 days post-transplant highly expressed Gal-9, while $CD8^+$ T cells exhibited greater exhaustion at both 30 and 90 days. Co-culture experiments demonstrated that ER-derived monocytes exacerbated T-cell exhaustion. Exogenous Gal-9 suppressed the reversal of CD8+ T cell exhaustion in a dose-dependent manner, an effect that was significantly rescued by MG-T-19.
Finally, TCR repertoire analysis revealed distinct TRBV gene usage preference between CCR and ER patients. Affinity prediction indicated that dominant TCR clones in both groups retained some affinity for AML antigenic peptides.

Conclusions: Hematopoietic and immune reconstitution differ between AML and AA post-HSCT. TCR clones from both CCR and ER patients retain leukemia-associated antigen reactivity, but T cells in ER exhibit a significantly enhanced exhaustion signature. This phenomenon is likely driven by monocyte-derived Gal-9 upregulation at 30 days post-HSCT, impairing $CD8^+$ T cell-mediated GVL effects and promoting relapse. Pharmacologic inhibition (MG-T-19) significantly reduces exhaustion, highlighting its therapeutic potential.

APPLICATION OF PLASMA FOURIER-TRANSFORM INFRARED SPECTROSCOPY (FT-IR) FOR MONITORING OF ACUTE MYELOID LEUKEMIA AND EXTRAMEDULLARY RELAPSE AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

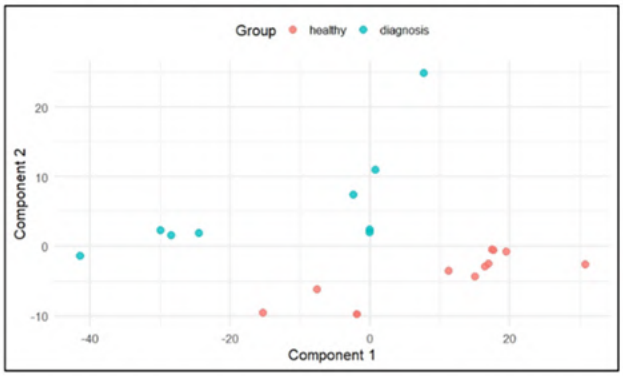
*Alessandro Leoni[1,2], **Besjana Xhahysa**[2], Luca Garuffo[2], Alessia Cavalleri[2], Federica Trenta[2], Federica Re[2], Silvia Mutti[2], Daniele Avenoso[1,2], Mirko Farina[1], Enrico Morello[1], Domenico Russo[1,2], Michele Malagola[1,2], Simona Bernardi[2]*
[1]ASST degli Spedali Civili di Brescia, Brescia, Italy, [2]University of Brescia, Brescia, Italy

Background: Relapse of Acute Myeloid Leukemia (AML) remain a major cause of treatment failure. Among relapse patterns, extramedullary disease, referred to as myeloid sarcoma, representing a rare yet clinically significant condition characterized by infiltration of the leukemic blasts into tissues outside the bone marrow. Its diagnosis is often challenging and requires a multimodal approach that integrates imaging, histopathology and immunophenotyping to confirm the myeloid origin of infiltrating cells. Prognosis depends on factors such as localization, overall burden, biological characteristic and response to therapy.

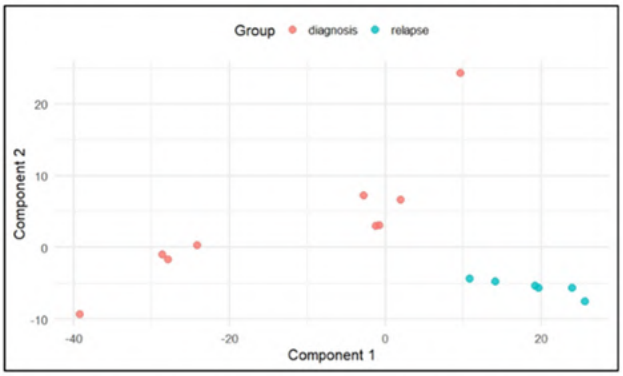
Methods: In this single-Centre study, we applied a liquid biopsy approach based on Fourier-Transform Infrared (FT-IR) spectroscopy to analyze plasma samples from patients with AML collected at diagnosis, pre- and post- allogenic hematopoietic stem cell transplantation (allo-HSCT), at bone marrow (BM) relapse, and at the onset of myeloid sarcoma, as well as from healthy controls. Spectral data were normalized using standard normal variate and evaluate through multivariate and machine-learning analysis with leave-one-patient-out cross-validation.

Results: The global comparison between healthy and pathological subjects demonstrated strong discriminatory performance (AUC=0.866; Accuracy=0.826), with an optimized sensitivity of 100% and specificity of 80%, indicating the presence of a characteristic FT-IR spectral signature associated with the AML and extramedullary disease (Fig. 1A). Comparison between the diagnostic phase and those from BM relapse or sarcoma showed excellent discrimination (Fig 1B-C), as did the comparison between medullary and extramedullary relapse (Fig 1D). These finding suggests that, despite shared features, the metabolic, molecular and structural profile captured by FT-IR differ between the two relapse patterns, reflecting distinct biochemical characteristics linked to their clinical presentations. Post-HSCT spectral analysis revealed a progressive reversion toward a physiological profile, with normalization observed in 94.4% of patients by day +90, consistent with a partial metabolic recovery and re-establishment of immune and hematopoietic homeostasis.

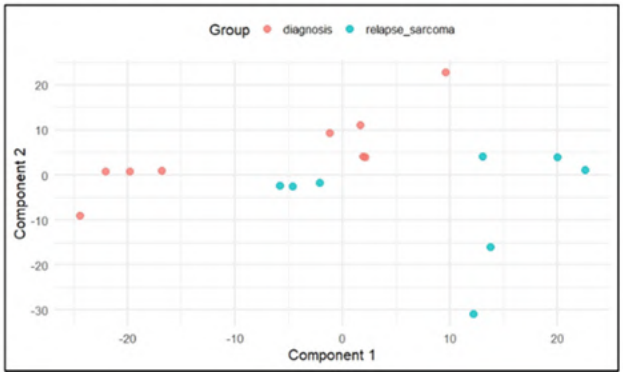
1A – PLS-DA - Healthy vs AML diagnosis



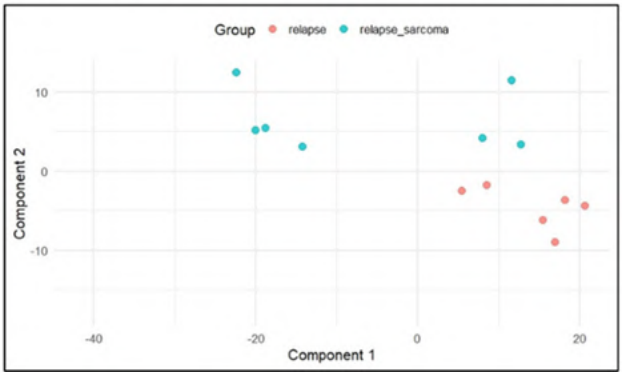
1B – PLS-DA - AML diagnosis vs BM relapse



1C – PLS-DA - AML diagnosis vs Myeloid Sarcoma



1D – PLS-DA – BM relapse vs Myeloid Sarcoma



Conclusions: In conclusion, our findings indicate for the first time that plasma-based FT-IR spectroscopy represents a promising liquid biopsy tool for monitoring AML and its post-HSCT. The method's ability to discriminate the diagnostic phase from relapse, differentiate relapse types, and capture the progressive normalization of the spectral profile in post-transplant samples (up to 94.4% of patients by day +90) suggest that plasma biochemical variation reliably reflect patients' clinical and metabolic status, supporting its potential use in clinical practice. This partially normalization could reflect improvements in amino acid availability, lipid composition, and systemic inflammatory status, key components of immunometabolic recovery. FT-IR thus offers a sensitive and non-invasive approach for detecting biochemical alterations, potentially providing complementary biomarkers for disease monitoring, immune reconstitution assessment and early relapse detection. When compared to other liquid biopsy approach, FT-IR offers unique advantage of rapidity, cost-effectiveness and reagent-free assessment.
Further investigation are needed to validate these FT-IR-derived signatures, such as lipid subclasses, protein secondary structures, and nucleic acid–related bands and to assess their integration into precision monitoring strategies for AML patients.

Disclosure: Nothing to declare.

REFINED DISEASE RISK INDEX OUTWEIGHS PRE-TRASPLANT RESPONSE IN PREDICTING RELAPSE AFTER ALLOGENEIC HAEMATOPOIETIC STEM CELL TRANSPLANTATION: RESULTS FROM THE NATIONAL CANCER INSTITUTE IN LIMA, PERÚ

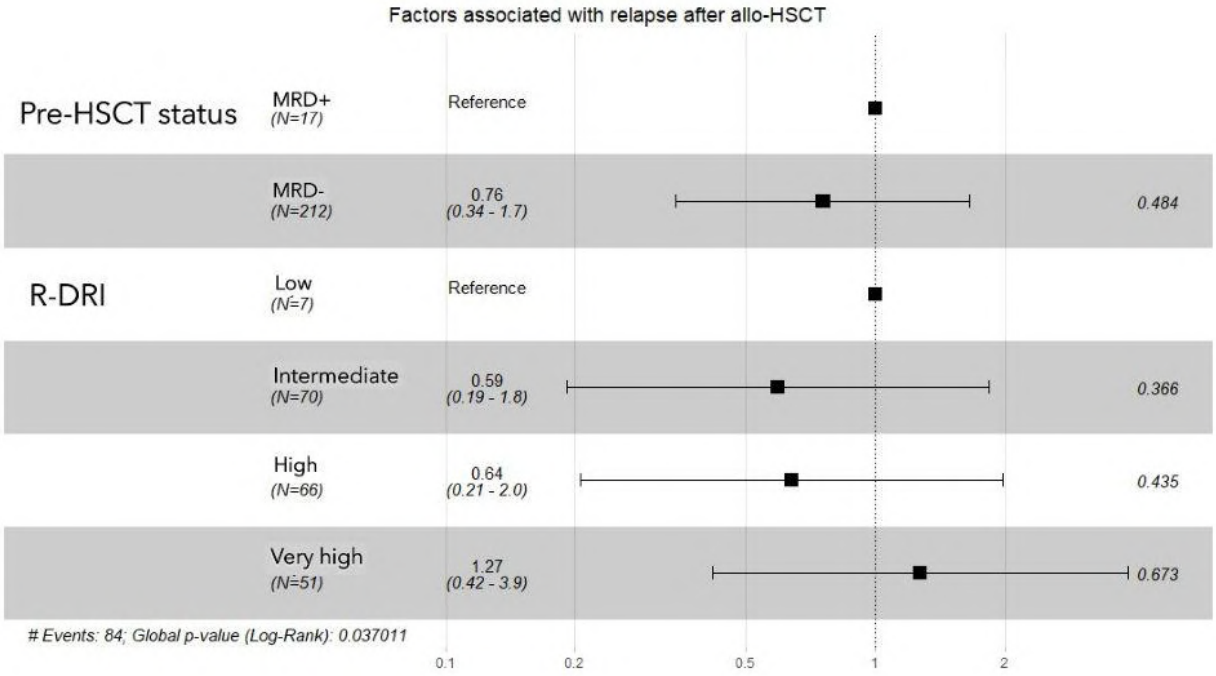
Naty López-Córdova[1], *Jule Vasquez-Chavez*[1], *Cindy Alcarraz-Molina*[1], *Lourdes Lopez-Chavez*[1], *Victor Mallma-Soto*[1], *Tatiana Vidaurre*[1], *Shirley Quintana-Truyenque*[1]
[1]*Instituto Nacional de Enfermedades Neoplásicas, Lima, Peru*

Background: Post-transplant relapse remains a major challenge after allogeneic hematopoietic stem cell transplantation (allo-HSCT). Identifying factors associated with the risk of relapse is critical for patient stratification and post-transplant management. We aimed to evaluate clinical and disease-related predictors of relapse, with particular focus on pre-transplant response and disease risk.

Methods: We retrospectively analysed 235 adult patients undergoing allo-HSCT at a single centre. Data were collected from the unit registry and both physical and electronic medical records. Relapse was defined as disease recurrence after transplantation. Time to relapse and progression-free survival were analysed using Kaplan–Meier estimates. Factors associated with relapse were assessed using Cox proportional hazards models. Variables evaluated included age, sex, underlying diagnosis, measurable residual disease (MRD) status of response before HSCT, and refined Disease Risk Index (R-DRI). Multivariable models were adjusted for R-DRI.

Results: Relapse occurred in 94 patients (40%), with a median time to relapse of 8 months. Most relapses (89%, n=84) occurred within the first year post-transplant. The most relapsed diagnosis was acute lymphoblastic leukaemia (ALL) with 57 (60.6%), acute myeloid leukaemia (AML) with 19 (20.2%), and chronic myeloid leukaemia (CML) with 7 (7.4%) relapsed patients (4 of them were from the blastic phase group). Underlying diagnosis showed a trend toward association with relapse risk, although statistical significance was not reached (p=0.056).
In a univariate analysis, age and sex were not associated with risk of relapse. The R-DRI showed a significant overall association with relapse (p=0.01). Patients with negative MRD before HSCT experienced a lower risk of relapse compared to MRD-positive patients (hazard ratio [HR] 0.57; 95% CI 0.30–1.10; p=0.09). However, this association did not remain significant after adjustment for R-DRI (Figure 1) (HR 0.76; 95% CI 0.34–1.66; p=0.48). Among patients with available GVHD data, those who developed GVHD experienced a significantly lower incidence of relapse compared to those without GVHD (Fisher's exact test, p = 0.0003), consistent with a graft-versus-leukaemia (GvL) effect. Of the 94 patients who relapsed, 84 (89%) did so while receiving immunosuppressive therapy, including 76 during GVHD prophylaxis and 7 during active GVHD treatment, while 10 relapsed during routine observation. Post-transplant relapse was strongly associated with the clinical context at evaluation (Fisher's exact test, $p<2.2\times10^{-16}$). This association reflects the clinical circumstances at the time of relapse and cannot be interpreted as an independent risk factor for relapse.

Among relapsed patients, no significant association was observed between underlying diagnosis and timing of relapse (<6 vs ≥6 months; p=0.12), nor between relapse timing and the presence of graft-versus-host disease (GVHD) (p=0.84). Likewise, time to relapse did not differ significantly across diagnostic groups (p=0.61).



Conclusions: Relapse after allo-HSCT is predominantly driven by disease-related risk rather than pre-transplant response alone. The R-DRI remains a key predictor of relapse, while the lower incidence of relapse observed in patients with GVHD supports a GvL effect. Associations between relapse and immunosuppressive or clinical context variables reflect post-transplant circumstances rather than causal risk factors. These findings highlight the central role of disease biology in relapse risk stratification.

VENETOCLAX AND HYPOMETHYLATING AGENT WITH DONOR LYMPHOCYTE INFUSION FOR RELAPSED ACUTE MYELOID LEUKAEMIA POST ALLOGENEIC STEM CELL TRANSPLANTATION

*Luani Barge[1,2], **William Fischer**[1], Pramila Krishnamurthy[1], Kelly Rowe[1], Teresa Cheesman[1], Michelle Kenyon[1], Mili Shah[1], Madson Correia de Farias[1], Shreyas Hanmantgad[1], Varun Mehra[1], Victoria Potter[1]*

[1]King's College Hospital, London, United Kingdom of Great Britain and Northern Ireland (the), [2]University of Queensland, Brisbane, Australia

Background: Relapse remains a significant cause of mortality following haematopoietic stem cell transplantation (HSCT) in patients with myeloid malignancies. Donor lymphocyte infusion (DLI) may be used as salvage therapy but requires disease control for efficacy. Venetoclax/hypomethylating agent (ven/HMA) provides a lower intensity, often outpatient therapy to reduce disease burden. There is limited data on efficacy of this strategy particularly from an intention to treat perspective.

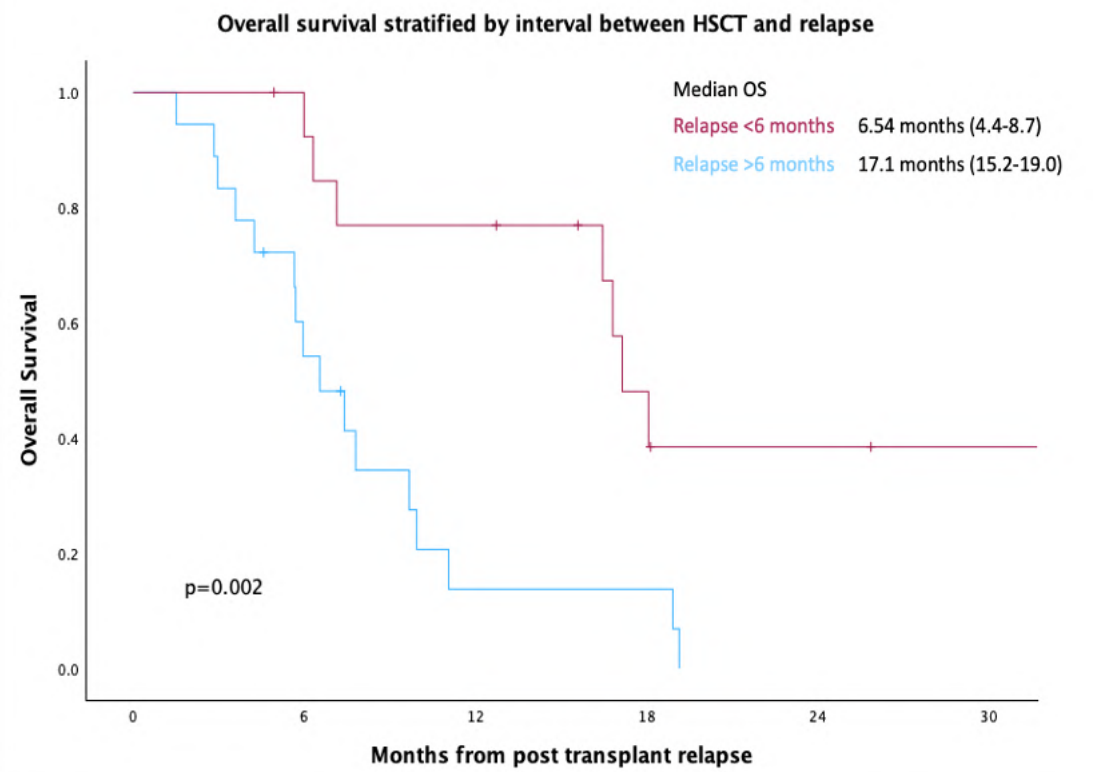
Methods: We performed a retrospective analysis of all patients with relapsed myeloid malignancies following allogeneic stem cell transplant intended for ven/HMA/DLI between 2020-2025 at King's College Hospital. Descriptive statistics were performed for baseline characteristics, Kaplan-Meir estimates for survival outcomes and Cox regression for baseline characteristics associated with overall survival (OS).

Results: Median age was 62.4years (range 24.9-79.9), 20(62.5%) were male, 9(21.1%) received venetoclax prior to HSCT and 5(15.6%) received DLI for mixed chimerism or MRD prior to relapse. Venetoclax was combined with azacytidine n=30 or decitabine n=2 typically for 3 cycles followed by HMA monotherapy based on trust funding. Characteristics at disease relapse are shown in table 1. Median follow up from relapse was 18.1 months.
Thirty-one of 32 patients commenced ven/HMA, for a median of 2 cycles with 10 proceeding to azacytidine monotherapy and one to low dose cytarabine. Twenty-three patients (71.9%) received at least one DLI (1 n=13, 2 n=3, 3 n=7). Reasons for not proceeding to DLI were graft versus host disease (GVHD) (3), persistent disease (3), clinical deterioration or death prior to DLI (2) and second allogeneic transplant (1).
Complete remission (CR/CRi) was achieved in 18 patients (56.3%), 10 MRD negative. Two patients achieved aplasia as best response and nine had persistent disease. Median time to best response was 2 cycles (range 1-6). Estimated median duration of response was 12.3 months (95%CI 1.2-23.3).
GVHD data was available for 26 patients. Two patients experienced aGVHD and one cGHVD from the time of relapse however only one patient developed GVHD after DLI. One year cumulative incidence of any GVHD was 11.7% (95%CI 0-24.5%).
The estimated median OS from relapse was 9.9 months (95%CI 5.3-14.5). Among those who achieved a complete response median OS was 17.1 months (95%CI 9.1-24.6) compared to 5.7 months (95%CI 3.0-8.4) among those who did not (p=0.002). Of the 15 patients with ≥2years follow-up three remain alive, all of whom are in remission.
In univariate analysis only relapse >6 months from HSCT was associated with superior OS (hazard ratio [HR] 0.27 95%CI 0.11-0.68, p=0.005). There was a trend towards improved survival in those with mixed chimerism at relapse (HR0.50, 95%CI 0.21-1.17, p=0.11). None of the other baseline characteristics in table 1 were statistically significant. Only relapse >6 months retained significance in a multivariate analysis (HR 3.35 95%CI 1.24-9.07, p=0.017) Kaplan-Meir estimates shown in figure 1.

Table 1. Characteristics at disease relapse	**n (%)**
<6months from HSCT to relapse	14 (43.8)

Diagnosis at relapse	Acute myeloid leukaemia (AML)	23 (71.9)
	Burden at relapse <1% /1-5% /6-20% />20%	4/ 1/ 8/10
	ELN favourable / intermediate/ adverse	1 / 3/ 18
	Myelodysplastic syndrome with excess blasts	6 (18.8)
	Other^	3 (9.4)
Myeloablative conditioning		8 (25)
T cell depletion	Alemtuzumab	13 (40.6)
	Anti-thymocyte globulin	16 (50)
	Post-transplant cyclophosphamide	2 (6.3)
	T replete	1 (3.1)
Donor type	Matched sibling	5 (15.6)
	Matched unrelated donor	19 (59.4)
	Mismatched (<9/10) unrelated donor	6 (18.8)
	Haploidentical	2 (6.3)
Mixed (<95% CD3) chimerism at relapse, n(%)		18 (58.1)
Biallelic T53 at diagnosis or relapse, n(%)		9 (28.1)
AML-MR mutations at relapse, n(%)		13 (40.6)

^blastic plasmacytoid dendritic cell neoplasm, chronic myelomonocytic leukaemia 1, myelodysplastic/myeloproliferative neoplasm with 13% blasts



Conclusions: Ven/HMA/DLI is a viable treatment option for post-transplant relapse however only a minority of patients initially intended for treatment are likely to attain long term disease control. To the best of our knowledge this is one of the largest cohorts of patients treated with Ven/HMA/DLI.

Disclosure: Nothing to declare

P113

MOLECULAR AND FUNCTIONAL CHARACTERIZATION OF SOLITARY EXTRAMEDULLARY RELAPSE OF AML AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Julia Frimmel[1], *Monika Brüggemann*[1], *Annette I. Garbe*[1], *Katharina Fleischhauer*[2], *Andreas Heinold*[2], *Hossein Emami*[1], *Thuja Arrieta-Bolanos*[2], *Esteban Arrieta-Bolanos*[2], *Leo Ruhnke*[3], *Armin Zebisch*[4], *Friedrich Stölzel*[1]
[1]*University Hospital Schleswig-Holstein, Kiel, Germany,* [2]*University Hospital Essen, Essen, Germany,* [3]*University Hospital Dresden, Dresden, Germany,* [4]*Medical University Graz, Graz, Austria*

Background: Allogeneic hematopoietic stem cell transplantation (allo-HCT) can cure acute myeloid leukemia (AML), but relapse remains the main cause of treatment failure. Most relapses are medullary, whereas extramedullary (EM) relapse may arise in conjunction or independently of marrow involvement. Solitary EM relapse after allo-HCT is rare and poorly characterized, with limited tissue-based data available. Improved molecular and functional characterization is needed to optimize diagnostics and therapy.

Methods: We analyzed nine patients with solitary EM relapse after allo-HCT. DNA capture-based next-generation sequencing (NGS) applying a 101-gene myeloid NDC assay was performed on snap-frozen or formalin-fixed, paraffin-embedded EM tissue. In four patients who had received allo-HCT from HLA-mismatched (including haploidentical) donors , genomic loss of the patient-specific HLA was assessed on snap-frozen EM tissue using PCR-based NGS. Leukemic blasts isolated from one EM lesion underwent a 72-hour drug response profiling (DRP) analyzing 46 compounds; cytotoxicity was measured by using the CellTiter-Glo luminescent Cell Viability Assay and apoptosis by imaging real-time live cell caspase-3/7 binding.

Results: The median age at EM relapse was 45 years (range, 25–68 years). EM relapse sites included skin (n= 4), pleura (n= 1), brain (n= 1), breast (n= 1), lymph node (n= 1), and soft tissue (n= 1). Four patients had previously received a second allo-HCT. The median interval from allo-HCT to EM relapse was 440 days (range, 150-1289 days). Two patients received haploidentical grafts; among the remaining transplants, HLA mismatches in the graft-versus host direction involved HLA-B (n= 1) and/or DPB1 (n= 2), in addition to one matched sibling and three fully matched unrelated (12/12 MUD) grafts. No HLA loss was detected in EM samples from the four informative patients transplanted with an HLA-mismatched donor. DNA capture sequencing revealed *RAS* pathway mutations (*CBL, NRAS, KRAS)* in five of nine patients. In total, eight activating signaling mutations (*FLT3, NRAS, KRAS, JAK2*) in seven patients and nine chromatin-modifying/epigenetic mutations (*ASXL1, EZH2, BCOR, BCORL1, KMT2A*-PTD) in five patients were identified. Seven patients harbored structural variants, including *FLT3*- ITD (n = 3), *KMT2A* rearrangements (n = 2), *KMT2A*-PTD (n = 1), *BCR::ABL1* (n = 1), rearrangements involving *ETV6* and *PDGFRB* (n= 1), and an *IKFZ1* deletion (n= 1). No mutations in DNA methylation-related genes were detected.

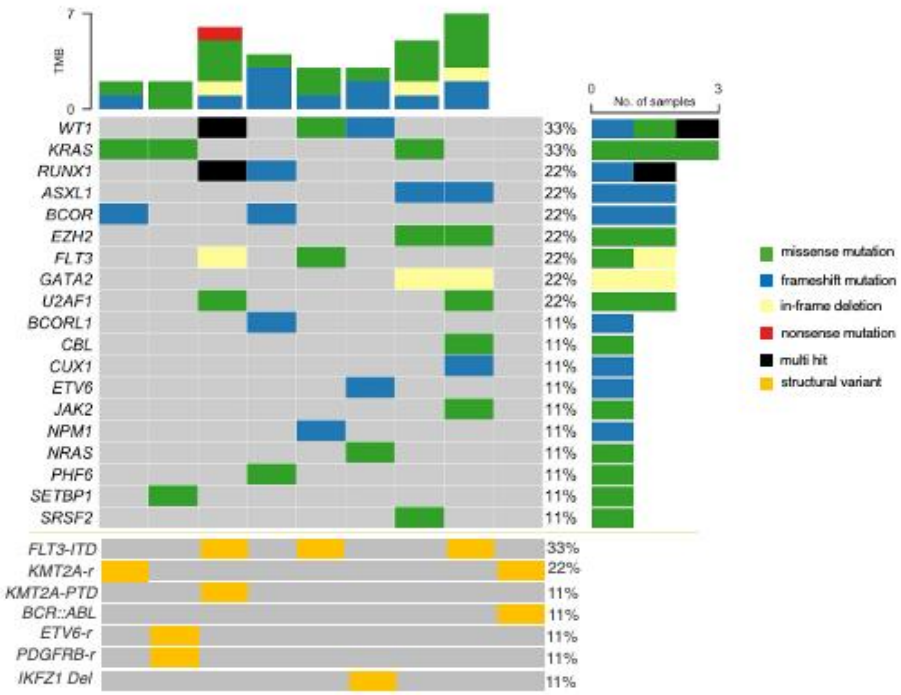


Figure 1. Oncoplot of somatic variants in nine EM AML relapses after allo-HCT.

First drug response profiling based on a single patient sample identified venetoclax as one of the effective agents, with caspase 3/7-dependent apoptosis confirmed for this agent.

Conclusions: In this cohort, solitary EM relapse of AML after allo-HCT appeared to be enriched for *RAS*-pathway and other signaling mutations, as well as chromatin-modifying and epigenetic alterations, whereas no mutations in DNA methylation-related genes were detected. The mechanism of relapse has yet to be fully understood, however, in our small cohort, we could not identify a role for genomic loss of mismatched HLA in informative patients. Ex vivo drug response profiling combined with molecular characterization in EM relapse will help to better define the underlying mechanisms and the most effective, individualized therapy, to optimize patient outcomes.

AZACITIDINE AS POST-TRANSPLANT MAINTENANCE THERAPY IN ACUTE MYELOID LEUKEMIA AND MYELODYSPLASTIC SYNDROMES: EFFECTS, SAFETY AND IMMUNE RECONSTITUTION DYNAMICS

Silvia Viola[1,2], *Elisabetta Terruzzi*[2], *Marilena Fedele*[2], *Paola Perfetti*[2], *Stefano Bonfanti*[1,2], *Francesca Duca*[1,2], *Elsa Masedu*[1,2], *Carlo Gambacorti-Passerini*[1,2], *Andrea Aroldi*[2], *Matteo*

Parma[2]
[1]*University of Milano-Bicocca, Monza, Italy,* [2]*Fondazione IRCCS San Gerardo dei Tintori, Monza, Italy*

Background: Disease relapse after allogenic hematopoietic stem cell transplantation (HSCT) is a major adverse prognostic event in patients with acute myeloid leukemia (AML) and myelodysplastic syndromes (MDS). To reduce this risk, post-transplant maintenance strategies have been incorporated into clinical practice. Azacitidine (AZA) is currently the only available maintenance option for high-risk MDS and adverse-risk AML without FLT3 mutations, although published efficacy data remain inconsistent. In this single-center retrospective study, we compared survival outcomes, safety, and immune reconstitution patterns in patients receiving and not receiving post-HSCT AZA.

Methods: We evaluated 83 adult patients undergoing HSCT in our center between September 2019 and November 2024. Patients were grouped as follows:

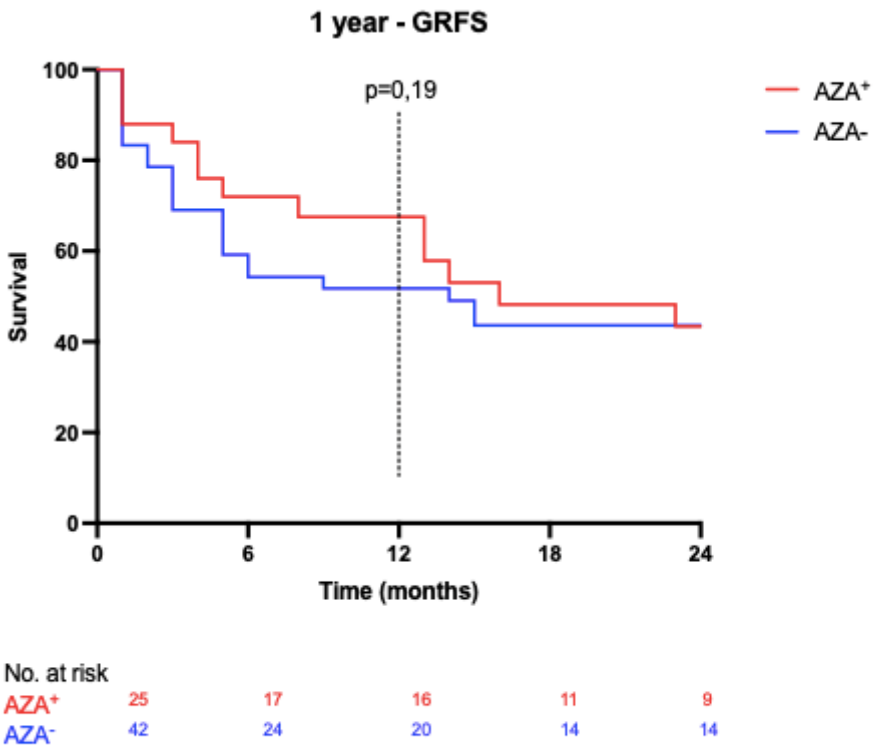
1. AZA^+ (n = 25): patients receiving post-HSCT AZA at 32 mg/m²/day subcutaneously for 5 consecutive days every 28 days, for a planned total of 12 cycles. Most had ELN adverse-risk AML or high/very high-risk R-IPSS MDS.
2. AZA^- (n = 42): patients not receiving AZA post-HSCT, diagnosed with AML or MDS across variable risk categories.

A third, smaller cohort (n = 16) included patients with FLT3-mutated AML receiving FLT3-targeted maintenance therapies (Sorafenib or Gilteritinib) ($FLT3^+$). Patients' baseline characteristics are summarized in Table 1. Immune reconstitution was assessed through lymphocyte-subset analyses at predefined post-transplant time points (days +60, +120, +180, +365, +730).

	Total (N=83)	**AZA^+ (N=25)**	**AZA^- (N=42)**	**$FLT3^+$ (N=16)**
Sex - N° (%)				
Males	43 (52%)	12 (48%)	24 (57%)	7 (44%)
Females	40 (48%)	13 (52%)	18 (43%)	9 (56%)
Median Age at Diagnosis, yrs. (range)	56 (48-63)	55 (49.50-63.50)	60.50 (53-63.25)	48 (36.50-57)
Diagnosis - N° (%)				
MDS	24 (29%)	8 (32%)	16 (38%)	0
AML	59 (71%)	17 (68%)	26 (62%)	16 (100%)
ELN Risk Profile - N° (%)				
Favorable	11 (19%)	1 (6%)	10 (38%)	0
Intermediate	14 (23%)	2 (12%)	5 (19%)	7 (44%)
Adverse	34 (58%)	14 (82%)	11 (43%)	9 (56%)

IPSS-R Risk Score - N° (%)				
Very Low	2 (8%)	1 (12%)	1 (6%)	
Low	2 (8%)	1 (13%)	1 (6%)	
Intermediate	7 (29%)	3 (38%)	4 (25%)	
High	5 (21%)	1 (12%)	4 (25%)	
Very High	8 (34%)	2 (25%)	6 (38%)	
Karyotype - N° (%)				
Normal	35 (42%)	6 (24%)	15 (36%)	14 (88%)
Complex	10 (12%)	1 (4%)	8 (19%)	1 (6%)
Others	35 (42%)	16 (64%)	18 (43%)	1 (6%)
NE	3 (4%)	2 (8%)	1 (2%)	0
TP53 Mutation - N° (%)	13 (16%)	6 (24%)	7 (17%)	0
Additional Criteria - N° (%)				
MDS and AML Therapy-related	11 (13%)	4 (16%)	6 (14%)	1 (6%)
AML Myelodysplasia-related	17 (20%)	7 (28%)	8 (19%)	2 (13%)
sAML following MPN	7 (9)	3 (12%)	4 (9%)	0

Results: AZA maintenance was not associated with increased rates of acute or chronic graft-versus-host disease (aGvHD/cGvHD) compared with AZA^- patients (aGvHD: 20% vs. 36%, p = 0.26; cGvHD: 20% vs 24%, p = 0.77). No increase in infections of any kind (64% vs. 79%, p = 0.25), nor any increase in CMV (32% vs. 40%, p = 0.65) or EBV (36% vs. 43%, p = 0.61) reactivation was observed. Survival outcomes showed non-inferiority of the AZA^+ cohort relative to AZA^- patients, with median overall survival (OS) and progression-free survival (PFS) not reached in both group (p = 0.68; p = 0.73). Median GvHD-free/Relapse-free survival (GRFS) was longer in AZA^+ patients (16 months) than in the AZA^- cohort (14 months), with a trend toward improved GRFS at 1-year post-HSCT (p = 0.19). Regarding immune reconstitution, AZA^+ patients displayed an early trend toward higher NK-cell counts during the first post-transplant months compared with AZA^- individuals (1-year post-HSCT median NK-cell counts: 298/µL vs. 220/µL, p = 0.11). Moreover, at 1-year post-HSCT, AZA^+ patients showed significantly higher median levels of total T cells (1768/µL vs. 1121/µL, p = 0.03), $CD8^+$ T cells (731/µL vs. 387.5/µL, p = 0.04), and NK cells (298/µL vs. 170.5/µL, p = 0.01) compared with the $FLT3^+$ cohort, supporting a favorable immunologic pattern consistent with the known immunomodulatory effect of AZA.



Conclusions: Post-HSCT Azacitidine maintenance is safe and well tolerated. Despite a higher baseline-risk profile, AZA-treated patients achieved OS and PFS comparable to untreated patients and demonstrated early signals of improved GRFS and enhanced immune reconstitution. Overall, these findings support the use of Azacitidine as a post-transplant maintenance strategy in patients with high-risk AML and MDS.

DONOR LYMPHOCYTE INFUSION AFTER ALLOGENEIC TRANSPLANTATION FOR MYELOID MALIGNANCIES: CLINICAL OUTCOMES AND THE ROLE OF CD3⁺ CELL DOSE

Lina Rüsing[1], *Stephanie Winter*[1], *Julia Cserna*[1], *Nina Dominik*[1], *Armin Bumberger*[1], *Philipp Melhorn*[1], *Hanna Knaus*[1], *Philipp Wohlfarth*[1], *Georg Hopfinger*[2], *Karoline Gleixner*[1], *Wolfgang Sperr*[1], *Margit Mitterbauer*[1], *Werner Rabitsch*[1], *Hildegard Greinix*[1], *Antonia Müller*[1], *Nina Worel*[1], *Margit Mitterbauer*[1]
[1]*Medical University of Vienna, Vienna, Austria,* [2]*Klinik Favoriten, Vienna, Austria*

Background: Relapse remains the leading cause of treatment failure after allogeneic hematopoietic cell transplantation (allo-HCT) for myeloid malignancies. Donor lymphocyte infusion (DLI) can induce potent graft-versus-leukemia effects but is limited by graft-versus-host disease (GvHD). Although $CD3^+$ T cells mediate the immunologic activity of DLI, the optimal cumulative $CD3^+$ dose that balances disease control and toxicity remains undefined.

Methods: We retrospectively analyzed 77 patients with myeloid malignancies who received DLI after allo-HCT between 01/2005 and 09/2025. The primary objective was to evaluate the association between cumulative $CD3^+$ dose and clinical outcomes and development of acute (grade 2–4) or chronic (moderate–severe) GvHD. Patients were stratified into three dose groups: $<0.5\times10^7$/kg (Group A, n=20), $0.5–3\times10^7$/kg (Group B, n=29), and $>3\times10^7$/kg (Group C, n=28). Fine–Gray competing-risk regression and nonlinear spline models were used to assess dose–response patterns.

Results: Median age was 56 years (IQR 44–61); 36% were female. Underlying diseases included AML (n=61), CML (n=10), and other myeloid neoplasms (n=6). Median cumulative $CD3^+$ dose was 1.6×10^7/kg (IQR 0.5–5.0), with a median of two DLI (range 1–4). DLI were given prophylactically in 25%, preemptively (MRD positive or mixed chimerism) in 32%, and therapeutically in 43% of patients.
Among therapeutic DLI recipients, median time from HCT to hematologic relapse was 15.5 months, and to molecular relapse 4.5 months. Five patients relapsed >5years post-HCT, and one relapsed 13 years after transplant. At DLI, 66 patients were in complete remission (n=23 MRD positive; n=3 mixed chimerism), while 11 had active extramedullary disease. Progression-free survival differed significantly across indications: prophylactic (13.4 years), preemptive (2.8 years), and therapeutic DLI (2.0 years) (p=0.03).
GvHD ≥ grade 2 acute or ≥ moderate chronic occurred in 22 patients, including severe chronic GvHD in nine and grade ≥3 acute GvHD in four; one patient died from GvHD. Higher $CD3^+$ doses (Groups B/C) were associated with increased risk of ≥moderate chronic GvHD (p=0.003).
In Fine–Gray models, cumulative $CD3^+$ dose showed no association with GvHD incidence (SHR 1.02, 95% CI 0.94–1.11, p=0.65). A borderline association with relapse was observed in the prophylactic or preemptive indication (SHR 1.06, 95% CI 1.00–1.13, p=0.052), although spline models did not confirm a significant nonlinear dose–response relationship.
At last follow-up, 41 patients (53%) were alive including 47% of patients given DLI prophylactically, 64% after preemptive and 48% after therapeutic DLI. Of note, 48% remained in complete hematologic remission after a median follow-up of 6.8 years.

Characteristic	Overall cohort (n = 77)
Age, years, median (IQR)	56 (44–61)
Female sex, n (%)	28 (36%)
Underlying disease, n (%) Acute myeloid leukemia (AML)	 61 (79%)

Characteristic	Overall cohort (n = 77)
Chronic myeloid leukemia (CML) Other myeloid malignancies	10 (13%) 6%)
Donor type, n (%) Related donor Unrelated donor	 30 (39%) 47 (61%)
Median cumulative $CD3^+$ DLI dose, $\times 10^7$/kg, median (IQR)	1.6 (0.5–5.0)
Indication for DLI, n (%) Prophylactic Preemptive Therapeutic	 19 (25%) 25 (32%) 33 (43%)
Disease status at DLI, n (%) Complete remission Active disease (extramedullary)	 66 (86%)* 11 (14%)
Median Follow-up in years	6.8
*MRD pos n=23; Mixed chimerism n=3	

Conclusions: Cumulative $CD3^+$ DLI dose did not show a clear dose–response relationship for relapse, survival, or GvHD. Higher doses were associated with more chronic GvHD but not with improved outcomes. Because patients receiving therapeutic DLI inherently have higher relapse risk and often receive escalated dosing, associations between higher dose and relapse likely reflect indication bias rather than causality.
More than half of patients achieved long-term survival including patients given DLI after relapse of myeloid disease, underscoring that durable responses are attainable with DLI-based strategies

RETROSPECTIVE ANALYSIS OF THE INCIDENCE OF RELAPSE AFTER ALLOGENEIC STEM CELL TRANSPLANTATION FOR MYELOID MALIGNANCIES: TREATMENT CHALLENGES FOR PATIENTS IN NORTH MACEDONIA

Aleksandra Pivkova Veljanovska[1], *Lazar Chadievski*[1], *Milche Cvetanoski*[1], *Bozidar Kochoski*[1], *Martin Stojanoski*[1], *Merve Purde*[1], *Arita Fazliu*[1], *Zaklina Anchevska Trajkovska*[1], *Sonja Genadieva Stavrik*[1]
[1]*University Clinic for Hematology, BMT Unit, Skopje, Republic of North Macedonia*

Background: Relapsed disease after allogeneic stem cell transplantation (allo SCT) is one of the leading causes of posttransplant death among patients with myeloid malignancies. Posttransplant interventions, in conjunction with optimal conditioning regimens and donor selection, are increasingly supported by evidence for their potential to prolong patient survival by promoting antileukemia or graft-versus-leukemia effects. Aims of the study: Retrospective analysis of the outcomes of patients with relapsed myeloid malignancies after allo SCT. The second aim was to present institutional strategies aimed at reducing post-transplant disease relapse.

Methods: A total of 78 patients with myeloid malignancies treated with allo-SCT during a 5-year period at the University Clinic for Hematology, Skopje, North Macedonia were included in the study. Patients were referred for allogeneic HSCT according to donor availability (matched related, matched unrelated and haploidentical donors. Multivariable Cox Proportional Hazards models were made for time to relapse (TtR) and time to death following relapse (TtD). The analysis of the transplant outcome is based on pretransplant factors, graft versus host disease (GVHD) and post relapse management. Kaplan Meier Estimates were used to predict median survival time with 95% confidence intervals and Cox Proportional Hazard models to estimate hazard rates.

Results: Overall survival (OS) at one-year posttransplant was 81.1% (95% confidence interval [CI], 70% to 100%) in MRD transplants and 69.5% (95% confidence interval [CI], 65% to 100%) in MUD transplants and 55.5% (95% confidence interval [CI], 40% to 100%) in haploidentical donor transplants. TRM during the first year posttransplant was 10%. There is a statistically significantly higher DFS rate in MUD compared to MRD transplants and in haploidentical transplants (p= 0.0476, Log-rank, Mantel-Cox test, Chi square = 6.089. The TtR after transplantation was 6,5 months (range, 3 to 25 months). High risk cytogenetics had a 2.22 increased HR for relapse (p=0.086) [0.89-5.54]. For TtD, patients with GVHD prior to relapse had a marginally significant 57% lower HR for death (p=0.074) [0.17-1.09], while patients who developed GVHD after relapse had a 2.74 greater risk of death (p=0.123) [0.76-9.82]. Patients that received DLI had a 90% reduced risk of death (p<0.001) [0.03-0.26]. The relapse after allogeneic HSCT was treated with chemotherapy in 26.4% of patients, HMAs and venetoclax in 34.4%, targeted therapy in 10.4%, DLI 10%, second allogeneic transplant in 4,5% of relapsed patients.

Conclusions: Patients with myeloid malignancies who experienced relapse after allo SCT had poor prognosis. Development of GVHD prior to relapse trended toward improved survival after relapse. In this cohort, maintenance chemotherapy prior increased time to relapse and DLI improved survival after relapse.

Disclosure: no conflict of interest

P118

HIGH-DOSE CRYOPRESERVED BONE MARROW FROM DECEASED DONORS MAY REDUCE RELAPSE IN HLA-MISMATCHED ALLOGENEIC TRANSPLANTATION: DAY 180 POST-TRANSPLANT HOPE UPDATE

Sagar Munjal[1], *Muneer Abidi*[2], *Jeremy Pantin*[3], *Preethi Prasad*[1], *Vicki Graves*[1], *Scott Goebel*[4], *Erik Woods*[1]
[1]*Ossium Health, San Fransisco, United States of America (the),* [2]*Henry Ford Cancer Center, Michigan, United States of America (the),* [3]*Sarah Cannon Tristar Centennial Medical Center, Nashville, United States of America (the),* [4]*Indiana University of Indiana, Indianapolis, United States of America (the)*

Background: Historically, transplant outcomes have been closely tied to the degree of HLA matching, with higher degrees of mismatch correlating with poorer survival. We are evaluating the safety and efficacy of 4–8/8 HLA-matched cryopreserved hematopoietic progenitor cells (HPCs) derived from bone marrow harvested from deceased solid organ donors (ages 7–55 years) under two programs: the HOPE Expanded Access Program and the PRESERVE-I clinical trial (NCT05589896). These cells are processed using minimal manipulation. Initial engraftment success has been reported in the first patient treated with cryopreserved HPC-marrow. Four patients have enrolled in HOPE. This report presents Day 180 data for the first three HOPE-treated patients.

Methods: Three patients had acute myeloid leukemia (AML) in first complete remission (CR1) and lacked suitable matched donors. A fourth patient had a living donor who could not donate due to an allergic reaction to G-CSF. Patient 1 (age 68) and Patient 2 (age 69) received reduced-intensity conditioning (RIC); Patient 3 (age 63) and Patient 4 (age 34) received myeloablative conditioning (MAC). Transplants used 4/8 HLA-matched grafts for Patients 1–3 and 6/8 for Patient 4. CD34+ cell doses were 5.27, 4.45, 4.80, and 5.57 × 10^6 cells/kg, respectively. GVHD prophylaxis included tacrolimus, mycophenolate mofetil, and post-transplant cyclophosphamide (50 mg/kg on Days +3 and +4).

Results: Day 180 update: three of four patients remain Day +180 post-transplant. Neutrophil engraftment occurred on Days +16, +20, and +15; platelet engraftment on Days +21, +34, and +18, respectively, for the first three patients. Full donor chimerism (100%) was confirmed on Days +30 and +60 for the first three patients. No cytokine release syndrome (CRS) events were reported. Acute GVHD was manageable in these three patients: Patient 1 Grade 2 GI with Stage 2 lower GI involvement, onset Day +26; Patient 2 Grade 3 GI with Stage 2 GI and Stage 1 skin involvement, onset Day +54; Patient 3 Grade 2 GI with

Stage 1 skin involvement. All GVHD cases were steroid-responsive and resolved. No significant viral reactivation was reported.
At Day 180, all patients remained relapse-free with sustained cell counts. Survival at Day 180 was 100%. Patient 1 subsequently died on Day 282 from non-relapse causes, determined not to be related to HPC-marrow.

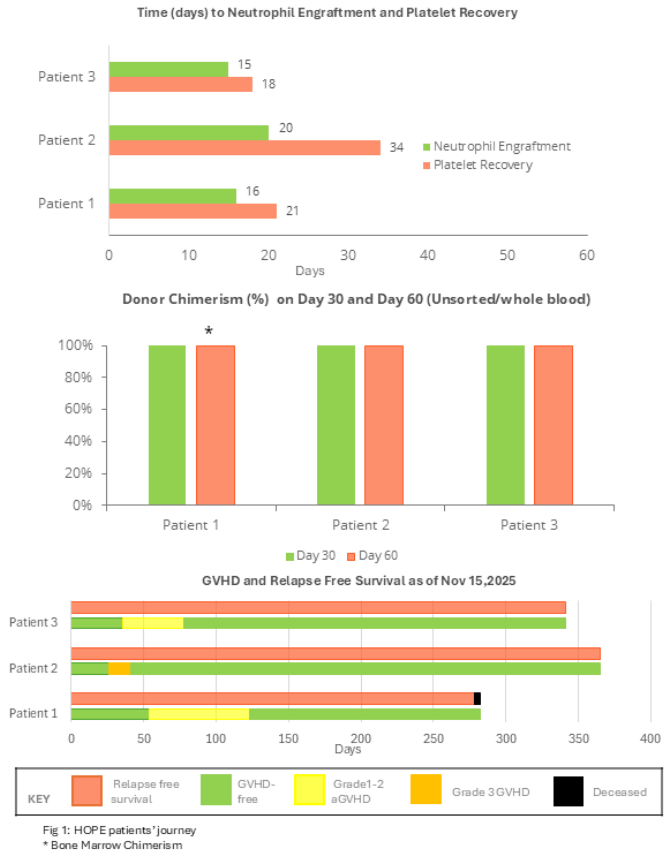

Fig 1: HOPE patients' journey
* Bone Marrow Chimerism

Table 1: Patient demographics and characteristics for first four patients

Patient	Age (years)	Gender (M/F)	Race		Disease	Conditioning Regimen (MAC vs. RIC)	CD34+ Dose (x10^6/kg)
Patient 1	68	Female	African American		AML (CR1)	RIC	5.27
Patient 2	69	Female	African American		AML (CR1)	RIC	4.45
Patient 3	63	Male	African American		AML (CR1)	MAC	4.80

Patient 4	34	Male	White		AML (CR1)	MAC	5.57

Conclusions: These preliminary findings indicate that high-dose, cryopreserved CD34+ cells from deceased donors are feasible and safe for infusion, supporting timely engraftment and disease control in HLA-mismatched allo-HCT. The absence of relapse and chronic GVHD through Day 180, together with manageable acute GVHD, highlights the potential of this novel graft source for patients with unmet medical needs.

COMPARISON OF UMBILICAL CORD BLOOD TRANSPLANTATION OUTCOMES BETWEEN FLT3-MUTATED AND -WILD-TYPE AML IN A MATCHED-PAIR COHORT

Aya Nishida[1], *Mika Kuno*[1], *Otoya Watanabe*[1], *Kyosuke Yamaguchi*[2], *Daisuke Kaji*[1], *Kosei Kageyama*[2], *Yuki Taya*[2], *Shinsuke Takagi*[1], *Hisashi Yamamoto*[1], *Go Yamamoto*[1], *Yuki Asano-Mori*[1], *Atsushi Wake*[2], *Shuichi Taniguchi*[1], *Naoyuki Uchida*[1]
[1]*Toranomon Hospital, Tokyo, Japan,* [2]*Toranomon Hospital Kajigaya, Kanagawa, Japan*

Background: FLT3-mutated acute myeloid leukemia (AML) has long been associated with poor prognosis. The introduction of FLT3 inhibitors has improved outcomes, and according to ELN 2022, FLT3-mutated AML is now classified as intermediate risk. While allogeneic hematopoietic stem cell transplantation (allo-HSCT) is commonly performed, data on umbilical cord blood transplantation (UCBT) in FLT3-mutated AML remain limited. UCBT is thought to provide a stronger graft-versus-leukemia (GVL) effect compared with other graft sources. We aimed to compare UCBT outcomes between FLT3-mutated and wild-type AML and to identify prognostic factors using a matched-pair cohort.

Methods: We retrospectively analyzed relapsed or refractory adult AML patients who underwent their first UCBT at Toranomon Hospital between January 2019 and December 2023. Patients without FLT3 mutation testing, with active infections, or with ECOG performance status >2 at transplantation were excluded. Among 177 eligible patients in the total cohort, 36 had FLT3 mutations. Matched-pair cohorts of FLT3-mutated and FLT3–wild-type AML were created using age, sex, ELN 2022 risk (excluding FLT3 mutation), disease

status, HCT-CI score, conditioning intensity, and year of transplantation as covariates. The caliper width was set at 0.2 times the standard deviation. Survival probabilities were estimated using the Kaplan–Meier method, with group comparisons assessed by log-rank tests. Cox regression and Fine–Gray models were used for multivariate analyses, accounting for competing risks. This report summarizes interim 1-year results.

Results: Each cohort included 31 patients. All patients in the FLT3-mutated cohort had ITD mutations. The median age was 56.4 years in both cohorts. The numbers of patients with de novo AML were 30 and 29, and those with ECOG performance status 0–1 at transplantation were 29 and 27 in FLT3-mutated and FLT3–wild-type cohorts respectively, showing no significant differences. There were also no significant differences in total nucleated cell (TNC) count, $CD34^+$ cell count, or CFU-GM number per kilogram of body weight of the cord blood units used.
The FLT3-mutated cohort showed a trend toward better 1-year progression-free survival (PFS; 70.6% vs. 51.6%, P = 0.14) and overall survival (OS; 70.6% vs. 54.5%, P = 0.39) compared with the wild-type cohort, along with a significantly lower relapse rate (7.0% vs. 27.0%, P = 0.02), while non-relapse mortality (NRM) did not differ significantly (21.0% vs. 34.5%, P = 0.55) in univariate analysis. In multivariate analysis, factors associated with poor OS were older age (>59 years) and higher HCT-CI (≥2); factors associated with poor PFS were older age (>59 years), higher HCT-CI (≥2), FLT3 wild-type status, and reduced-intensity conditioning; male sex was associated with higher NRM. No factors were significantly associated with relapse. In the FLT3-mutated cohort, 19 patients received post-transplant maintenance with gilteritinib, showing 78.6% PFS and OS, 5.3% relapse, and 16.1% NRM.

Conclusions: In this matched-pair cohort analysis of first-time UCBT recipients, FLT3-mutated AML was associated with superior PFS and a lower relapse rate compared with FLT3–wild-type AML. Post-transplant FLT3 inhibitor maintenance therapy showed potential benefit, although results should be interpreted cautiously due to possible selection bias. Larger studies are warranted to validate these findings.

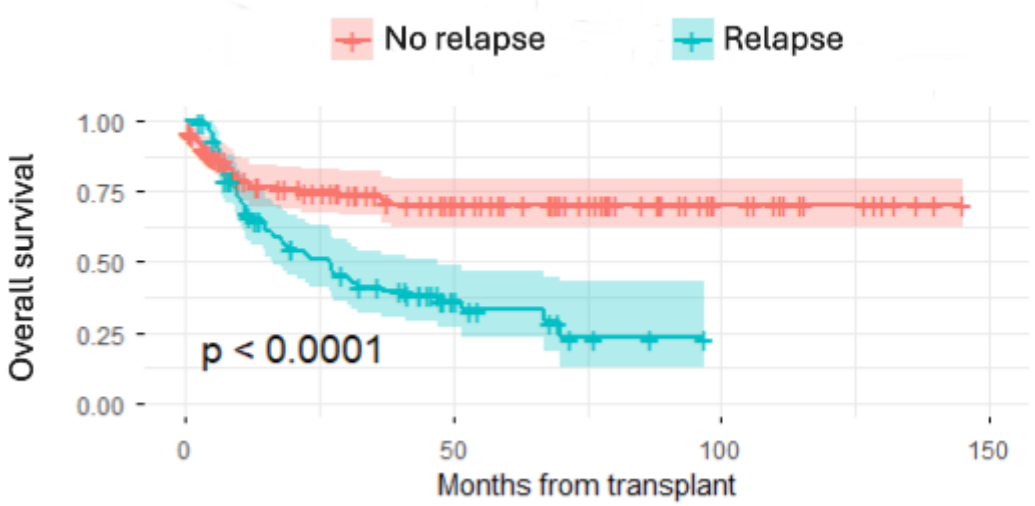
POST-TRANSPLANT RELAPSE AS A MAJOR DETERMINANT OF OVERALL SURVIVAL AFTER ALLOGENEIC HAEMATOPOIETIC STEM CELL TRANSPLANTATION: RESULTS FROM A SINGLE CENTER IN AN UPPER-MIDDLE INCOME COUNTRY

*Shirley Quintana-Truyenque[1], **Naty López-Córdova**[1], Cindy Alcarraz-Molina[1], Laura Chavez-Jimenez[1], Lourdes Lopez-Chavez[1], Victor Mallma-Soto[1], Fatima Muro-Cieza[1], Tatiana Vidaurre[1], Jule Vasquez-Chavez[1]*
[1]Instituto Nacional de Enfermedades Neoplásicas, Lima, Peru

Background: Relapse remains an important cause of treatment failure after allogeneic hematopoietic stem cell transplantation (allo-HSCT). Despite advances in transplant strategies and rescue treatments, the impact of post-transplant relapse on long-term survival continues to be significant. We aimed to evaluate the overall survival (OS), progression-free survival (PFS), and the impact of relapse on survival outcomes in a real-world cohort of allo-HSCT recipients.

Methods: We conducted a retrospective study including 235 adult patients undergoing allo-HSCT at a single centre. Data were collected from the unit registry and both physical and electronic medical records. Overall survival was defined as the time from HSCT to death from any cause or last follow-up. Progression-free survival was defined as the time from HSCT to relapse or death. Relapse was detected by molecular testing in chronic myeloid leukaemia and by flow cytometry in the rest of the diseases. Survival curves were estimated using the Kaplan–Meier method and compared using the log-rank test. Median follow-up was estimated using the reverse Kaplan–Meier method.

Results: Median age at HSCT was 28 years (range 15–63), and 123 patients (52%) were male. The most frequent diagnoses were acute lymphoblastic leukaemia (ALL, n=115), acute myeloid leukaemia (AML, n=63), mixed phenotype leukaemia (n=17), chronic myeloid leukaemia (n=15, 9 of them in blastic phase), and myelodysplastic syndrome (n=8). Before HSCT, 212 patients (90.2%) were in complete remission, 17 (7.2%) had measurable residual disease (MRD+), and 6 (2.6%) had unknown disease status.
Relapse occurred in 94 patients (40%), with a median time to relapse of 8 months (range 1–43). Most relapses (89%, n=84) occurred within the first year after HSCT, including 48 cases within the first six months. With a median follow-up of 49.8 months (range 0.8–140), OS at 2 and 5 years for the entire cohort was 64.5% and 54.7%, respectively. PFS at 2 and 5 years was 43.2% and 38.8%, respectively.
Patients who relapsed had significantly inferior survival compared with those without relapse (Figure 1). OS at 2 and 5 years was 50.9% and 32.9% in relapsed patients versus 76.6% and 72.8% in non-relapsed patients (log-rank $p<0.001$). Relapse was the strongest determinant of mortality in the cohort, according to the univariate analysis.



Conclusions: Relapse after allo-HSCT remains frequent and is the strongest determinant of long-term survival. These findings emphasise the critical need for optimised relapse prevention strategies and early post-transplant approaches to improve outcomes in high-risk patients.

Disclosure: Nothing to declare.

Graft-versus-host Disease - Basic and Translational

OS04-06

PENTRAXIN 3 AS EARLY BIOMARKER TO PREDICT ACUTE GRAFT-VERSUS-HOST DISEASE AND TRANSPLANT-RELATED MORTALITY

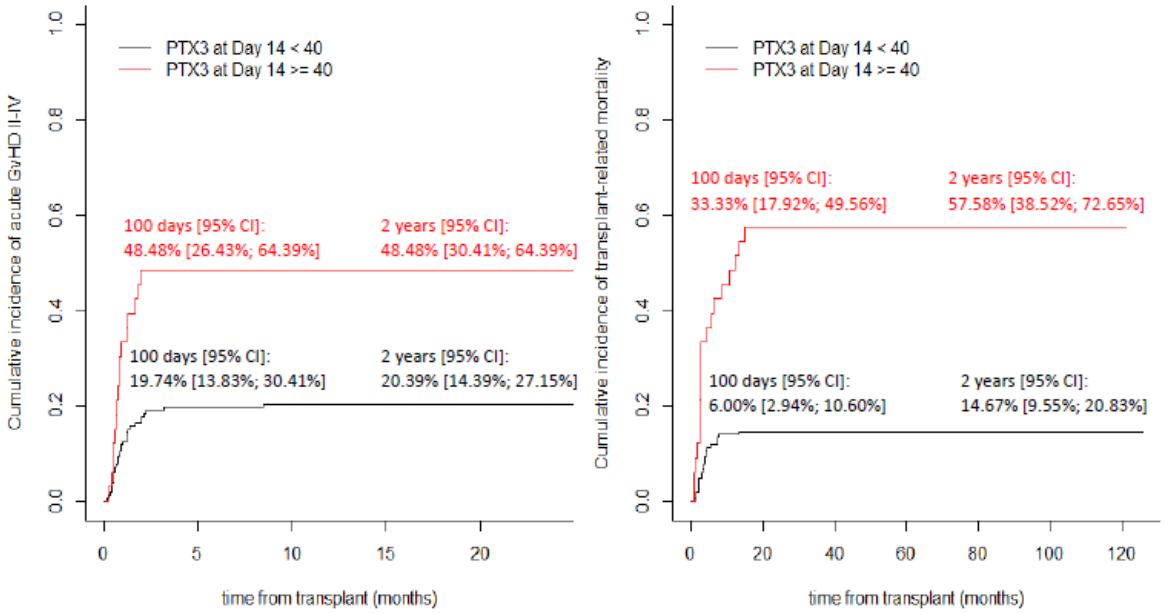
Clinical and Research Center, Rozzano, Italy, [6]Vita-Salute San Raffaele University, Milan, Italy

Background: In the context of allogeneic hematopoietic stem cell transplantation (allo-HSCT), different biomarkers have been studied for their potential in prediction of Graft-versus-Host Disease (GvHD) and transplant-related mortality (TRM). Pentraxin3 (PTX3) is an essential component of the humoral arm of innate immunity, involved in controlling infections and modulating inflammation.

Methods: We conducted a prospective multicenter observational study to ascertain the potential of plasma PTX3, measured before conditioning, at day of cell infusion, days +7 and +14 after allo-HSCT, in predicting the main transplant outcomes (OS, TRM, relapse-free survival, incidence of acute GvHD II-IV and moderate-severe chronic GvHD). Moreover, we evaluated PTX3 levels at acute GvHD diagnosis and day+7 follow-up, for their ability to predict aGvHD clinical course.

Results: We enrolled 207 consecutive adult allo-HSCT patients, mainly affected by acute leukemia (67%). Donors were haploidentical (n=62), sibling (n=68), unrelated (n=77). Peripheral blood was the graft source in 55% of cases. Through adjusted univariate regression analysis, evaluating the role of PTX3 levels at longitudinal timepoints in predicting the main transplant outcomes, we identified Day+14 after transplant as a relevant timepoint, in which higher PTX3 concentration predicted more frequent occurrence of acute GvHD II-IV (HR 1.64, 95% CI 1.17-2.3, Holm adj. p-value=0.0168) and higher TRM (HR 2.19, CI 1.62-2.95, p<0.0001). Coherently, Day+7 PTX3 levels showed a trend towards higher acute GvHD II-IV risk (HR 1.45, CI 1.07-1.98, p=0.0540) and higher TRM (HR 1.4, CI 1.05-1.88, p=0.0690). We then performed adjusted univariate regression analysis evaluating PTX3 levels in patients with acute GvHD (any grade) and outcome of GvHD. PTX3 values at GvHD diagnosis and day+7 follow-up could not predict peak acute GvHD severity (II-IV vs I), steroid refractoriness or subsequent development of moderate-severe chronic GvHD, however, we cannot exclude an effect of the limited sample size (samples were not available for all GvHD cases). Focusing on Day+14 post allo-HSCT timepoint, we identified a cut-off of plasma PTX3 rounded as 40 ng/ml, to predict the occurrence of acute GvHD II-IV in the first 100 days after transplant. Patients with PTX3 ≥40 ng/ml at Day+14 had a higher 100-day cumulative incidence of acute GvHD II-IV (48.48% [26.43%; 64.39%] vs 19.74% [13.83%; 30.41%]), higher 100-days TRM (33.33% [17.92%; 49.56%] vs 6.00% [2.94%; 10.60%]) and higher 2-years TRM (57.58% [38.52%; 72.65%] vs 14.67% [9.55%; 20.83%]).



Finally, we estimated multiple Fine-Gray regression models for predicting acute GvHD II-IV and TRM from Day 14 from transplant and the only variable retained in the final model after backward variable selection was PTX3 concentration. From these models, PTX3 concentration ≥40 ng/ml at Day+14 could predict a higher risk of acute GvHD II-IV occurring after Day+14 (HR 2.84, CI 1.44-5.63, p=0.0027) and a higher risk of TRM occurring after Day+14 (HR 5.12, CI 2.8-9.36, p<0.0001).

Conclusions: This prospective multicenter observational study confirms plasma PTX3 levels at Day+14 after allo-HSCT as a valuable biomarker in identifying patients at risk of acute GvHD and TRM, providing a window for additional prophylactic or preemptive strategies.

OS11-01

TGF-B–ENRICHED ENTERAL NUTRITION MODULATES SYSTEMIC INFLAMMATION IN ACUTE GASTROINTESTINAL GRAFT-VERSUS-HOST DISEASE

Lena Riegler[1], *Sangya Chatterjee*[1], *Ina Martin*[1], *Tamina Rueckert*[1], *Marie Czech*[1], *Valentin Wenger*[1], *Francesca Biavasco*[1], *Claudia Wehr*[1], *Joerg Buescher*[2], *Alina Hartmann*[1], *Annette Schmitt-Graeff*[1], *Wolfgang Melchinger*[1], *Natalie Köhler*[1], *Robert Zeiser*[1], *Christine Greil*[1]
[1]*University of Freiburg, Freiburg, Germany,* [2]*Max Plank Institute of Immunobiology and Epigenetics, Freiburg, Germany*

Background: Although acute gastrointestinal graft-versus-host disease (GI-aGVHD) is a severe immune-complication after allogeneic hematopoietic stem cell transplantation (allo-HCT) with substantial impact on non-relapse mortality, evidence supporting the use of enteral nutritional supplements remains sparse. Given the shared pathophysiological features between Crohn's disease and GI-aGVHD, we here investigate a TGF-β-enriched drinking supplement (Modulen IBD®) shown to be effective in Crohn's disease.

Methods: In a pilot clinical study assessing feasibility, patients scheduled for allo-HCT (n = 3 to 4) received 250 ml Modulen IBD® daily from the first day of conditioning therapy until withdrawal of consent; serum and stool samples were analyzed.
Mechanistic effects were explored using a well-established major histocompatibility complex-mismatched murine allo-HCT model (BALB/c → C57BL/6). Mice received either Modulen IBD® or vehicle orally from day 0 to 14 after transplantation before examination of stool and tissue samples.
Finally, we initiated a phase II clinical trial enrolling patients at onset of GI-aGVHD. Patients receive 250 ml of Modulen IBD® three times a day in addition to guideline-based steroid treatment. Serum and stool samples are collected at onset of GI-aGVHD, after 1 and 2 weeks and at discontinuation.

Results: In pilot study patients, targeted liquid chromatography-mass spectrometry (LC-MS) of serum samples revealed changes in the fatty acids (FA) signature after treatment with Modulen IBD® including increased levels of anti-inflammatory long-chain FA (LCFA) oleic, eicosatrienoic and linoleic acid as well as elevated kynurenic acid.
In the murine allo-HCT model, histological aGVHD scores were significantly reduced in the colon, small intestine and liver of Modulen IBD®-treated mice. Comparable to the human samples, serum LC-MS showed an increase in oleic and eicosatrienoic acid. Pro-inflammatory LCFA like palmitic, stearic and arachidonic acid decreased as well as amino acids like arginine, ornithine, leucine and aspartate, all the latter being linked to promote aGVHD. In colon tissue and stool butyrate levels were elevated, stool 16s rRNA gene sequencing showed an increased abundance of *Lactococcus* and *Bacillus*. Flowcytometry of colonic immune cells showed increased intracellular levels of TGF-β in $Ly6G^+$ neutrophils, of IL-10 in $CD4^+$ T-cells and increased $Ly6C^+$ monocytes in the colon epithelium, accompanied by reduced $CD3^+$ T-cell infiltration in the colon. Enhanced IL-10 abundance in $CD4^+$ T-cells was also observed in the serum.
Enrollment of patients in the phase II clinical study is still ongoing.

Conclusions: Modulen IBD® seems to induce an anti-inflammatory phenotype in the gut, likely driven by three complementary mechanisms:
1. Cytokine-mediated immunomodulation due to increased levels of anti-inflammatory cytokines such as IL-10 and with changes in colonic T-cell infiltration, hinting for reduced local alloreactivity.
2. Changes in the microbiome, including a shift towards butyrate-producing bacteria important for endogenous epithelial TGF-β production.
3. Alterations in metabolic profiles characterized by reduced pro-inflammatory and increased anti-inflammatory lipids and amino acids. The observed changes in kynurenic acid and butyrate levels suggest enhanced support for intestinal barrier integrity and local immune regulation.

Overall, TGF-β-enriched enteral supplementation seems to be a promising additional therapy in patients with GI-aGVHD. The ongoing phase II clinical study will provide further data.

Clinical Trial Registry: The phase II clinical study is registered as FRKS005255 at Freiburger Register für Klinische Studien. The ethics approval was granted on 10/23/2024 under number 24-1255-S1.

ASCC1 DEFICIENCY IN DONOR T CELLS AGGRAVATES AGVHD THROUGH TRANSCRIPTIONAL DOWNREGULATION OF IL-10

Min Ling[1,2], *Jiashuo Wu*[1,2], *Wei Ding*[1], *Jingyi Xu*[1], *Keli Yue*[1,2], *Jiangying Liu*[1], *Xiaojun Huang*[1,2]
[1]*Peking University People's Hospital, Beijing, China,* [2]*Peking University, Beijing, China*

Background: Acute graft-versus-host disease (aGVHD) continues to hamper the efficacy of allogeneic hematopoietic cell transplantation (alloHCT). Independent of HLA disparity, our previous study has demonstrated the dominant contribution of non-HLA genetic features to aGVHD across different types of alloHCT. In this study, we identified for the first time a significant correlation between the loss-of-function variations in donor gene Activating Signal Cointegrator 1 Complex Subunit 1 (ASCC1) and an increased risk of aGVHD. However, the intrinsic function of ASCC1 in T-cell biology and the underlying molecular mechanisms remain unexplored.

Methods: ASCC1 was disrupted in human peripheral blood mononuclear cells (PBMCs) using CRISPR-Cas9 technology. T-cell differentiation and cytokine production were assessed following in vitro stimulation. Furthermore, we generated a T-cell-specific *Ascc1*-knockout (KO) C57BL/6 (H-2K^{b}) mouse model using the Cre-LoxP system. T cells from wild type (WT) or *Ascc1*-KO mice were transplanted into lethally irradiated CB6F1 (H-2K$^{b/d}$) recipients. Mechanistic insights were derived from transcriptome sequencing (RNA-seq) of both human and murine T cells, followed by functional rescue experiments using the recombinant target protein.

Results: Both human and murine ASCC1-deficient T cells exhibited significantly enhanced reactivity. This was characterized by skewed differentiation towards Th1 and Tc1 subsets, reduction in regulatory T cells (Tregs), elevated productions of proinflammatory cytokines

(IFN-γ and TNF-α), and increased cytotoxic potential (CD107a). In the alloHCT setting, mice receiving Ascc1-deficient T cells developed exacerbated GVHD, characterized by rapid weight loss, higher GVHD scores (representing worsening ruffled fur, posture, and diarrhea), and extensive tissue damage in the skin, small intestine, and liver. Recovered Ascc1-deficient T cells displayed an enhanced effector memory phenotype, accompanied by a significantly lower expression of exhaustion molecules (PD-1 and TIM-3). This observation suggests the persistent hyper-inflammatory state of Ascc1-deficient T cells recovered in recipient mice. Consequently, the survival of recipients transplanted with *Ascc1*-KO T cells was significantly reduced compared to the WT group. Transcriptomic profiling revealed a conserved mechanism: ASCC1 deficiency consistently downregulated the transcription of an anti-inflammatory cytokine, Interleukin-10 (IL10), in both human and murine T cells. This reduction was also confirmed at the protein level. Crucially, in vitro treatment with recombinant IL-10 effectively reversed the hyper-reactive phenotype of Ascc1-KO T cells, restoring normal differentiation patterns and dampening excessive proinflammatory cytokine production.

Conclusions: Our study implicates ASCC1 as a pivotal negative regulator of T-cell reactivity. The loss of ASCC1 reversed this anti-inflammatory capacity, at least partially through the transcriptional downregulation of IL10, leading to unleashed T-cell responses and severe aGVHD. These findings underscore the significance of the ASCC1-IL-10 axis as a novel non-HLA immunoregulatory pathway and propose new avenues for investigating the immunogenetic mechanism of T-cell alloreactivity. From a clinical perspective, our research suggests that genotyping donor ASCC1 may enhance risk stratification for aGVHD and targeting the IL-10 pathway could provide innovative therapeutic strategies to prevent aGVHD in high-risk patients.

T CELL RESISTANCE TO GLUCOCORTICOIDS IN GRAFT-VERSUS-HOST DISEASE

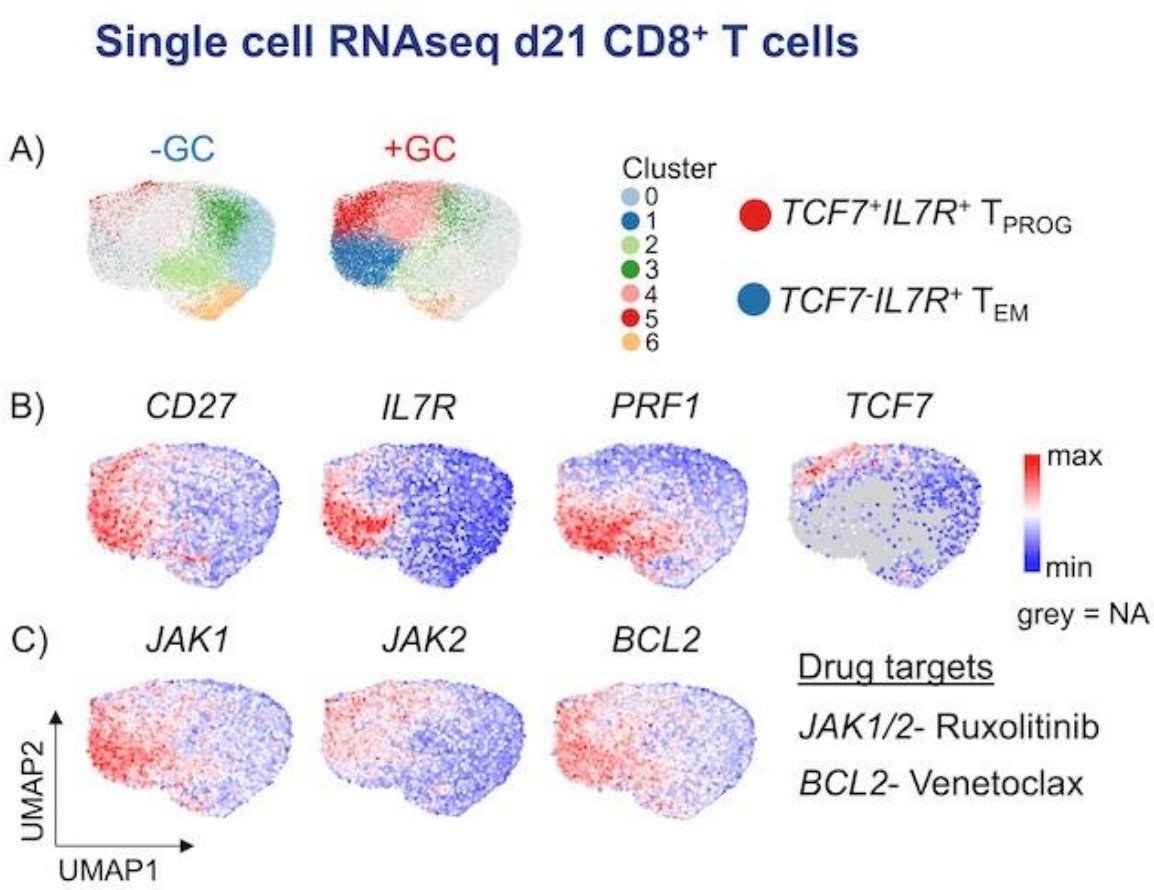
Andrew McIntyre[1], *Lisanne Schoutens*[1], *Elisa Armbrecht*[1], *Andrew Gravett*[1], *Nicolas Sanschagrin*[1], *Maria Greco*[1], *Lai Cheng*[1], *Callum Wright*[2], *Matthew Collin*[2], *Ronjon Chakraverty*[1]
[1]*MRC Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, United Kingdom of Great Britain and Northern Ireland (the),* [2]*Translational and Clinical Research Institute, Newcastle University, Newcastle upon Tyne, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Gut biopsies from patients with glucocorticoid (GC)-refractory graft-versus-host disease (GVHD) are frequently characterised by large clonal expansions of $CD8^+$ T cells[1]. Experimental models of GVHD have suggested that these T cell expansions are

sustained by progenitor-type T cells expressing the transcription factor TCF1, which possess inherent proliferative and self-renewal potential[2,3]. We hypothesised that a similar progenitor-type population can be found in humans and is resistant to GC treatment.

Methods: We drove the expansion and differentiation of human T cells by repeated stimulation with anti-CD3/CD28 beads over three weeks, comparing the addition of clinically relevant concentrations of methylprednisolone versus no GC controls. We determined output population architecture and function using a combination of multiparametric flow cytometry, bulk and single cell transcriptional profiling.

Results: GC-treated $CD8^+$ T cells showed increased proliferation and overall expansion than control cells, concomitant with greater retention of surface markers (e.g., IL-7RA, CD27, CXCR4) and a transcriptional profile (e.g., *KLF2, LTB, BCL2)* associated with a 'less-differentiated', memory-associated state. *In vitro* assays indicated intact cytokine-generating function and killing capacity of the GC-resistant $CD8^+$ T cells versus controls. These GC-driven changes to T cell proliferation and phenotype were largely restricted to $CD8^+$ T cells, occurring independently of $CD4^+$ T cells. scRNAseq revealed that the $CD8^+$ T cell population showed a distinct differentiation trajectory (Fig. A) composed primarily of two *IL7RA*-expressing clusters: a major effector memory-like cluster expressing cytotoxic genes (e.g., *PRF1*) and a smaller cluster composed of progenitor-like cells, expressing *TCF7* (encoding TCF1) and *LEF1* (Fig. B) To test the clinical relevance of these findings *in vivo*, we interrogated patient scRNAseq data derived from n=19 biopsies of acute lower gut GVHD[1], treated with (n=14) or without GC (n=5) at the time of biopsy. We identified strong enrichment for our $TCF7^{hi}$ progenitor-like cluster in patients with severe GVHD treated with GC (median 35.1% versus 9.5% of $CD8^+$ T cells, $p<0.05$).
The ruxolitinib targets JAK1/2 were enriched in our GC-induced $CD8^+$ T cell states (Fig. C). To address how JAK1/2 inhibition would influence the GC-resistant phenotype, we applied RUX at clinically relevant concentrations and showed that its addition blocked proliferation in GC-treated cultures to a greater extent than controls. However, RUX simultaneously further enriched for the TCF-1^{hi}IL-$7RA^{hi}$ progenitor-like population, which displayed elevated expression of the anti-apoptotic molecule, BCL-2. To target the progenitor population, we additionally applied clinically relevant concentrations of venetoclax (VEN). VEN treatment alone did not block proliferation but reduced the frequency of progenitor-like cells arising in the presence of GC. When combined, VEN and RUX blocked proliferation and reduced progenitor frequency in parallel to increased activated caspase-3 expression by CD8 T cells, particularly in the presence of GC.



Conclusions: These data suggest that treatments used for GVHD including GC and RUX may select for progenitor-like CD8+ T cells with the potential to sustain tissue injury and lead to refractory disease. Strategies combining drug targets which can inhibit T cell proliferation whilst preventing the retention of multipotent and proliferative progenitor populations may be required to overcome the limitations of current GVHD treatment approaches.

OS11-04

HOW DOES A SINGLE PRETRANSPLANT ORAL HIGH DOSE OF VITAMIN A PREVENT CHRONIC GRAFT VERSUS HOST DISEASE? TRANSCRIPTOMIC INSIGHTS INTO MECHANISM

Pooja Khandelwal[1], *Aaron Webster*[1], *Nathan Luebbering*[1], *Lucille Langenberg*[1], *Kristie Ramos*[1], *Stella Davies*[1]
[1]*Cincinnati Children's Hospital Medical Center, Cincinnati, United States of America (the)*

Background: Oral high dose vitamin A given once before allogeneic hematopoietic stem cell transplant (HSCT) reduced chronic graft versus host disease (cGVHD) in a randomized double blinded placebo-controlled trial in children (*Blood* 2024) but the mechanism of this effect was unclear. Vitamin A reduces NFκβ -mediated pro-inflammatory gene expression, e.g. TNFa and IL-6 in macrophages. We hypothesized that vitamin A induces a tolerogenic phenotype in host dendritic cells in the gut, which in turn reduces inflammatory phenotype of engrafted donor cells, thereby reducing cGVHD.
Objective: To examine differences in expression of pro-inflammatory and pro-fibrotic pathways in donor cells between recipients of vitamin A and placebo at day+100 post HSCT.

Methods: Peripheral blood mononuclear cells from eight children (four vitamin A, four placebo; Table 1) enrolled in the randomized trial were profiled by single-cell RNA sequencing. Vitamin A and placebo patients were matched 1:1 by age, HLA match, stem cell source, preparative regimen intensity and acute GVHD prophylaxis. All four placebo recipients developed cGVHD at a median of day+290 (range 170-392 days) post HSCT, whereas no vitamin A recipients developed cGVHD with >4 years' follow-up. Cells with >15% mitochondrial genes, doublets, and ambient RNA contamination were removed. Pseudobulk differential expression was performed using placebo as reference. Ingenuity Pathway Analysis (Qiagen) identified enriched canonical pathways and upstream regulators. Pathway and DEG significance was defined as FDR < 0.05.

Vitamin A Patient#	**Age at HSCT (years)**	**HLA Match**	**Stem cell source**	**Conditioning intensity**	**Acute GVHD prophylaxis**	**Chronic GVHD (yes/no)**
1	9.8	10/10	Bone marrow	Myeloablative	CSA/MMF/abatacept	No
2	12.5	10/10	Bone marrow	Myeloablative	CSA/MMF	No
3	20	10/10	Bone marrow	Reduced intensity	CSA/MMF/abatacept	No
4	7.5	10/10	Bone marrow	Myeloablative	CSA/MTX	No
Placebo patient #	**Age at HSCT(years)**	**HLA Match**	**Stem cell source**	**Conditioning intensity**	**Acute GVHD prophylaxis**	**Day post HSCT of chronic GVHD diagnosis**
1	9.6	10/10	Bone marrow	Myeloablative	CSA/MTX	392

2	13	9/10	Bone marrow	Myeloablative	CSA/MMF/abatacept	170
3	19.5	10/10	Bone marrow	Myeloablative	CSA/MMF/abatacept	212
4	8	10/10	Bone marrow	Myeloablative	CSA/MMF/abatacept	368

Table 1. Demographics

Results:

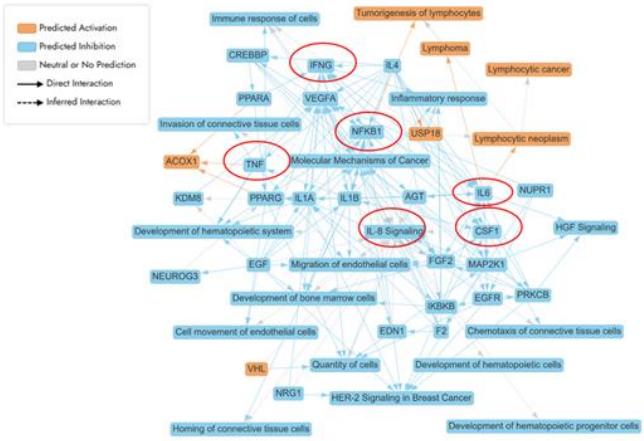

Figure 1B. Dendritic cells ingenuity pathway analyses

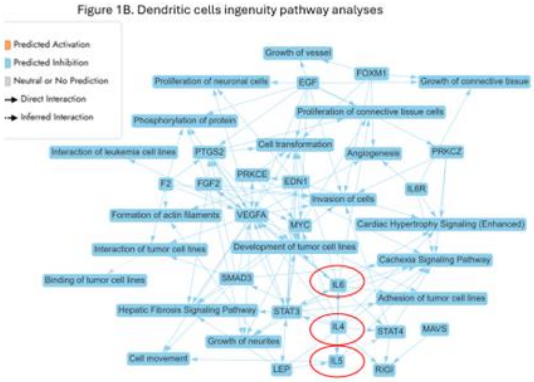

Figure 1C. Naïve B- cells ingenuity pathway analyses

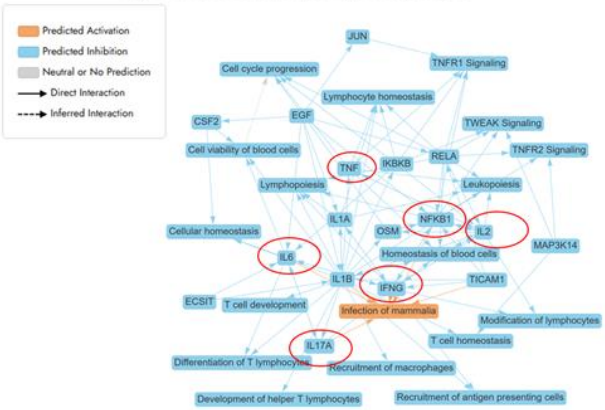

Figure 1D. CD4+T-cells ingenuity pathway analyses

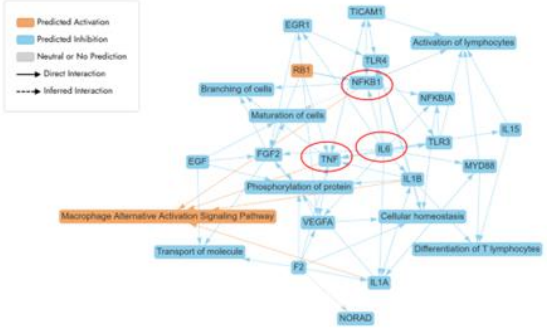

Figure 2. Proposed Mechanism of Vitamin A to reduce chronic GVHD

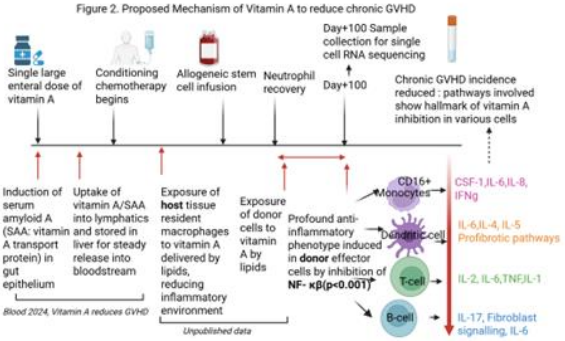

UMAP demonstrated similar numerical distribution of cells in vitamin A and placebo recipients. However, there were striking differences in functional cellular phenotypes, with suppression of pro-inflammatory pathways mediated by NFκβ in vitamin A recipients. Non-classical (CD16+) monocytes showed reduction in CSF1, IL-6, IL-8, NFκβ, IFN-γ in the vitamin A cohort compared to placebo (Figure 1A all blue shaded pathways, $p<0.001$). Classical (CD14+) monocytes showed significant downregulation of IL17A, TNF, IL-6 in the vitamin A cohort($P<0.001$). Dendritic cells also demonstrated downregulation of proinflammatory signaling genes including IL-6, IL-4, IL-5 and profibrotic pathways (Figure 1B $p < 0.001$). Notable downregulation in naïve B cells showed downregulation in IL-17A, IL-2, IL-6 TNFR1, IL-1β, IFNγ, reduction in fibroblast signaling and inhibition of macrophage

activation pathways (Figure 1C $p < 0.001$), while CD4 T- cells in the vitamin A cohort involved downregulation of IL-6 and TNF (Figure 1D $p < 0.001$). Collectively, profound anti-inflammatory activity and reduction of profibrotic pathways and macrophage activation was observed in the vitamin A cohort compared to placebo (Figure 2).

Conclusions: Vitamin A given as a single large enteral dose before HSCT induces significant downregulation of proinflammatory and profibrotic signaling pathways in donor monocytes, T-cells, B cells and dendritic cells more than three months later, likely contributing to lower incidence of cGVHD.

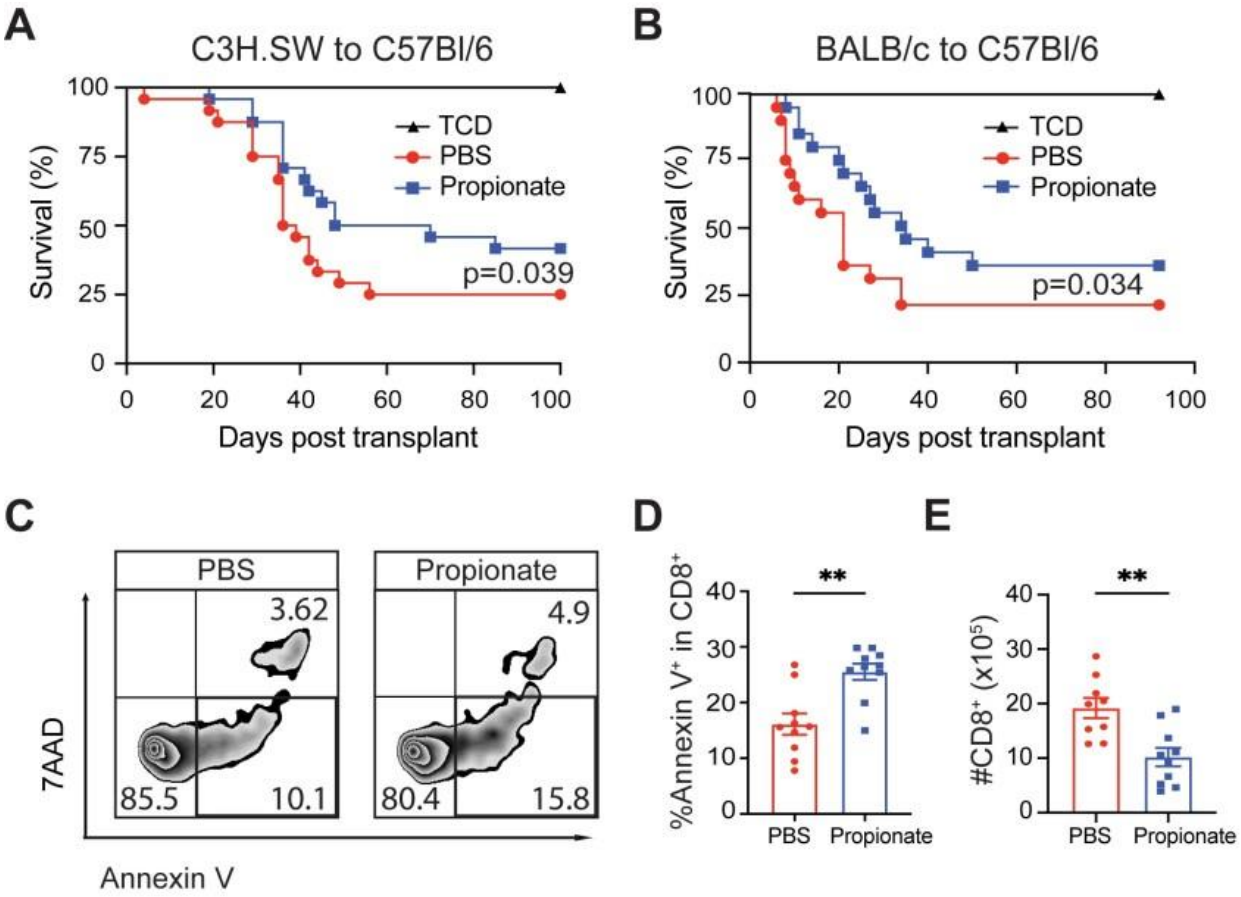
MICROBIOTA-DERIVED PROPIONATE INDUCES DELETIONAL TOLERANCE AND DECREASES GRAFT-VERSUS-HOST DISEASE

Ali Turan[1,2], Alex E. Wolfe[2], Mercy Mirimo-Martinez[2], Saranya Chakka[2], Angi Dai[3], Amara Herman[2], Shubhpreet K. Gosal[2], Jonathan U. Peled[3,4], ***Kate A. Markey***[2,5]
[1]Abdullah Gul University, Kayseri, Turkey, [2]Translational Science and Therapeutics Division, Fred Hutchinson Cancer Center, Seattle, United States of America (the), [3]Adult Bone Marrow Transplantation Service, Department of Medicine, Memorial Sloan Kettering Cancer Center, New York, United States of America (the), [4]Weill Cornell Medical College, New York, United States of America (the), [5]Division of Medicine, University of Washington, Seattle, United States of America (the)

Background: Functionally diverse, anaerobe-rich microbial communities have consistently been associated with improvements in clinical outcomes in patients receiving allogeneic hematopoietic stem cell transplantation (HCT). We have used mouse models of HCT to investigate the capacity of propionate – a microbe-derived short-chain fatty acid – to modify immunopathology.
We previously demonstrated that pre-HCT Flt3-L promoted deletional tolerance via expanding $CD8^+$ DC, which in turn, drive activation-induced cell death of donor $CD8^+$ T cells. Here, we demonstrate that microbe-derived propionate can act upstream of this process, and our results contribute important insight into the mechanism by which propionate regulates alloimmunity.

Methods: We used a $CD8^+$ T cell-dependent model (C3H.SW→ C57Bl/6) and a $CD4^+$ T cell-dependent model (BALB/c→C57Bl/6) of HCT, and administered oral propionate (15mM/kg/dose) from d-4 to d+9, or PBS control. For quantifying leukemia relapse, we used GFP^+ MLL-AF9 primary mouse leukemia. *B. thetaiotaomicron* was administered by oral gavage of log-phase live bacteria at $\sim 10^8$ CFU/dose. We performed 16s rRNA amplicon-based sequencing on fecal pellets to assess the intestinal microbiome. Statistical analyses were performed using GraphPad Prism or R (for competing risk analyses in leukemia experiments).

Results: In steady-state C57Bl/6 mice, exogenous propionate administration increased cecal but not systemic Flt3L concentration (p=0.0013; propionate vs. PBS control in cecal contents; n = 10/grp). In both the C3H.SW→C57Bl/6 and BALB/c→C57Bl/6 models, we observed improved GVHD survival with propionate treatment compared with PBS-treated control mice (n=20-24/group from 3 independent replicate experiments (Fig.A-B). We hypothesized that this was due to the deletion of incoming donor CD8+ T cells, and when we labeled donor T cells with the Cell Trace Violet (CTV) dye to track early proliferation, we found that propionate reduced $CD8^+$ T cell proliferation (%CTV^{low}) (n=10/grp, p=0.035). In parallel, we observed an increase in $CD8^+$ T cell apoptosis using Annexin V staining on d+3 after HCT, and a decrease in the absolute number of donor $CD8^+$ T cells (Fig.C-E). Furthermore, in propionate-treated mice, we observed improved gut integrity at day 3 post-HCT, as measured by FITC-dextran (n=10/group, p=0.0057), and supported by qPCR assays of specific genes associated with gut integrity (p=0.0325 for *HNF4a*; p=0.02 for *ZO-1*). The intestinal microbiome was also reshaped by propionate administration. We observed an enrichment of SCFA-producing taxa, including *Clostridium*, *Prevotella*, and *Robinsoniella*, suggesting a protective feed-forward loop. To establish a 'living' therapy to provide long-term propionate *in vivo*, we administered the propionate-producing bacteria *B. thetaiotaomicron* from d-7 to d+7 in the C3H.SW→ C57Bl/6 model and this phenocopied the administration of propionate alone (n=24/grp, p=0.05). Furthermore, we demonstrated that our tolerance induction strategy did not impair GVL, by performing in vivo relapse experiments in the C3H.SW→ C57Bl/6 model with GFP^+ MLL-AF9 primary mouse leukemia cells (p=0.09 for relapse rate using competing-risk analysis).



Conclusions: Our studies highlight multiple preciously unappreciated pathways by which microbe-derived SFCAs promote tolerance. This highlights that microbe-targeted interventions that enhance propionate availability during the early peri-transplant period may facilitate favorable long-term outcomes with decreases in alloreactivity, improved intestinal tract integrity and maintenance of protective intestinal microbial communities.

Background: Acute graft-versus-host disease of the lower gastrointestinal tract (GI-GvHD) remains a major cause of non-relapse mortality following allogeneic hematopoietic cell transplantation (allo-HCT). While high-dose corticosteroids are the standard first-line therapy, up to 70% of patients with grade III–IV GI-GvHD develop steroid-refractory disease (SR-GvHD), which is associated with poor survival. Previous studies have suggested a role for tissue-resident lymphocyte populations in GvHD pathogenesis, but data on their prognostic relevance in GI-GvHD are limited. We aimed to determine whether selected intestinal immune cell subsets at the time of GI-GvHD diagnosis are associated with subsequent response to corticosteroid therapy.

Methods: We retrospectively analysed intestinal biopsies from 50 patients who developed acute GI-GvHD following allo-HCT at the Medical University of Graz between 01/2015 and 06/2021. Biopsies were taken at first clinical diagnosis of acute GvHD. Patients were categorized into steroid-sensitive (SS, n=26) and steroid-refractory (SR, n=24) groups based on clinical response. Multicolour immunofluorescence and image analysis were used to quantify different T cell subsets, like Th17 and tissue-resident memory T cells (TRMs), mast cells, and group 3 innate lymphoid cells (ILC3s). Logistic regression analyses adjusted for clinical covariates and Mann-Whitney-U-Test were performed to identify independent predictors of steroid-refractory disease. A control group of 13 patients with normal-appearing intestinal mucosa (from adenoma resections) was included.

Results: SR-GvHD patients showed significantly higher TRM content compared to SS patients (median 34.3% vs. 23.6% of all T cells, p=0.009). Within the TRMs compartment, SR-GvHD was characterized by a shift toward $CD4^+$ TRMs and a decrease in $CD8^+$ TRMs. Increased TRMs proportions were also associated with higher GI-GvHD organ severity (stage 3–4 vs. stage 1–2: 33.4% vs. 22.9%, p=0.005). In adjusted logistic regression, a higher proportion of TRMs independently predicted SR-GvHD (adjusted OR 1.07, 95% CI 1.01–1.16, p=0.044). In contrast, no significant differences in other T cell subsets ($CD4^+$, $CD8^+$, Th17) were observed between response groups. Mast cells were significantly reduced in SR-GvHD (0.68% vs. 1.85%, p=0.002), while ILC3 levels were higher in GvHD patients compared to controls but not associated with steroid response. Sensitivity analyses excluding patients pre-treated with corticosteroids (n=15) confirmed the robustness of these findings.

Conclusions: Intestinal TRMs, particularly $CD4^+$ TRMs, are associated with poor response to steroid therapy in acute GI-GvHD and may serve as tissue-level biomarkers for early risk stratification. These results highlight the importance of the local immune contexture of the gut and support further investigation into TRM-targeted strategies for steroid-refractory GvHD.

OS11-07

IDENTIFICATION OF A PLASMA IMMUNE MARKER PANEL FOR EARLY DETECTION OF ACUTE GRAFT-VERSUS-HOST DISEASE IN CHILDREN

Coco de Koning[1], *Willemijn J. Klein Lebbink*[2], *Hannah Kunstek*[2], *Rana Dandis*[2], *Annemarie M.J. Wensing*[1], *Caroline A. Lindemans*[2], *Stefan Nierkens*[2,1]
[1]*University Medical Center Utrecht, Utrecht, Netherlands (the),* [2]*Princess Máxima Center for Pediatric Oncology, Utrecht, Netherlands (the)*

Background: Acute Graft-versus-Host-Disease (aGvHD) is a common complication following allogeneic hematological cell transplantation (HCT), significantly contributing to treatment-related-morbidity and -mortality. To optimize clinical outcome, there is an urgent need for individualized aGvHD treatment approaches. These may include earlier initiation of therapy or tailored dosing regimens that balance the control of symptoms with the minimization of treatment-related toxicity. Therefore, reliable predictive markers are essential to support the personalized adjustment of aGvHD management protocols. With current validation of prognostic markers for severity and survival after aGvHD, clinically validated predictive markers for aGvHD in pediatric HCT recipients are lacking.

Methods: In this study, we performed a multiplex-based search for plasma immune markers associated with aGvHD in children and young adults, using least absolute shrinkage and selection operator (LASSO) logistic regression applied to plasma proteomics data from a two-stage retrospective cohort of pediatric HCT-recipients. The primary objective was to identify predictive plasma immune biomarkers of aGvHD grade II-IV in the pediatric HCT setting. All consecutive patients receiving their first HCT between Jan-2016 and Nov-2023 at the Wilhemina Children's Hospital and Princess Máxima Center, in Utrecht, were included. Biobanked EDTA-plasma samples were collected one week prior to aGvHD diagnosis, or at a matched timepoint for non-aGvHD patients.

Results: A total of 223 children and young adults (mean age 9 Years, range 0-20 Years) were included and randomly divided into a training (n=165) and test cohort (n=58). Overall, 20.1% of patients developed aGvHD grade I and 29.6% grade II-IV. LASSO regression applied to the training cohort data identified plasma immune markers that were subsequently validated and quantified in absolute concentrations in the test cohort. The final selected immune marker panel consisted of CCL17 and galectin-1, combined with either CXCL10 and IL6, or with Reg3a. The calculated area under the curve (AUC) of the receiver operator characteristic (ROC) curve was 0.9 for the panel combining CCL17, galectin-1, CXCL10, and IL6, with 75% sensitivity, 86% specificity, 75% positive predictive value (PPV), and 86% negative predictive value (NPV). The panel combining CCL17, galectin-1, and Reg3a performed even better ($p < 0.001$) with an AUC of 0.95, 92% sensitivity, 86% specificity, 79% PPV, and 95% NPV.

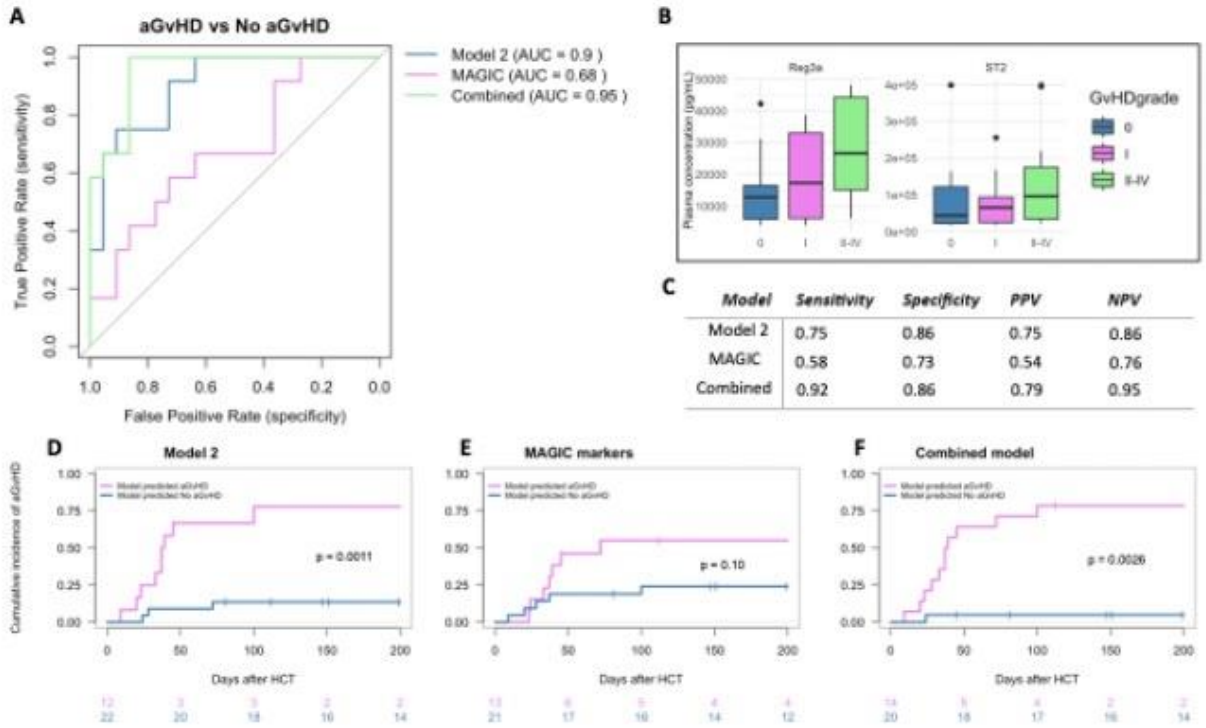

Figure 1: Comparison of plasma immune marker panel and MAGIC marker score to predict aGvHD grade II-IV. A) ROC-curves for multivariable logistic regression models differentiating aGvHD and no aGvHD patients based on absolute marker concentrations in the test cohort. ROC-curves for Model 2, comprising CCL17, galectin-1, CXCL10, and IL6 (AUC = 0.9), calculated MAGIC markers MAP Score based on Reg3a and ST2 (AUC = 0.68), and a combination of markers, existing of CCL17, galectin-1, and Reg3a (AUC = 0.95). ROC-curves are plotted for grade II-IV patients. B) Boxplots showing plasma concentrations of the identified plasma immune markers and the MAGIC markers Reg3a and ST2 for controls, grade I, and grade II-IV patients. C) Table showing sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for the multivariable models. D) Cumulative incidence for aGvHD stratified in high and low risk (threshold = 0.4) by Model 2 in the test cohort, plotted for grade II-IV patients. E) Cumulative incidence for aGvHD stratified in high and low risk (threshold = 0.4) by the MAGIC markers in the test cohort, plotted for grade II-IV patients. F) Cumulative incidence for aGvHD stratified in high and low risk (threshold = 0.4) by the combined marker panel (CCL17, galectin-1, and Reg3a) in the test cohort, plotted for grade II-IV patients.

Conclusions: Pending prospective validation, our two-stage retrospective study design identified the first immune marker panel that can potentially predict aGvHD, approximately one week prior to onset of symptoms, in pediatric HCT-recipients. When measured (bi-)weekly after graft infusion, the identified plasma immune marker panel can potentially predict if pediatric HCT-recipients will develop aGvHD grade II-IV within approximately one week after measurement. The potential prediction of aGvHD by the identified immune marker panel enables the development of an individualized approach for preemptive treatment.

RESTRICTION OF SLC7A5-MEDIATED L-LEU UPTAKE IN ALLOGENIC T CELLS EFFICIENTLY PREVENTS ACUTE GRAFT-VERSUS-HOST DISEASE AND MAINTAINS GRAFT-VERSUS-TUMOUR RESPONSE

Background: The amino acid transporter SLC7A5, which mediates the uptake of L-Leu and other essential amino acids in activated T cells and in malignant cells, has become an important target in controlling inflammation and cancer. However, its role in acute graft-versus-host disease (aGVHD) and graft versus tumour (GVT) has not been explored before.

Methods: We first determined whether SLC7A5 deletion in T cells affects mortality in a fully MHC-mismatched model of aGVHD. For this purpose, B6.SJL mice or C57BL/6 β-actin-eGFP were used as bone marrow (BM) cell donors, while Tmt+SLC7A5^{WT}, Tmt+SLC7A5$^{\Delta CD4}$ or CD45.1+SLC7A5^{WT} mice were used as splenic T cells (STC) donors, and BALB/cJRj were transplant recipients. L-Leu-deprived and isocaloric regular diet were obtained from Research Diets, Inc. After 2–3 weeks on formulated diets, all BALB/c mice were irradiated and injected with allogeneic CD45.1+ TCDBM cells and allogeneic Tmt+ SLC7A5WT STC cells. For the GVT model, KLN205 cells were subcutaneously (sc.) inoculated into the left flank of BALB/cJRj recipient mice, the following day of allogenic transplantation. BALB/c irradiated and transplanted with complete BM from BALB/c donors fed with regular or (-)Leu diet were used as controls. Tumour sizes were measured with an electronic calliper every 2–5 days by a specialised researcher blinded to experimental groups.

Results: In this study, we demonstrate that SLC7A5 genetic deletion affected the activation and proliferation of allogenic T cells, promoted apoptosis and reduced IFNγ and granzyme B secretion by CD4 and CD8 T cells. Genetic deletion of SLC7A5 completely prevented aGVHD-induced lethality in mice but did not control tumour growth. On the other hand, the administration of an L-Leu-free diet efficiently reduced aGVHD mortality in mice by controlling allogenic T cell expansion, inducing apoptosis, and affecting granzyme B secretion. However, CD8 T cells do not fail to activate or secrete IFNγ in the absence of Leu and show an increased proportion of central memory T cells, which contribute to the GVT

response.Genetic deletion of SLC7A5 in T cells severely compromises mTORC1, glycolysis and mitochondrial oxidation. However, removing L-Leu mildly reduces mTORC1 signaling, completely blocks glycolysis but improves mitochondrial function, favoring the generation of central memory responses and expression of stemness marker TCF1. Dietary L-Leu restriction controls the increase of metabolites derived from tricarboxylic acid cycle and ketogenesis induced by aGVHD, with potential proinflammatory effects. Hence, dietary restriction of L-Leu is sufficient to target SLC7A5 in allogenic cells during aGVHD, preserving GVT response.

Conclusions: This study addresses a critical knowledge gap by defining the role of the amino acid transporter SLC7A5 in aGVHD and GVT responses. By integrating genetic and dietary approaches, including a leucine-restricted diet, this work demonstrates how modulation of leucine availability and SLC7A5-dependent transport influences T-cell activation, expansion, and effector function during aGVHD. The study also identified β-hydroxybutyrate as a key metabolic marker for SLC7A5-dependent T cell expansion in aGVHD. Notably, the study provides insight into whether dietary and metabolic interventions can attenuate pathogenic alloreactivity while preserving GVT activity, highlighting a novel, non-pharmacologic strategy to improve outcomes after allogeneic hematopoietic stem cell transplantation.

ATG EXPOSURE AND IMMUNE RECONSTITUTION IN CHILDREN WITH HEMOGLOBINOPATHIES FOLLOWING HSCT: DIFFERENT PATTERNS FOR ATG-GRAFALON AND THYMOGLOBULINE

Ysabel Alessa Schwietzer[1], *Anne Kruchen*[1], *Manon Queudeville*[1], *Johanna Schrum*[1], *Matthias Bleeke*[1], *Ingo Müller*[1]
[1]*University Medical Centre Hamburg-Eppendorf, Hamburg, Germany*

Background: Anti-thymocyte globulin (ATG) is central to graft-rejection and GvHD prophylaxis in pediatric allogeneic HSCT. ATG exposure, not nominal dose, determines immunosuppression, viral susceptibility and immune reconstitution (IR). Rabbit ATG preparations differ markedly in antibody spectrum and pharmacokinetics (PK), resulting in non-interchangeable exposure–response profiles.

Methods: Eighty-six pediatric patients (90 HSCTs; 4 re-transplantations; median age 11.13 years) underwent transplantation for hemoglobinopathies (2011–2025) using treosulfan/fludarabine/thiotepa conditioning. Serotherapy consisted of ATLG (Grafalon®) (n=57), ATG-T (Thymoglobuline®) (n=35). ATG levels were measured daily from day −7 to +7 and twice weekly until week 4. AUC_{total}, AUC_{pre} and AUC_{post} HSCT were calculated. Reconstitution of CD4+, CD8+, CD19+ and CD16/56+ cells was assessed to day +180. Endpoints included engraftment, GvHD, viral reactivation, donor chimerism and overall and disease-free survival (OS/DFS).

Results: OS and DFS were excellent (97.67% and 94.17%). Graft rejection and autologous recovery occurred in 2.33% and 3.49%. The incidence of aGvHD II–IV was comparable between ATLG and ATG-T (16.7% vs. 14.3%), and cGvHD II–IV was low (7.41 and 5.71%). ATG-T exposure correlated more strongly with body weight than ATLG exposure (ATG-T r=0.7333, p=0.0311; ATLG r=0.3191, p=0.0448), indicating that weight-based dosing disproportionately affects ATG pharmacokinetics. CD4+ IR at day +100 showed the strongest exposure–response relationship: higher AUC_{post} was consistently associated with delayed CD4+ recovery (r=-0.44, p=0.0052). Stratification by AUC_{post} (<100; 100–200; >200 µg*day/mL) demonstrated a graded exposure–response effect (p=0.0014), highlighting delayed CD4+ reconstitution as a sensitive indicator of ATG overexposure.
Viral reactivations for CMV, HSV, VZV, ADV, HHV-6, BK and JC occurred at similar frequencies across serotherapy preparations. EBV reactivation, however, was substantially more common after ATG-T than ATLG (56.5% vs 20.4%). NK-cell recovery also differed by product: ATG-T was associated with higher early NK counts (day +30: 192/µL vs 143/µL), whereas ATLG showed higher late NK-cell recovery (day +180: 160/µL vs 130/µL). Overall, ATG-T displayed faster clearance and earlier recovery across additional subsets.
Complete donor chimerism (≥99%) occurred in 41/54 ATLG vs 22/35 ATG-T recipients; mixed chimerism was more frequent after ATG-T (24.1% vs 37.1%; OR 1.86; RR 1.54; p=0.18). In the ATLG cohort, 46.3% also received post-transplant cyclophosphamide (ptCy), which was associated with reduced severe cGvHD without evidence of impaired IR. Low-grade cGvHD occurred more often in the ATLG group.

Conclusions: ATG exposure is a key determinant of IR in pediatric hemoglobinopathy HSCT. ATLG and ATG-T display distinct PK/PD profiles, underscoring the need for individualized, product-specific exposure–response assessment. Weight-based dosing results in substantial variability, particularly in older children. Our data provide the opportunity for adapting ATG dosing to the individual risk profile for mixed chimerism vs. GvHD.

SKIN TAPE STRIPPING ENABLES NON-INVASIVE MONITORING OF INFLAMMATORY CYTOKINES IN ACUTE SKIN GVHD

Nakisa Kamari-Kany[1], *Katrine Kielsen*[1,2], *Mads Delbo Larsen*[1], *Bo Kok Mortensen*[1], *Tania Masmas*[1], *Sarah Weischendorff*[1], *Amalie Thorsti Møller Rønnstad*[3], *Iben Frier Ruge*[3], *Claus Henrik Nielsen*[1], *Niels Ødum*[2], *Jacob P. Thyssen*[3], *Klaus Müller*[1]
[1]*Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark,* [2]*University of Copenhagen, Copenhagen, Denmark,* [3]*Bispebjerg Hospital, University of Copenhagen, Copenhagen, Denmark*

Background: Acute GvHD remains a major contributor to transplant-related morbidity and mortality after allogeneic HSCT. Over the past decade, several blood-based biomarkers have been identified for predicting and monitoring aGvHD severity. However, these markers provide limited insights into early, localized immune processes in the skin, which is the organ

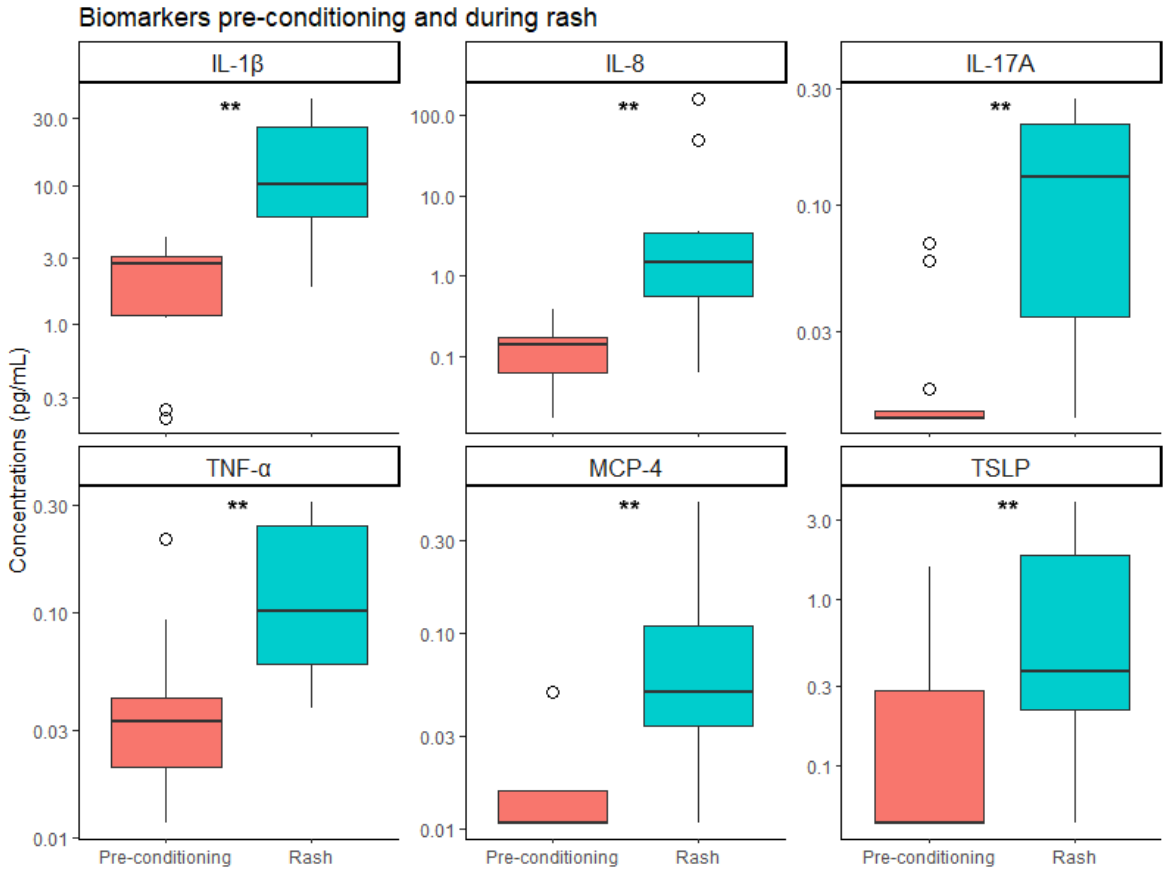
most frequently affected by aGvHD. Thus, there is a need for minimally invasive approaches that enable longitudinal assessment of local immune reactions in the skin following allogenic HSCT.
In this prospective study, we evaluated the feasibility of monitoring biomarkers in skin using skin tape stripping in patients with acute skin GvHD.

Methods: We included 16 patients (five children and 11 adults) undergoing HSCT between 2024-2025 in Denmark. Patient and transplant characteristics are specified in Table 1.
Skin tape stripping using D-squame technology (Clinical & Derm, Dallas, TX) was performed prior to conditioning (n =12) and at the time of diagnosis/suspicion of skin aGvHD (n=16). Thereafter, patients were followed with additional skin tape sampling either at changes in aGvHD staging or skin morphology, or weekly if the skin condition remained stable (n=25). Overall sampling was performed as previously described by Thyssen et. al (JACI, 2023). Following storage at -80°C, skin tape strips were eluted in a phosphate-buffered saline supplemented with Tween20® and analytes were measured using the Meso Scale S-plex and V-plex platforms, for eotaxin-1, IFN-γ, IL-1α, IL-1β, IL-1RA, IL-4, IL-6, IL-7, IL-8, IL-10, IL-12, IL-17A, IL-17C, TNF-α, TNF-β, MCP-1, MCP-4, MIP-1α, MIP-1β, TNF-α, TNF-β, and TSLP.

Table 1: Patient and transplant characteristics	
Sex, no. (%)	
Male	11 (69)
Age at transplantation (years), median (range)	
Recipients	46.5 (8.1-67.6)
Disease at transplantation, no. (%)	
Malignant	15 (94)
Benign	1 (6)
Donor type, no. (%)	
Matched sibling donor	3 (19)
Matched unrelated donor (10/10)	9 (56)
Matched unrelated donor (9/10)	3 (19)
Haploidentical donor	1 (6)
Stem cell source, no. (%)	
Bone marrow	6 (38)
Peripheral blood	10 (62)

Conditioning regimen, no. (%)	
TBI (12 GY) + CY/VP16	6 (38)
Treo + Flu (RIC)	8 (50)
Other conditioning regimens	2 (12)

Results: IL-1α, IL-1RA, IL-1β, IL-4, IL-6, IL-8, IL-10, IL-17A, IL-17C, TNF-α, TNF-β, MCP-1, MCP-4, and TSLP were measurable in skin samples both before and after HSCT, while eotaxin-1, IFN-γ, IL-7, IL-12, MIP-1α, and MIP-1β generally were below the limit of detection.
Affected skin from patients presenting with an erythematous rash exhibited higher concentrations of IL-1β, IL-8, IL-17A, TNF-α, MCP-4, and TSLP compared with healthy skin sampled prior to conditioning (IL-1β: 2.7 vs. 8.4 pg/mL, p=0.005; IL-8: 0.1 vs. 0.8 pg/mL, p=0.02; IL-17A: 0.01 vs. 0.1 pg/mL, p=0.004; TNF-α: 0.03 vs. 0.08 pg/mL, p=0.007; MCP-4: 0.01 vs. 0.05 pg/mL, p=0.01; and TSLP: 0.05 vs. 0.33 pg/mL, p=0.06).
Combined longitudinal measurements of affected skin during rash (including active erythema and beginning brownish resolution), revealed median levels of IL-1β, IL-8, IL-17A, TNF-α, MCP-4, and TSLP to be significantly higher compared with pre-conditioning levels (Figure).



Conclusions: In conclusion, this study demonstrates the feasibility of non-invasive monitoring of skin inflammatory biomarkers in patients with aGvHD. Elevated levels of both pro-inflammatory and immunoregulatory cytokines reflect the presence of a rash post-HSCT. These findings support the potential of skin tape stripping as a clinical tool for *in vivo* monitoring of aGvHD activity.

THERAPEUTIC TARGETING OF CCR7 IMPROVES OUTCOMES IN A PRECLINICAL MODEL OF ACUTE GRAFT-VERSUS-HOST DISEASE

Andrea Hoyos Domingo[1,2], *Rosa María Andreu Martínez*[1,2], *Alberto Martínez Cano*[1,2], *Leila Pérez Sánchez*[1], *Valle Gómez García de Soria*[1,2], *Carlos Cuesta Mateos*[1], *María Josefa Calzada García*[1,2], *Ana María Marcos Jiménez*[1,2], *Cecilia Muñoz Calleja*[1,2]
[1]*Instituto de Investigación Sanitaria Hospital Universitario de la Princesa (IIS-Princesa), Madrid, Spain,* [2]*Universidad Autónoma de Madrid (UAM), Madrid, Spain*

Background: Graft-versus-host disease (GvHD) is a major cause of morbidity and mortality after allogeneic haematopoietic cell transplantation (allo-HCT) and strategies for its prophylaxis are not free from serious adverse effects. Understanding the pathogenesis of GvHD is a cornerstone for developing novel therapeutic approaches to HCT. GvHD is triggered in the secondary lymphoid organs (SLOs) when donor-derived alloreactive T cells recognize host antigens presented by either patient- or donor-derived dendritic cells (DCs). To do this, both T lymphocytes and mature DCs reach the SLOs through a migratory process largely mediated by the chemokine receptor CCR7, making CCR7 an attractive therapeutic target for this complication.
In a previous preclinical GvHD model following xenotransplantation of human lymphocytes into mice, we showed that an anti-human CCR7 antibody delays or even prevents GvHD, increasing the survival of treated mice (Cuesta-Mateos *et al*., Bone Marrow Transplant. 2020). However, this model excluded any contribution of recipient DCs to the disease, since human lymphocytes do not effectively recognize mouse MHC molecules. We therefore aimed to confirm the pathogenetic and therapeutic role of CCR7 in an allogeneic murine model.

Methods: The approach consisted of a murine MHC-disparate GvHD model in sublethally irradiated C57BL/6 mice receiving either bone marrow alone (BM control group) or bone marrow plus BALB/c splenocytes (GvHD groups). Recipients in the GvHD groups were treated with PBS (PBS group) or 200 µg of anti-CCR7 4B12 (therapeutic anti-CCR7 group) every 3 days for 12 days, starting treatment on day 1 post-transplant, and then on a weekly basis until day 65. Survival and score of disease severity were assessed weekly until day 180.

Results: Survival analysis demonstrated marked differences among the study groups. Mice treated with the anti-CCR7 antibody maintained a survival rate of 75% throughout the entire observation period (180 days). In contrast, the PBS group exhibited a 50% reduction in survival within the first 60 days, stabilizing at approximately 25% from day 100 onwards,

while BM group showed a sharp decline during the first 20 days and maintained a survival rate of 40% from day 30 onwards (Figure 1A). Clinical score assessment, measured according to criteria detailed in *Table 1*, revealed that mice treated solely with the vehicle (PBS group) exhibited severe clinical signs throughout the first two months and remained clinically affected thereafter (Figure 1B). Remarkably, the anti-CCR7-treated group maintained values near zero throughout the follow-up, indicating the absence of clinically relevant signs in mice receiving anti-CCR7 therapy.

CRITERIA	SCORE 0	SCORE 1	SCORE 2
FUR TEXTURE	Normal	Mild-to-moderate ruffling	Severe ruffling/poor grooming
WEIGHT LOSS	≤10%	>10%	
POSTURE	Normal	Hunching noted only at rest	Severe hunching impairs movement
SKIN INTEGRITY	Normal	Scaling of paws	Obvious areas of denuded skins
DIARRHEA	No	Mild-to-moderate diarrhea	Severe diarrhea
FUR LOSS AROUND EYES	No	Light fur loss	Obvious fur loss
EARS INTEGRITY	Normal	Loss of integrity in only one ear	Loss of integrity in both ears
TAIL INJURIES	No	Scaling of tail	Visible injuries

Table 1. Assessment of clinical score of graft-versus-host disease in transplanted animals.

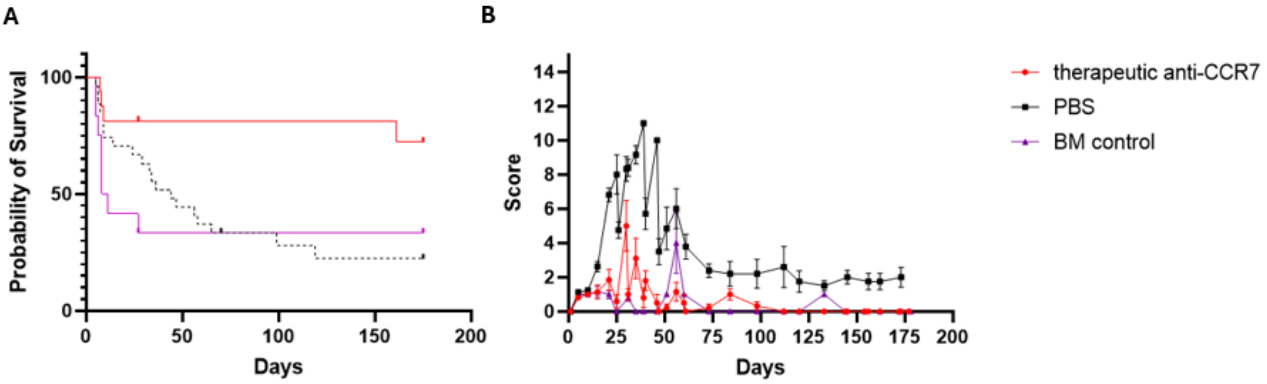

Figure 1. Probability of survival and clinical evaluation of graft-versus-host disease (GvHD) in a transplanted animal model. A. Probability of survival after GvHD model is established. Survival probability was plotted against days post-transplantation. The key statistical differences were therapeutic anti-CCR7 vs. PBS (p=0.0092) and therapeutic anti-CCR7 vs. BM (p=0.0130). Group comparisons were analyzed with log-rank test. The marks on the curve indicate censored subjects. **B.** Assessment of clinical score of GvHD. The severity of the disease was quantified weekly for 180 days using a clinical score detailed in Table 1, and is presented as the mean ± SEM. The key statistical differences were therapeutic anti-CCR7 vs. PBS (p<0.0001) and PBS vs. BM (p<0.0001). Group comparisons were analyzed with one-way ANOVA, followed by Sídák's multiple comparisons test. The number of mice per group was: PBS (black, n=21), BM (purple, n=13) and anti-CCR7 (red, n=17) carried out in three independent experiments.

Conclusions: In a murine model of GvHD, anti-CCR7 treatment markedly improves survival and mitigates clinical severity compared with PBS and BM controls, emphasizing its potential translational value as a promising addition to the therapeutic options for human GvHD. Future studies will investigate the mechanistic roles of donor CCR7⁺ T cells and donor versus recipient DCs in mediating this therapeutic effect.

PRE-TRANSPLANT T/NK-LIKE DERIVED EXTRACELLULAR VESICLES ASSOCIATE WITH GVHD AND DISTINCT IMMUNE RECONSTITUTION PATTERNS, INFLUENCED BY GUT MICROBIOME AND CHEMOTHERAPY EXPOSURE IN PEDIATRIC STEM CELL TRANSPLANTATION

Francesca Gottardi[1,2], *Serena De Matteis*[1], *Davide Leardini*[1,2], *Edoardo Muratore*[1,2], *Francesco Baccelli*[1,2], *Francesco Venturelli*[1], *Raffaella Barbaro*[2,1], *Giovanni Barbara*[1,2], *Federica D'Amico*[2], *Simone Rampelli*[2], *Francesco Iannotta*[2], *Alessandro Cartani*[2], *Irene Salamon*[1,2], *Francesca Vaglio*[1,2], *Gianluca Storci*[1], *Marco Candela*[2], *Arcangelo Prete*[1], *Massimiliano Bonafè*[2], *Riccardo Masetti*[1,2], *Francesca Bonifazi*[1,2]
[1]*IRCCS Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy,* [2]*University of Bologna, Bologna, Italy*

Background: Extracellular vesicles (EVs) released by immune and tissue-derived cells may carry early predictive information on allogeneic stem cell transplant (allo-SCT) complications. Their biological role in shaping post-transplant immune reconstitution and gut microbiota recovery remains unclear, especially in pediatric recipients. We prospectively evaluated the

dynamic profile of circulating EV subsets before and after allo-SCT and investigated their association with clinical outcomes, immune reconstitution, and intestinal microbiota diversity.

Methods: Thirty-one pediatric patients undergoing allo-SCT were enrolled (Table I). Pre-transplant plasma and stool samples were uniformly collected within 7 days from the start of conditioning. EVs were characterized using MACSPlex Immuno-Oncology flow cytometry (37-marker panel) and validated for key immunological markers (CD69, CD56, HLA-DR, CD69/HLA-DR) using ExoView™, enabling single-vesicle phenotyping across tetraspanin-captured EVs (CD9/CD63/CD81). Additional clinical variables included: age, diagnosis, time elapsed since last chemotherapy before SCT, and antibiotic exposure within 60 days before conditioning. Gut microbiota was profiled by 16S rRNA gene sequencing, and immune reconstitution was assessed through serial immunophenotyping at 1, 3, 6 and 12 months.

Results: Higher pre-transplant levels of HLADR$^+$, HLAABC$^+$, CD56$^+$, CD25$^+$, CD69$^+$ and CD69$^+$/HLA-DR$^+$EVs, validated across both MACSPlex and ExoView platforms, were strongly associated with the subsequent development of grade II–IV acute GVHD. Conversely, patients who later experienced disease relapse displayed the opposite pattern, exhibiting significantly lower CD69$^+$HLA-DR$^+$EVs counts (Fig. 1A-B). Even if small number of events prevent reaching significance in cumulative incidence analysis for relapse, this suggests divergent immunological trajectories underlying GVHD versus relapse biology.
The interval between last chemotherapy exposure and transplantation showed opposite associations for EVs and microbiota: shorter intervals were linked to higher CD69$^+$HLA-DR$^+$EVs levels, while longer intervals correlated with higher gut microbial diversity (Fig. 1C). In contrast, antibiotic exposure in the 60 days preceding conditioning showed no significant association with either EVs abundance or microbiota diversity in this cohort.
Higher pre-transplant CD69$^+$/HLA-DR$^+$EVs levels were associated with reduced gut microbial diversity, indicating a potential inflammatory or tissue-stress signature linking intestinal mucosal status and EVs release (Fig. 1D).
Correlation heatmaps at 1, 3, and 6 months revealed time-dependent associations between EVs subsets and immune recovery (Fig. 1E). At 1 month, CD56$^+$ and CD25$^+$EVs inversely correlated with Tregs; at 3 months, multiple EVs subsets showed strong negative associations with dendritic cells and CD4$^+$CD8$^+$ T-cell counts, while CD69$^+$ and CD25$^+$EVs correlated positively with M-MDSC expansion. At 6 months, CD25$^+$, CD69$^+$, and HLA-ABC$^+$EVs negatively correlated with γδ T-cell reconstitution. No significant correlations were observed at 12 months.

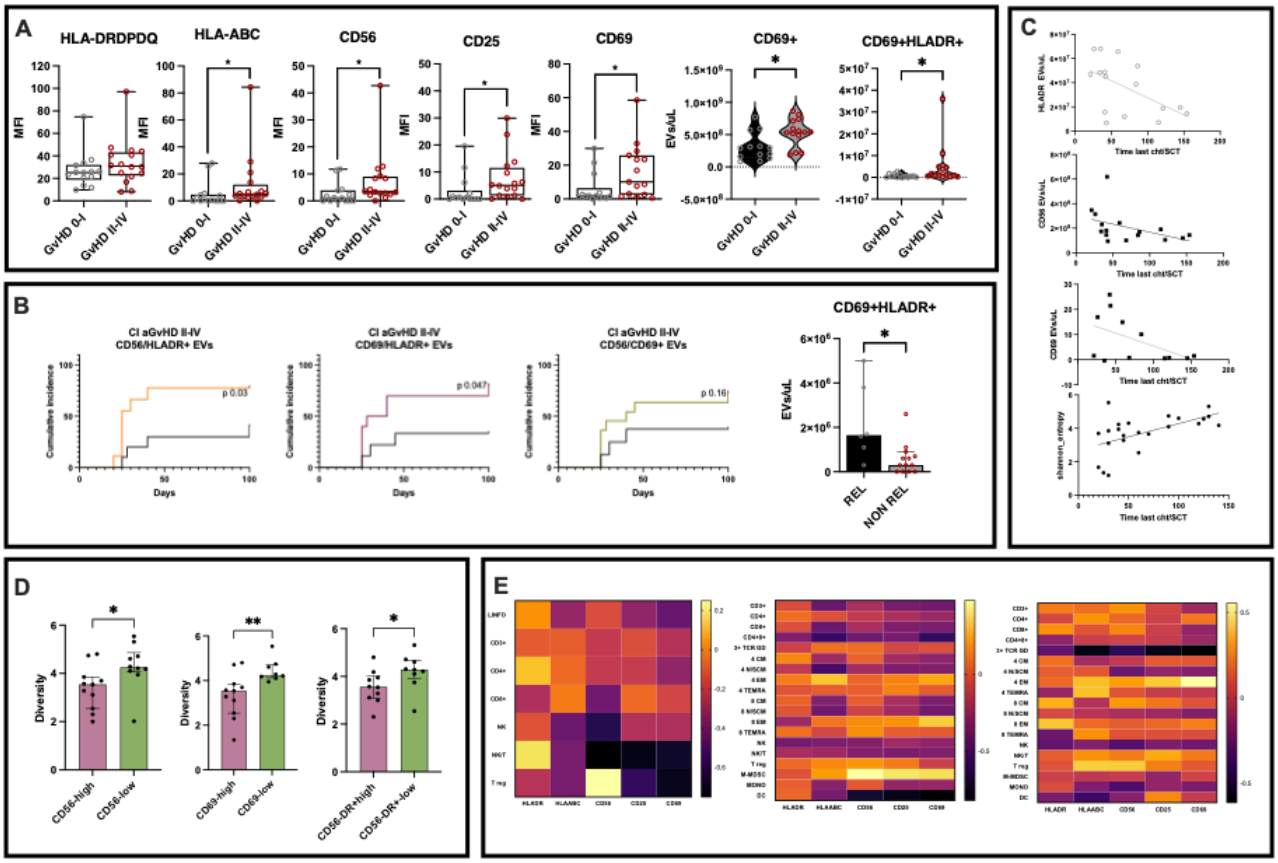

Table I: Baseline demographic, clinical and transplant characteristics

Conclusions: Circulating EVs profiles obtained just prior to conditioning capture both inflammatory activation and tissue-stress signals relevant to microbiota status, immune reconstitution, and GvHD. In particular, $CD69^{+}$/$HLA\text{-}DR^{+}$ EVs emerge as a multimodal biomarker linking mucosal biology, chemotherapy timing, and clinical outcomes. Integration of EVs profiling with microbiome and immunological monitoring may support early risk stratification and personalized supportive care in pediatric allo-SCT.

HIGH THROUGHPUT METABOLIC ANALYSES DEMONSTRATE AMINO ACID PATHWAY PERTURBATIONS IN ACUTE GRAFT-VERSUS-HOST DISEASE

*Joanne Tan[1,2], Tiffany Khong[1], Sean Byars[1], **Dan Le**[3], Katy Jeppe[1], Chris Barlow[1], Sridurga Mithraprabhu[1], Andrew Spencer[1,2]*

[1]Monash University, Clayton, Australia, [2]The Alfred Hospital, Prahan, Australia, [3]Alfred hospital, Prahran, Australia

Background: Acute graft-versus-host disease (aGVHD) is a serious inflammatory complication affecting 20–50% of allogeneic haemopoietic stem cell transplant (alloHSCT) recipients, arising when donor immune cells attack host tissues. While the cytokine and immune cell alterations associated with aGVHD are increasingly well characterized, its metabolomic landscape remains less understood. Altered lipid, amino acid, and microbiota-derived metabolite pathways have been linked to aGVHD (1–3). To define its metabolic signature, we analyzed the serum metabolome of alloHSCT recipients to distinguish patients who developed aGVHD from those who did not.

Methods: Serum samples from alloHSCT recipients and day-100 post-transplant controls were analyzed using untargeted metabolomic profiling by high-performance liquid chromatography–mass spectrometry. Sparse Partial Least Squares Discriminant Analysis (sPLS-DA) was used to identify discriminatory metabolites. Metabolites with non-zero loadings on at least one selected component were retained. All sPLS-DA and clustered heatmap analyses were performed in R version 4.3.3 using the 'mixOmics' package. Pathway enrichment analysis was performed with MetaboAnalystR 4.0, referencing the Kyoto Encyclopedia of Genes and Genomes (KEGG) database for Homo sapiens.

Results: A total of approximately 1,400 metabolites across 59 metabolic pathways were analyzed in 31 patients with acute graft-versus-host disease (aGVHD) and 51 alloHSCT controls. Patient characteristics are summarized in **Table 1**. sPLS-DA identified 210 discriminatory metabolites, which were used to construct a heatmap signature distinguishing patients with aGVHD from controls (**Figure 1**). Notably, 1-pyrroline-5-carboxylic acid (P5C; loading score [LS] = −0.266) was the top discriminatory metabolite which was decreased in aGVHD (fold change = 0.77). Pathway enrichment analysis revealed significant alterations in tryptophan metabolism ($p < 0.001$, FDR = 0.0118), tyrosine metabolism ($p < 0.001$, FDR = 0.0118), arginine biosynthesis ($p = 0.001$, FDR = 0.026), arginine and proline metabolism ($p = 0.002$, FDR = 0.044), and glycine, serine, and threonine metabolism ($p = 0.004$, FDR = 0.044). After correction for multiple comparisons using the Holm–Bonferroni method, the tryptophan and tyrosine pathways remained statistically significant.

Table 1: Basic patient characteristics

	Patients (N)	Percentage (%)
Age, median (interquartile range), year	60 (46 - 67.8)	-

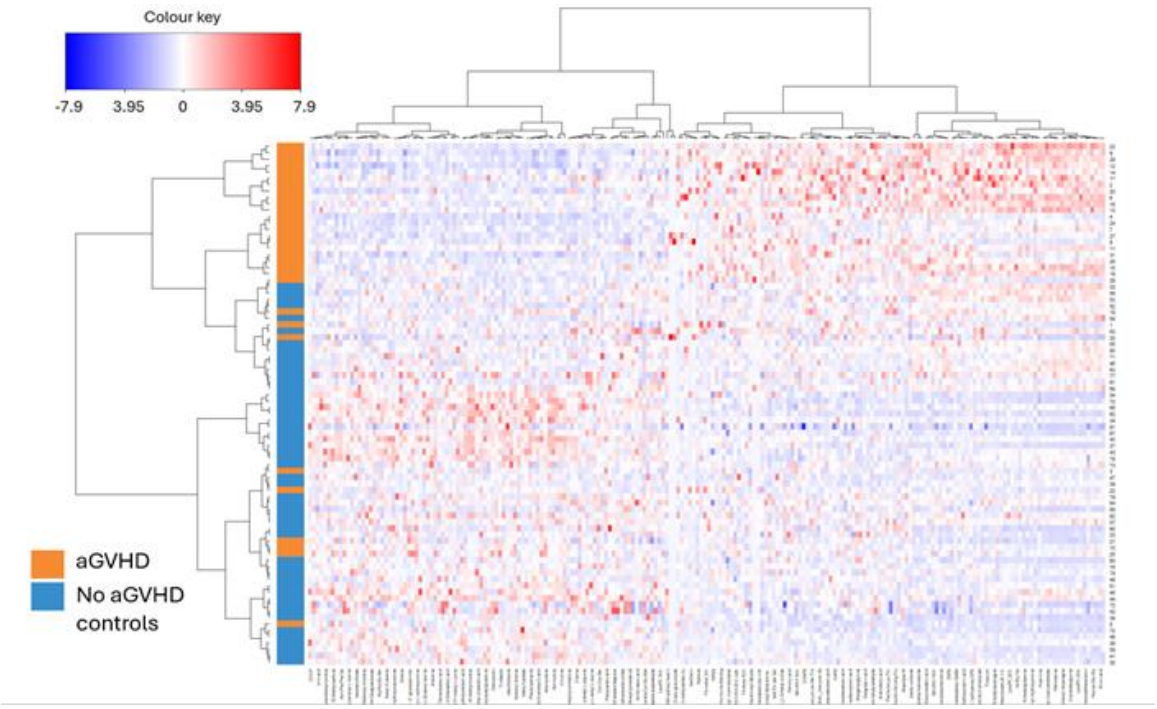
Methotrexate	3	3.7
Alemtuzumab	5	6.1
Others	2	2.4
Anti-thymocyte globulin use, n, %	1	1.2
Acute GVHD Grade 2 to 4	29	35.4

Figure 1: Clustered heat map of 210 discriminatory metabolites comparing the metabolic signature of patients with aGVHD and alloHSCT controls. Samples (y-axis) and metabolites (x-axis) are hierarchically clustered based on their scaled abundance profiles. Heatmap colours denote standardised metabolite intensities (z-scores), with red indicating higher and blue lower relative abundance compared with the mean level of each metabolite.



Conclusions: Our analysis reveals significant perturbations in amino acid pathways at aGVHD onset, many of which are integral to immune and inflammatory responses. Notably, P5C, a key intermediate in proline, ornithine, and glutamate metabolism, emerged as the top discriminatory metabolite and may play a critical role in modulating allogeneic immune responses. Alterations in P5C, tryptophan, and tyrosine metabolism represent potential mechanistic drivers of aGVHD and merit focused investigation in preclinical models to elucidate their functional significance.

COMPARATIVE ANALYSIS OF GRAFT-VERSUS-HOST DISEASE INCIDENCE AND PATTERNS AFTER ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE VERSUS STANDARD PROPHYLAXIS

Jhonny Manuel Carranza Jara[1], María Suárez-Lledó[1], Cristian Alberdi[1], Paola Charry[1], Laia Guardia[1], Berta Solé[1], Joan Cid[1], Miquel Lozano[1], Maribel Díaz-Ricart[1], Wandry Ceballos[1], Laura Rosiñol[1], Enric Carreras[2], Francesc Fernández-Avilés[1], Montserrat Rovira[1], Carmen Martíne[1], ***María Queralt Salas***[1]
[1]Hospital Clinic, Barcelona, Spain, [2]Fundació i Institut de Reserca Josep Carreras Contra la Leucèmia, Barcelona, Spain*

Background: GVHD remains a major cause of morbidity and mortality complication following allogeneic hematopoietic cell transplantation (allo-HCT). Traditional prophylaxis has relied on calcineurin inhibitors (CNI) combined with methotrexate or mycophenolate mofetil (MMF). Over the last decade, post-transplant cyclophosphamide (PTCy)-based prophylaxis has become widely adopted after demonstrating a reduced incidence of acute (aGVHD) and chronic GVHD (cGVHD).
Although the overall protective effect of PTCy on GVHD is well established, comparative data on organ-specific involvement and severity relative to CNI-based prophylaxis remain limited. This study evaluates differences in incidence, clinical presentation, and severity of GVHD in patients receiving PTCy-based versus CNI-based prophylaxis.

Methods: We retrospectively analyzed all adults undergoing their first peripheral blood allo-HCT at our institution between 2014 and 2024. GVHD prophylaxis strategies evolved over time, with progressive adoption of PTCy across donor types. Acute and chronic GVHD were graded according to MAGIC and 2014 NIH criteria, with systematic assessment of organ involvement. Primary endpoints included cumulative incidence (CIF) of aGVHD and cGVHD (with relapse and death as competing risks), as well as severity and organ manifestations.

Non-Relapse Mortality, (95% CI) **1-year** **3-year**	14.0 (11.3-17.0) 16.6 (13.6-19.9)	12.5 (9.3-16.1) 14.6 (11.1-18.6)	16.9 (12.0-22.5) 20.1 (14.8-26.0)	0.029
Cumulative Incidence of Relapse, (95% CI) **1-year** **3-year**	31.9 (28.0-35.9) 24.2 (20.8-27.8)	21.9 (17.8-26.2) 31.2 (26.3-36.2)	28.7 (22.5-35.2) 33.5 (26.9-40.2)	0.43

Graft-versus-Host Disease (GVHD); acute Graft-versus-Host Disease (aGVHD); chronic Graft-versus-Host Disease (cGVHD).

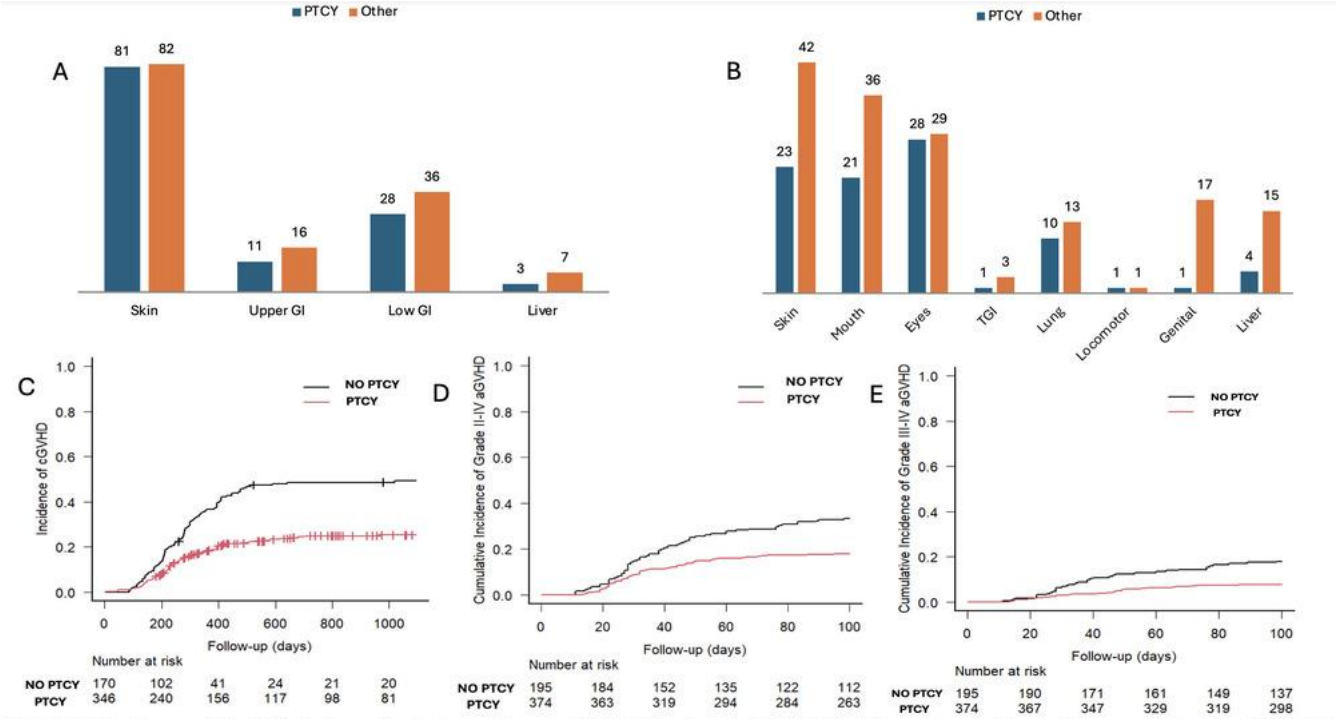

FIGURE 1: Incidence (%) of clinical manifestations of acute GVHD (A), chronic GVHD (B), 2-Year Cumulative Incidence of chronic GVHD (C), Day +100 Cumulative Incidence of Grade II-IV aGVHD (D) and Grade III-IV cGVHD (E)

A total of 569 patients were included; 374 (66%) received PTCy-based and 195 (34%) CNI-based prophylaxis. Baseline characteristics were comparable, although patients aged >64 years (17% vs. 7%, P=0.001) and those receiving alternative donor grafts (73% vs. 47%, P=0.001) were more frequent in the PTCy group.

PTCy was associated with a lower incidence of grades II–IV aGVHD (Day +100 CIF: 17.9% vs. 33.3%, P<0.001) and grades III–IV (7.8% vs 17.9%, p<0.001) (**Table 1).** Patterns of organ involvement were similar between groups, including skin (81% vs 83%), upper gastrointestinal (12% vs 16%), lower gastrointestinal (28% vs 36%) and liver involvement (3% vs 7%) (p>0.1) (**Table 1**). Rates of steroid-refractory aGVHD 22% vs 21%) and day +60 mortality rate were similar between groups (6% vs. 5%, P=0.15).

The incidence of cGVHD was markedly lower the PTCy-group (2-year CIF: 24.8% vs 48.6%, p<0.001), with a profound reduction in moderate-to-severe cGVHD (2-year CIR: 8.8% vs 40.9%, p<0.001) (**Table 1).** PTCy was associated with significantly reduced involvement of skin (23% vs 42%, p<0.001), oral mucosa (23% vs 42%, p0.019), liver (4% vs 15%, p=0.009), and genital tract (1% vs 17%, p=0.001), whereas ocular, gastrointestinal, pulmonary whileand musculoskeletal involvement remained similaracross groups (**Figure 1**). Refractory cGVHD with requirements of 2nd-line treatment were lower with PTCy (26% vs 67%, p<0.001).

Survival analyses demonstrated improved outcomes in the PTCy cohort, with superior overall survival (3-year: 65.1% vs. 54.6%, *P*<0.001), lower non-relapse mortality (3-year: 14.6% vs. 20.1%, *P*=0.029), and incidence of relapse than those receiving CNI-based prophylaxis (3-year: 31.2% vs. 33.5%, *P*=0.43) (**Table 1)**.

Conclusions: PTCy-based GVHD prophylaxis significantly reduced the incidence and severity of acute and chronic GVHD. While the clinical presentation of aGVHD was similar to conventional CNI-based approaches, PTCy was associated with a marked decrease in severe and organ-damaging forms of cGVHD. Importantly, these benefits translated into reduced non-relapse mortality and improved overall survival without compromising disease control.

IMPAIRED CIRCULATING T_{FH} SUBSETS AS EARLY INDICATORS OF CHRONIC GVHD PATHOGENESIS

Isabel Sandner[1], Katharina Habenicht[2], Julia Winker[1], Frederik Graw[1], Petra Hoffmann[3,4], Daniel Wolff[3], Andreas Mackensen[1], Thomas Winkler[2], Friederike Berberich-Siebelt[5], ***Silvia Spoerl***[1]

[1]Department of Internal Medicine 5, Hematology/Oncology, University Hospital Erlangen, Erlangen, Germany, [2]Division of Genetics, Department Biology, Nikolaus-Fiebiger-Center of Molecular Medicine, Friedrich-Alexander University Erlangen-Nürnberg, Erlangen, Germany, [3]Department of Internal Medicine III, University Hospital Regensburg, Regensburg, Germany, [4]Leibniz Institute for Immunotherapy, Regensburg, Germany, [5]Institute of Pathology, Julius-Maximilians-University Würzburg, Würzburg, Germany

Background: Chronic graft-versus-host disease (cGvHD) is a major long-term complication of allogeneic hematopoietic stem cell transplantation (allo-HSCT), driven by dysregulation of both T and B cell immunity. Clinically, it resembles autoimmune and rheumatologic disorders, with many patients developing autoreactive or allo-reactive antibodies contributing to tissue inflammation and fibrosis. Aberrant germinal center (GC) reactions are thought to underlie these pathogenic immune responses. T follicular helper (T_{FH}) cells, defined by CXCR5 and PD-1 expression, are central regulators of GC output, promoting memory B cell and plasmablast differentiation. In cGvHD, T_{FH} cells have been implicated in enhanced immunoglobulin production and autoantibody generation, correlating with clinical manifestations such as sicca symptoms, sclerotic skin changes, and pulmonary involvement. This study aims to identify additional T_{FH}-related signatures linked to the onset and progression of cGvHD.

Methods: In a prospective trial, peripheral blood from 66 transplanted patients was collected on median day +120 (range +91 to +190) after allo-HSCT. All patients received peripheral blood stem cells as source of stem cells, and GvHD prophylaxis consisted of either CNI+MTX (38,6%) or CNI+MMF (61,4%). In 24 patients, additional samples- besides the earlier day +120 time point- were obtained at cGvHD onset (median day +187, range +98 to +410) and then, 4 and 8 weeks later during treatment for cGvHD. $CD4^+$ T cell subsets, particularly cT_{FH} cells, were analyzed by flow cytometry.

Results: At day +120 after allo-HSCT, patients without GvHD, and also remaining cGVHD-free during follow-up, exhibited markedly higher frequencies of circulating PD-1$^+$ CXCR5$^+$ T_{FH} cells than individuals who subsequently developed cGvHD (median 9,63% versus 3,81 %, p=0,002). In those who later-on manifested cGvHD, cT_{FH} frequencies remained comparably low at the onset of clinical symptoms. Phenotypic analysis on day +120 revealed distinct distribution patterns of cT_{FH} subsets in the two groups. Patients who remained free of cGvHD exhibited lower frequencies of $cT_{FH}2$ (CXCR3$^-$CCR6$^-$ of T_{FH}) compared to those who later developped cGvHD (median 10,6 % versus 15,7 %, p=0,008), but higher proportions of $cT_{FH}1/17$ (CXCR3$^+$CCR6$^+$ of cT_{FH}) (18,15 % versus 7,0 %, p=<0,001) than those individuals who are subsequently diagnosed with cGvHD. These differences indicate that alterations in cT_{FH} subset composition are already detectable before the clinical onset of cGvHD and may reflect early dysregulation as well as changes in homing patterns within the adaptive immune compartment. Supporting the relevance of these early alterations, ROC analysis at day +120 demonstrated that cT_{FH} frequencies have a significant prognostic value for subsequent cGvHD development (AUC = 0.77; p = 0.0019).

Conclusions: Our analysis shows that the adaptive immune compartment in cGvHD patients becomes progressively disrupted, with a notable overall reduction in PD-1$^+$ CXCR5$^+$ T_{FH} cells in the peripheral blood accompanied by a selective increase of CXCR3$^-$CCR6$^-$ $cT_{FH}2$ subsets as disease emerges. This shift in T_{FH} composition reflects an early imbalance that can identify patients who later develop cGvHD during the course of this study, supported by solid predictive accuracy. Together, these findings point to cT_{FH} dynamics as an informative early marker of future chronic immune dysregulation.

PERTURBATIONS IN THE MICROBIAL DERIVED TRYPTOPHAN METABOLITES UNDERLIE ACUTE GRAFT-VERSUS-HOST DISEASE

*Joanne Tan[1], Tiffany Khong[1], Sean Byars[1], **Dan Le**[2], Katy Jeppe[1], Chris Barlow[1], Sridurga Mithraprabhu[1], Andrew Spencer[1]*
[1]Monash University, Clayton, Australia, [2]The Alfred Hospital, Prahan, Australia

Background: The gastrointestinal flora has been shown to shape immune homeostasis in allogeneic haemopoietic stem cell transplant (alloHSCT) recipients via their interactions with the host metabolome. Tryptophan-derived indole and kynurenine metabolic pathways depend on microbiota-driven enzymatic processes and may modulate aryl hydrocarbon receptor (AhR)-mediated intestinal resilience, thereby influencing the pathogenesis of acute graft-versus-host disease (aGVHD) (1). To characterize these changes, we analysed the serum metabolome of alloHSCT recipients to identify metabolic differences between patients who did and did not develop aGVHD, with a particular focus on tryptophan metabolism.

Methods: Serum samples were collected from alloHSCT recipients at the onset of aGVHD (prior to treatment) and from alloHSCT controls at day 100 post-transplant. Untargeted

metabolomic profiling was performed using high-performance liquid chromatography–mass spectrometry. Pathway enrichment analysis was performed using MetaboAnalystR 4.0, referencing the KEGG (Kyoto Encyclopedia of Genes and Genomes) database for *Homo sapiens*. All additional statistical analyses and data visualisation were performed in R version 4.3.3 using the 'mixOmics', and 'fmsb' packages. Differences in metabolite concentrations were assessed using Welch's *t*-test.

Results: A total of 82 patients (31 with aGVHD of any grade and 51 controls) and approximately 1,400 metabolites across 59 metabolic pathways were analysed. All patients had natural feeding at the time of serum collection and their characteristics are summarised in **Table 1**. Pathway enrichment analysis demonstrated that tryptophan metabolism was the most significantly altered pathway in patients with aGVHD compared with controls ($p < 0.001$; Holm-adjusted $p = 0.013$; false discovery rate (FDR) = 0.011). Several downstream tryptophan metabolites were significantly reduced in patients with aGVHD, including indole-3-acetate (fold change (FC) 0.56, $p = 0.005$), indolelactate (FC 0.74, $p = 0.006$), and acetyl-N-formyl-5-methoxykynurenamine (FC 0.64, $p = 0.04$). **Figure 1** illustrates the fold changes of tryptophan and its downstream metabolites. No significant differences between tryptophan metabolites were observed between patients with gastrointestinal (GI) and those with non-GI organ involvement of aGVHD.

Table 1: Basic patient characteristics

	Patients (N)	Percentage (%)
Age, median (interquartile range), year	60 (46 - 67.8)	-

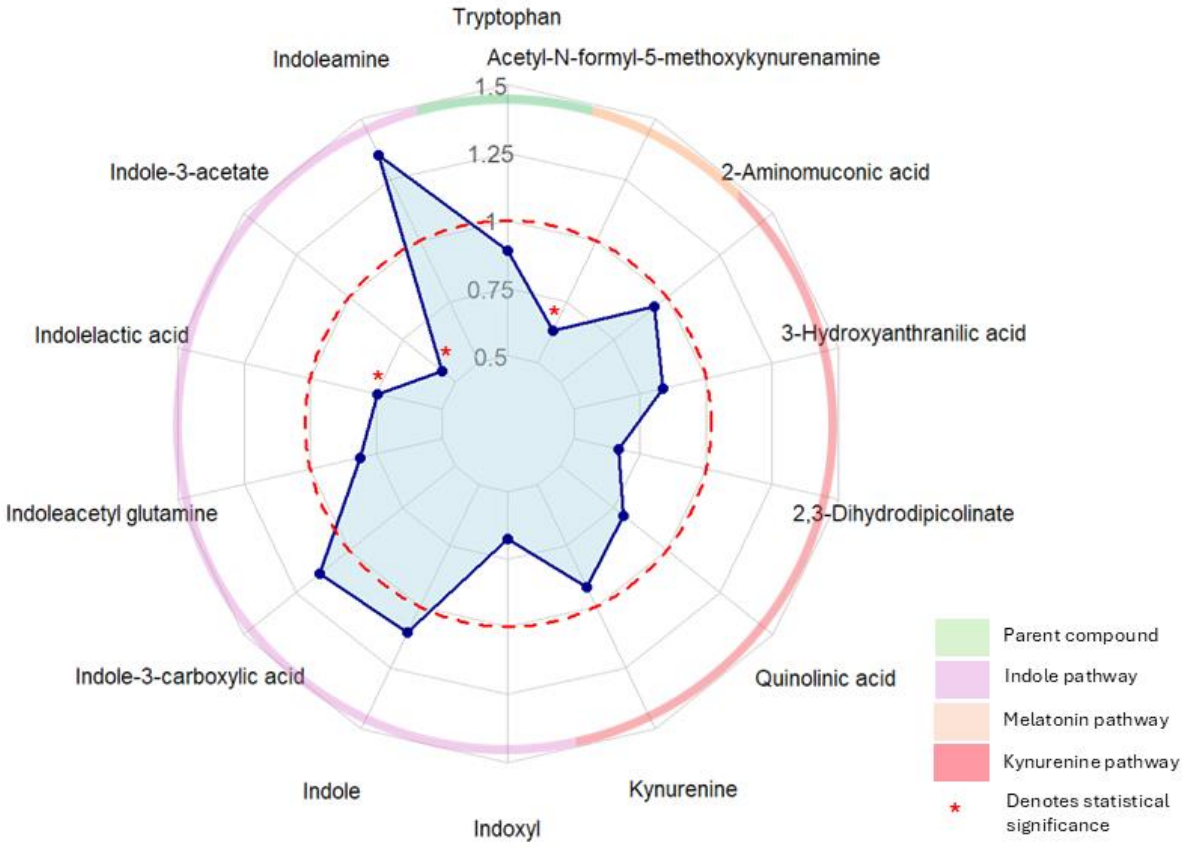
Anti-thymocyte globulin use, n, %	1	1.2
Acute GVHD Grade 2 to 4	29	35.4

Figure 1: Comparison of tryptophan metabolites in patients with and without aGVHD



Conclusions: Our analysis reveals an association between the development of aGVHD alterations in the tryptophan metabolic pathway at the host–microbiota interface, particularly within the indole pathway. The absence of differences in tryptophan metabolite levels between patients with and without gastrointestinal organ involvement suggests that these alterations are not driven by changes in bowel function. These findings support further investigation of host-microbial metabolic pathways as potential biomarkers and therapeutic targets for aGVHD prevention and treatment.

PRE-TRANSPLANT TREC LEVELS MODULATE POST-TRANSPLANT GUT INTRINSIC DNA-DAMAGE AND IMMUNE RESPONSES IN ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS

Adam Kuba[1,2], *Tibila Kientega*[2], *Isabelle Clément*[2], *Luděk Raida*[1], *Martina Divoká*[1], *Patrik Flodr*[1], *Tomáš Papajík*[1], *Francis Rodier*[2]
[1]*University Hospital Olomouc, Palacky University Olomouc, Olomouc, Czechia,* [2]*Centre de Recherche du Centre Hospitalier de l'Université de Montréal (CR CHUM), Montreal, Canada*

Background: The signal-joint T cell receptor excision circles (TREC) are an established marker of immunosenescence that inversely correlates with chronological age. Allogeneic hematopoietic stem cell transplant (HSCT) recipients present with premature onset of age-related decline of organ functions. Dysfunction of the lower gastrointestinal (LGI) tract negatively affects HSCT outcome. DNA-damage response (DDR) and cellular senescence (CS) represent cellular mechanisms capable of modulating tissue-intrinsic immune responses.
We hypothesized whether pre-transplant immunosenescence contributed to post-transplant accelerated organ senescence in HSCT recipients and analyzed pre-transplant TREC whole blood levels and DDR and CS markers in nucleated cells of the intestinal stroma of patients with LGI dysfunction after HSCT.

Methods: TREC levels were analyzed using triplex quantitative TaqMan™ PCR amplification of TREC, CD3, and unrearranged VD-J. The TREC value was estimated as the ratio of TREC to 100000 T cells.
Using the multiplex immunofluorescence (Lunaphore Comet™) we analyzed a tissue microarray marked with antibodies targeting immune cells, DDR and CS from 19 colonic

biopsies of patients with LGI symptoms. Promyelocytic leukemia protein (PML) and p53-binding protein 1 (53BP1) nuclear bodies as DNA-damage markers and CS marker p16INK4a were analyzed in all nucleated cells and in CD3 and CD68 cellular subsets infiltrating the intestinal stroma. Nuclear markers were quantified per nuclei count and per nuclear area. Immune cells were quantified per cell count and per stromal area. Mean fluorescence intensity was measured for every marker. PCR detection of viral DNA (CMV, EBV, HHV-6) in gut biopsies was performed.

Results: The cohort consisted of 19 patients with the median age of 53 years (range 18-68) allografted for various hematologic malignancies. All patients developed LGI symptoms in the median time of 64 days (range 12-524) after HSCT.
Patients with pre-transplant TREC levels above the average (469 TREC/10^5 T cells) were significantly younger than those with low TREC levels (44 years [range 18-53] and 57 years [range 40-68], respectively, *p<0.01*). Patients who developed LGI symptoms later than the median time (D+64) had significantly less pre-transplant TREC levels than those with earlier LGI symptoms onset (355 [range 229-904] and 512 [range 344-1014], respectively, *p=0.04*). Pre-transplant TREC levels below the average (pre-transplant TREC<AVG) was confirmed to have impact in the analysis of cumulative incidence of LGI symptoms (hazard ration 0.37, 95% CI: 0.12-1.21, *p=0.02*).
Consequently, we focused on the pre-transplant TREC<AVG subgroup of patients. In these patients, there were positive correlations found between the time of LGI symptoms onset and the expression of PML, 53BP1 and p16INK4a in the donor-derived $CD3^+$ T cells infiltrating the intestinal stroma (R=0.73, *p=0.01*; R=0.64, p=*0.03*; R=0.93, *p<0.001*; respectively). Furthermore, out of pre-transplant TREC<AVG patients, those who reactivated CMV, EBV and HHV-6 in the gut had lower pre-transplant TREC levels (p=0.05) and higher expression of p16INK4a in the intestinal stroma (p=0.06).

Conclusions: Our pilot results suggest that pre-transplant immunosenescence might contribute to premature functional decline and promote senescence on the organ level in HSCT recipients. Verification on larger cohorts is warranted.

SYNERGISTIC EFFECTS OF AXATILIMAB AND RUXOLITINIB IN AN INFLAMMATORY IN VITRO MODEL OF GVHD

Shannon Kahan[1], *Linda Solomon*[1], *Paul Wilson*[1], *Chryssa Kanellopoulou*[1]
[1]*Incyte Corporation, Wilmington, DE, United States of America (the)*

Background: Chronic graft-versus-host disease (cGVHD) is characterized by sustained dysregulation within both the myeloid and lymphoid compartments, driving persistent cytokine signaling and progressive tissue injury. Colony-stimulating factor 1

(CSF-1)–dependent monocytes and macrophages have emerged as important contributors to this chronic inflammatory milieu, consistent with the observed clinical activity of axatilimab, which targets and blocks the CSF-1 receptor (CSF-1R). At the same time, cytokines active in cGVHD frequently utilize the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway to shape lymphocyte activation and differentiation, supporting the therapeutic benefit of the JAK1/JAK2 inhibitor ruxolitinib. The intersection of CSF-1 responsive myeloid pathways with JAK-driven cytokine networks in cGVHD, however, remains incompletely defined. Clarifying these interactions may help guide rational combinations of CSF-1R and JAK inhibitors for treatment of cGVHD.

Methods: To evaluate the effects of combining CSF-1R and JAK inhibition on immune responses, peripheral blood mononuclear cells from healthy donors were stimulated in a two-way mixed leukocyte reaction (MLR). Cultures were treated with axatilimab, ruxolitinib, or both across a range of doses. Monocyte viability was quantified by flow cytometry, and supernatants were analyzed for a panel of cytokines implicated in cGVHD pathogenesis, including monocyte chemoattractant protein 1 (MCP-1), interferon gamma-induced protein 10 (IP-10), and interleukin 10 (IL-10), as well as other inflammatory mediators. The relative and combined contributions of each agent were evaluated by comparing monocyte survival and cytokine output across treatment conditions.

Results: Axatilimab and ruxolitinib exhibited a cooperative effect on monocyte depletion in inflammatory MLR cultures. Mean (SD) monocyte survival was reduced from 85% (8.83%) in untreated controls to 40% (16.1%) when both therapies were combined. Axatilimab or ruxolitinib alone did not significantly affect survival; mean (SD) monocyte survival was 71% (10.9%) with axatilimab and 90% (5.7%) with ruxolitinib. Cytokine profiling revealed selective pathway-specific effects with some cytokines affected by axatilimab or ruxolitinib individually and some synergistically affected by axatilimab and ruxolitinib together.

Conclusions: Our in vitro findings demonstrate that CSF-1R– and JAK-dependent cytokine networks function as interconnected drivers of cell survival and inflammatory activity relevant to cGVHD. Combined CSF-1R and JAK inhibition produced coordinated effects on monocyte viability and cytokine output not observed with either agent alone, suggesting that dual targeting disrupts reinforcing circuits between myeloid and lymphoid pathways. These results support the mechanistic rationale for therapeutic combinations of axatilimab and ruxolitinib to interrupt the immunologic programs sustaining cGVHD more effectively.

Disclosure: Shannon Kahan, Linda Solomon, Paul Wilson, and Chryssa Kanellopoulou are employees and shareholders of Incyte Corporation.

VON WILLEBRAND FACTOR-ENHANCED EASIX FORMULA CORRELATES WITH CGVHD SEVERITY IN THE INFLAMMATORY CGVHD PHENOTYPE AND CYTOKINE CONCENTRATIONS

Ana Zelić Kerep[1], *Ivan Sabol*[2], *Vesna Kušec*[3], *Lana Desnica*[1], *Antonija Babić*[1], *Nadira Duraković*[1], *Ranka Serventi-Seiwerth*[1], *Desiree Coen-Herak*[1], *Marija Miloš*[1], *Hrvoje Lalić*[1], *Radovan Vrhovac*[1], *Steven Živko Pavletić*[4], *Dražen Pulanić*[1]
[1]*University Hospital Center Zagreb, Zagreb, Croatia,* [2]*Ruđer Bošković Institute, Zagreb, Croatia,* [3]*Children´s Hospital Srebrnjak, Zagreb, Croatia,* [4]*National Institutes of Health, Bethesda, United States of America (the)*

Background: Chronic graft versus host disease (cGvHD) is an alloimmune allogeneic hematopoietic stem cell transplantation (allo-HSCT) complication. Endothelial injury and activation are crucial for cGVHD pathophysiology. EASIX score (Endothelial Activation and Stress Index) calculated by the formula lactate dehydrogenase (LDH) (U/L) x Creatinine (mg/dL) divided by platelet count (10^9/L) is an endothelial dysfunction parameter tested in acute graft versus host setting, predicting non-relapse mortality in patients who have undergone reduced-intensity conditioning allo-HSCT, and was also tested in conditions where endothelial injury has a significant pathophysiological role. In the context of cGVHD, von Willebrand factor (VWF) is a marker of endothelial dysfunction, potentially a valuable addition to the existing EASIX formula. In this exploratory analysis, we aim to evaluate EASIX score in cGVHD, assessing correlations with clinical cGVHD manifestations and cytokine concentrations, i.e. the hypothesis is that EASIX score may correlate with cGVHD clinical phenotypes and underlying cGVHD biology.

Methods: Patients with cGVHD (73 samples from 54 patients, Table 1) were enrolled in a protocol at the UHC Zagreb (4/2017 - 12/2019; Croatian Science Foundation project IP-2016-06-8046). Patients were evaluated by a multidisciplinary team, and clinical manifestations were documented in detail. Samples were grouped into 3 cGVHD phenotypes: inflammatory (n=21), sclerotic (n=22), mixed (n=21). Samples taken from patients who underwent alloHSCT, without cGvHD, were control samples (n=9). Patients with active infection or overlap cGvHD were excluded. Selected cytokine levels were analysed by commercial essays (BAFF and CXCL9 – both Quantikine, CCL15 -DuoSet ELISA kit; all by R&D Systems, Minneapolis, MN, USA). Cytokines and clinical phenotypes were determined according to the proposed biological cGvHD model (Cooke et al., The Biology of Chronic Graft-versus-Host Disease, BBMT, 2017). B-cell activating factor (BAFF) is a cytokine vital to B-cell survival and is a promising cGvHD biomarker. C-X-C motif ligand 9 (CXCL9) is an interferon-gamma inducible chemokine stimulating T-cell migration to target tissues, and C-C motif ligand 15 or MIP5 – macrophage inflammatory protein 5 (CCL15) is a monocyte/macrophage chemoattractant. The EASIX score was calculated using the standard formula. Formula was additionally expanded with von Willebrand antigen (VWF:Ag) and activity (VWF:RCo), as follows: LDH (U/L) x Creatinine (mg/dL) x VWF:Ag (or VWF:Rco, %) / platelet count (x10^9 /L), all a part of the standard cGVHD workup.

Results: When the standard EASIX formula was used, statistically significant correlation was observed in CXCL9 (Figure 1) and VWF:Ag, only in the inflammatory phenotype (p=0.03 and p=0.013, Spearman rank correlation). When the VWF-modified (VWF:Ag and VWF:RCo) formula was used, a significant correlation with CXCL9 (p<0.001, Spearman rank correlation) and BAFF (p=0.002) was observed for all cGVHD patients, and more interestingly, EASIX formula with VWF:Ag and VWF:RCo was significantly correlated with BAFF (VWF:Ag p=0.013, VWF:RCo p=0.009), CXCL9 (VWF:Ag p=0.006, VWF:RCo p=0.003) and 2015 NIH severity score (VWF:Ag p=0.030, VWF:RCo p= 0.020) in the inflammatory phenotype.

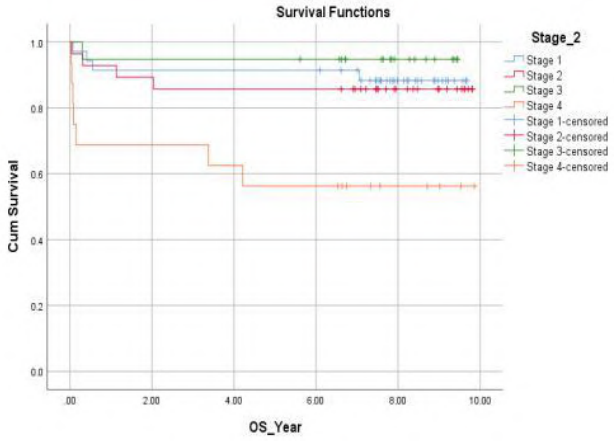
THE INTERPLAY BETWEEN CYTOMEGALOVIRUS REACTIVATION, CONDITIONING REGIMENS, AND GRAFT-VERSUS-HOST DISEASE IN ALLOGENEIC HSCT: A 10-YEAR RETROSPECTIVE ANALYSIS FROM RESOURCE-LIMITED SETTING

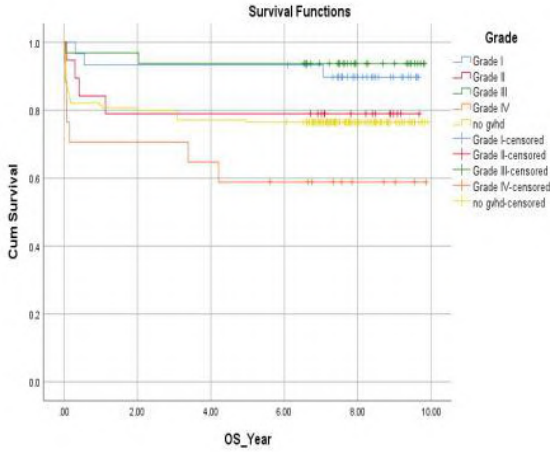
Najia Gul[1], Hira Tariq[1], Mahnoor Mahnoor[1], Raheel Iftikhar[1], ***Bushra Ahsan***[2]
[1]AFBMTC, Rawalpindi, Pakistan, [2]Shaukat Khanam Memorial Cancer Center, Lahore, Pakistan

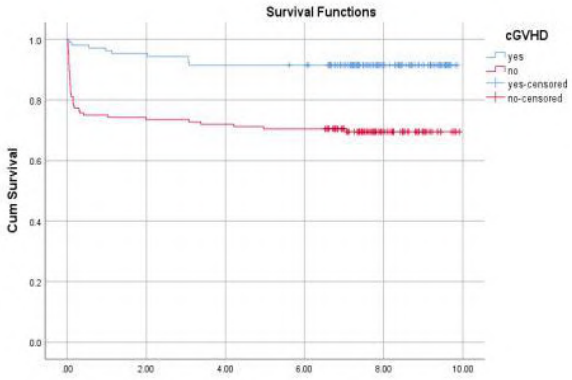
Background: Acute graft-versus-host disease (aGVHD) and chronic graft-versus-host disease (cGVHD) are the most common complications of hematopoietic stem cell transplantation (HSCT). Despite advancements in HLA matching and immunoprophylaxis, it remains a major cause of morbidity and mortality in low- and middle-income countries (LMICs).

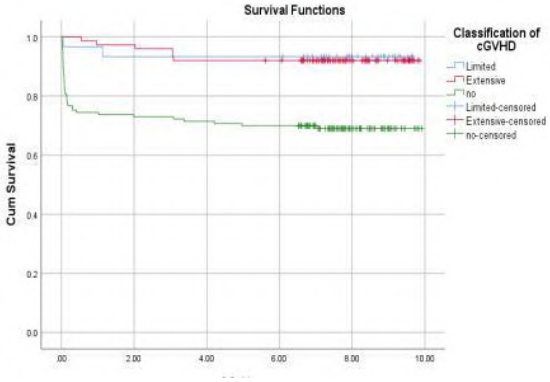
Methods: This 10-year retrospective single-center study included 238 patients with malignant and non-malignant hematological disorders who had received an allogeneic HSCT. The aGVHD was graded as per the Glucksberg-Seattle criteria. Logistic regression was applied to calculate the association of aGVHD and cGVHD with CMV reactivation and conditioning regimen, whereas the Kaplan-Meier and log-rank tests were used to calculate overall survival (OS) and its relationship with aGVHD and cGVHD, CMV reactivation, and conditioning regimen.

Results:









The median age of the cohort was 9 years (IQR: 4.5-20), with a male-to-female ratio of 2.3:1. The most common indication for HSCT was beta thalassemia major (35.7%). The majority of donors were siblings (88.7%), followed by parents (10.1%) and cousins (1.3%). The most common conditioning regimen used was myeloablative conditioning (MAC), which was given to 135 (56.7%) patients, followed by non-MAC in 71 (29.8%) and reduced intensity conditioning (RIC) in 32 (13.4%). aGVHD developed in 71/238 (29.8%), in which 21.8% had gut GVHD, followed by liver GVHD (7.6%) and eye GVHD (1%). Out of 71 cases, 13.4% had Grade III and 7.1% had Grade IV aGVHD. cGVHD developed in 106/238 (44.5%), in which 10.9% had gut GVHD, followed by liver GVHD (8.8%) and eye GVHD (3.4%), lung (17.6%), oral (16%), and skin (39.5%). Meanwhile, limited cGVHD was in 30 (12.6%) and extensive in 75 (31.5%). The overall survival (OS) was 79.4% with a mean survival of 8 years post allo-HSCT (95% CI: 7.5-8.5). There was significant association of stage (P=0.003) and grades (P=0.02) of aGVHD, cGVHD (P=0.0001), and classification of cGVHD (P=0.0001) with OS (Figures 1-4). On the multivariate analysis, RIC was associated with a higher incidence of aGVHD (OR: 4.0, p = 0.03). CMV reactivation occurred in 93/238 (39%) of patients and was significantly associated with a reduced risk of aGVHD (OR: 0.26, p = 0.001).

Conclusions: The association of RIC conditioning with a higher incidence and CMV reactivation with a lower incidence of aGVHD in LMICs highlights the need for optimization of conditioning regimens and institution of early CMV monitoring in LMIC settings to improve GVHD-related mortality and morbidity.

SINGLE-AGENT CSF-1R OR JAK INHIBITION REDUCES FIBROSIS IN A MURINE MODEL OF CHRONIC GRAFT-VERSUS-HOST DISEASE

Paul Wilson[1], *Shannon Kahan*[1], *Melissa Parker*[1], *Jörg Distler*[2], *Chryssa Kanellopoulou*[1]
[1]*Incyte Corporation, Wilmington, DE, United States of America (the),* [2]*University Hospital Düsseldorf, Heinrich-Heine University Düsseldorf, Düsseldorf, Germany*

Background: Chronic graft-versus-host disease (cGVHD) is characterized by persistent immune dysregulation, leading to tissue injury and fibrosis. Colony-stimulating factor 1 (CSF-1)–dependent myeloid pathways and Janus kinase/signal transducer and activator of transcription (JAK/STAT)-driven cytokine networks are both implicated in cGVHD pathogenesis. While CSF-1 receptor (CSF-1R) inhibition (axatilimab) and JAK1/JAK2 inhibition (ruxolitinib) have each shown clinical benefit, the potential for combined targeting of these pathways warrants further exploration.

Methods: A murine model of cGVHD was established in BALB/c (H-2^d) mice by transplantation of bone marrow cells and splenocytes from B10.D2 donors, which results in a minor antigen mismatch. Upon onset of clinical signs of GVHD, mice were treated with either anti–CSF-1R or ruxolitinib. Clinical status was monitored and disease severity was evaluated using standardized scoring criteria. At study endpoint, lung and skin tissues were harvested for assessment of fibrosis, hydroxyproline content, and dermal thickness. Additionally, RNA sequencing (RNA-seq) analysis was performed on skin samples to evaluate transcriptional changes associated with each treatment.

Results: Treatment with either anti–CSF-1R or ruxolitinib reduced clinical GVHD scores, decreased hydroxyproline levels in skin and lung tissues, and improved dermal thickness compared to controls. RNA-seq analysis of skin revealed transcriptional changes in response to each treatment, providing further insight into the molecular mechanisms underlying their therapeutic effects.

Conclusions: Both CSF-1R and JAK pathway inhibition individually attenuated in vivo tissue fibrosis and improved clinical outcomes in a murine cGVHD model. RNA-seq analysis of skin identified transcriptional changes associated with each treatment. These findings, derived from single-agent therapeutic approaches currently used in cGVHD, support the therapeutic potential of targeting CSF-1R and JAK pathways in this setting. Future studies will explore whether combination approaches could offer additional benefit.

Disclosure: Paul Wilson, Shannon Kahan, Melissa Parker, and Chryssa Kanellopoulou are employees and shareholders of Incyte Corporation. Jörg Distler has consultancy relationships with Active Biotech, Anamar, ARXX, AstraZeneca, Bayer Pharma, Boehringer Ingelheim, Callidatas, Calluna, Galapagos, GSK, Janssen, Kyverna, Ono Pharmaceutical, Merck, Novartis, Quell Therapeutics, Tyra, and UCB; has received research funding from Anamar, AstraZeneca, ARXX, BMS, Boehringer Ingelheim, Cantargia, Celgene, CSL Behring, Exo Therapeutics, Galapagos, GSK, Incyte, Inventiva, Kiniksa, Kyverna, Lassen Therapeutics, Mestag, Sanofi-Aventis, SpicaTx, RedX, UCB, and ZenasBio; has received writing support from Boehringer Ingelheim and Endeavor Biosciences; and is CEO of 4D Science and scientific lead of FibroCure.

ADAPTIVE AND MYELOID DYNAMICS AFTER ALLOGENEIC STEM CELL TRANSPLANTATION IN ACUTE OR CHRONIC GRAFT-VERSUS-HOST DISEASE UNDERGOING EXTRACORPOREAL PHOTOPHERESIS VERSUS NON–GRAFT-VERSUS-HOST DISEASE AND HEALTHY DONORS

Kristina Schreiner[1,2], Anying Huang[1,2], Vivien Simon[1,2,3], Cansu Karatas[1,2], Julian Stein[1,2], Kerstin Gruber[1,2,4], Clyde Boppel[1,2,4], Jan Weller[5], Christoph Schmid[2,6], Jochen Frietsch[7], Helene Schmeller[8], Tobias Holderried[8], Katrin Strauss[9], Elisa Sala[9], Giuliano Filippini[2,6], ***Helga Schmetzer***[1,2]
[1]*University Hospital of Ludwig-Maximilians-University, Munich, Germany,* [2]*Bavarian Center for Cancer Research (BZKF), Munich, Germany,* [3]*University of Bielefeld, Bielefeld, Germany,* [4]*University of Applied Sciences, Esslingen, Germany,* [5]*University Hospital of Hamburg-Eppendorf, Hamburg, Germany,* [6]*University Hospital of Augsburg, Augsburg, Germany,* [7]*University Hospital of Würzburg, Würzburg, Germany,* [8]*University Hospital of Bonn, Bonn, Germany,* [9]*University Hospital of Ulm, Ulm, Germany*

Background: Allogeneic stem cell transplantation (HSCT) is often associated with Graft-versus-Host Disease (GvHD) resulting from dysregulated alloreactivity. Extracorporeal photopheresis (ECP) is an established therapy for immunomodulation in GvHD, but underlying cellular mechanisms remain largely unclear. We compared myeloid and adaptive immune cell compositions from patients with acute GvHD (aGvHD) / chronic GvHD (cGvHD) receiving ECP to healthy individuals and patients without GvHD after HSCT (NoGvHD).

Methods: ECP was administered using the Therakos™ CELLEX™ Photophoresis system. Flow cytometric analysis of blood samples (Healthy N=10, NoGvHD N=19, cGvHD N=18, aGvHD N=6) was performed at baseline (d0) and after 13 weeks (d90), with or without ECP treatment, followed by statistical analyses.

Results: Baseline (d0): cGvHD vs. NoGvHD

- Adaptive: ↑ memory T-cells, ↓ Tregs, ↓ Bregs

- Myeloid: ↑ activated dendritic cells (DCs), ↓ myeloid derived suppressive cells (MDSCs)

NoGvHD (Course d0 → d90)

- Adaptive: T-cells, Tregs, Bregs → stable
- Myeloid: Monocytes, DCs, MDSCs → stable

cGvHD during ECP (Course d0 → d90)

- Adaptive: memory T-cells ↓ (composition similar to NoGvHD), T-cell proliferation ↓, Tregs ↑ (partial recovery), Bregs ↑ (partial recovery)
- Myeloid: activated DCs ↓, inflammatory monocytes ↓, MDSCs ↑ (composition similar to NoGvHD)

Post-treatment (d90): cGvHD vs. NoGvHD

- Adaptive: memory T-cells still ↑, but lower compared to d0,
  Tregs still ↓ despite partial recovery
- Myeloid: activated DCs stay ↑, MDSCs ↓

Conclusions: At baseline compared to NoGvHD, cGvHD before ECP showed pronounced adaptive and myeloid dysregulation. By d90, NoGvHD profiles showed stable levels of cells while ECP induced partial normalization of dysregulated immune compartments in cGvHD (compared to d0). Immune hyperactivation persisted but was attenuated after ECP. Clinical correlations will be presented at the congress.

Disclosure: This work was funded by an external collaborative research (ECR) grant provided by Therakos EMEA Limited.

EXPERIENCE IN HAPLOIDENTICAL TRANSPLANTATION OVER THE LAST 3 YEARS, IN THE TRANSPLANT UNIT OF MEXICO'S NATIONAL REFERENCE MEDICAL CENTER

Alba Edna Morales Hernandez[1], *Elsa Veronica Avila Arreguin*[1], *Maria Guadalupe Rodriguez Gonzalez*[1]
[1]*Instituto Mexicano del Seguro Social, Ciudad de México, Mexico*

Background: Allogeneic hematopoietic cell transplantation(HCT) is a potentially curative procedure for benign and neoplastic hematologic disorders. The probability of finding an HLA-compatible donor is 25%. The use of post-transplant cyclophosphamide(CYpost) on days +3 and +4 has reduced graft failure and the occurrence of graft-versus-host disease(GVHD). At our center, the dose of CYpost for haploidentical HCT has been adjusted to40 mg/kg. In this study, 46 patients who underwent haploidentical HCT in the last 3 years were described.

Objectives: To determine progression-free survival(PFS) and overall survival(OS) in patients who underwent haploidentical HCT in a transplant unit at a tertiary referral medical center in Mexico City from 2022 to 2025. To describe the demographic characteristics and clinical outcomes that patients have presented after haploidentical HCT.

Methods: Retrospective, descriptive, and observational study. Inclusion criteria: all patients who underwent transplantation in the hematopoietic cell transplant unit of one mexican medical center, from January 2022, to April 2025, with a haploidentical transplant.

Results:

Grado global aGvHD MAGIC	PIEL Percentaje 100%	HEPÁTICA Percentaje 100%	GI BAJO Porcentaje 100%	GI UPPER Percentaje 100%
0	15.2%	39%	71.7%	54.3%
1	52.2%	39%	17.4%	41.3%
2	21.7%	16%	6.5%	2.2%
3	2.2%	4%	2.2%	1.1%
4	0%	2.2%	2.2%	1.1%

Acute-Graft-Versus-host-disease-aGvHD-Characteristics

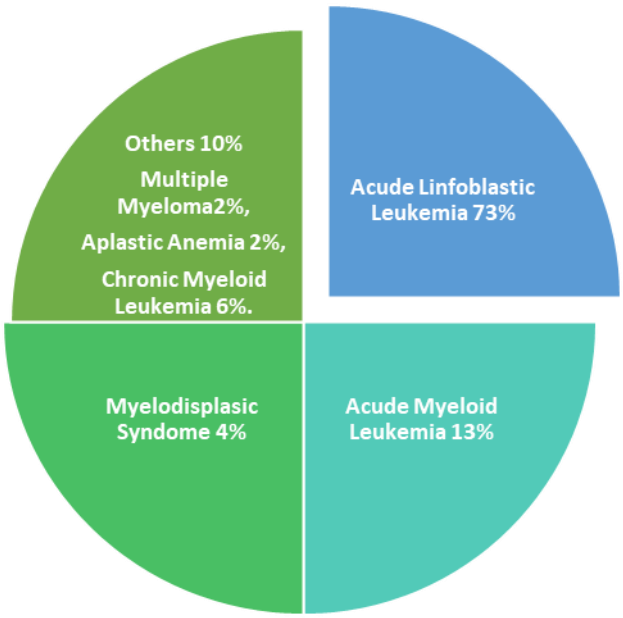

Figure1.Distribution-of-hematological-pathologies-undergoing-haploidentical-transplantation.

Patients who received haploidenticalHCT were 63% male and 37% female. The mean age

was 32 years. The post-transplant diseases are shown in Figure1. Hematopoietic cell donors were 65% male and 35% female, with 46.8% aged 18–35 years, 52.2% older than 35 years, and 1% underage. According to the EBMTscore, 8 patients(17.4%) had 3 points, 36 patients (78.3%) 4 points, and 2 patients(4.3%)5 points. Prior chemotherapy lines were as follows: 27% had one previous line of treatment, 30% had 2 lines, 39% had 3 lines, and 4% had 4 lines. A total of 82.6% of patients went to transplant with negative MRD. ABO blood group compatibility was found in 84.8% of patients, with 13% minor incompatibility and 2.2% major incompatibility. The dose of post-transplant cyclophosphamide in the haploidentical setting(CYpost-haploidentical) was 50 mg/kg in 41.3% of patients, 40mg/kg in 39.1%, and 35mg/kg in 19.6%. The dose was adjusted according to the complications. Cytokine release syndrome: gradeI in 60.9%, gradeII in 32.6%, and grade3–4 in 6.5%, with lower cyclophosphamide doses. The source of hematopoietic cells was: peripheral blood. No patients were transplanted with donors who had positive anti-HLA antibodies. The average waiting time to transplant was: 123 days. The mean engraftment day for neutrophils was +13, reticulocytes +15, and platelets +13. The mean length of stay was 40days. AcuteGVHD occurred in 78.3%, chronicGVHD in 8.7%, overlap syndrome in 4.3%, and 8.7% had no GVHD. Figure2 shows the GVHD characteristics. Mortality was 37%, due to infections: 17.4%(CMV 67% and Clostridioides 28.3%), relapse:15%(associated with the number of treatments), and graft failure:4.3%. Overall survival ranged from 184days to 5,526 days. Progression-free survival at 1,000 days was 85%.

Conclusions: 46 patients were analyzed, where the leading cause of mortality was infections, which confirms that measures should be taken regarding their control in the hematopoietic stem cell transplant unit. 63% of the surviving patients experienced low grades ofGVHD, which does not diminish their quality of life and is considered an acceptable alternative when a 100% compatible allogeneic donor is not available.

Background: Fecal microbiotherapy has shown promising results in pilot studies involving patients with refractory acute Graft-versus-Host Disease with gastrointestinal involvement (GI-aGvHD). We report the final results from ARES (NCT04769895), a multicenter, open-label, phase 3 study exploring the pooled allogeneic microbiotherapy MaaT013 in subjects with refractory-GI-aGvHD previously treated with systemic steroids and ruxolitinib.

Methods: AlloHCT recipients with GI-aGvHD, identified as corticosteroid-refractory and either refractory or intolerant to ruxolitinib, were eligible. The treatment included rectal administration of 3 MaaT013 doses (D1,D5,D10). Each MaaT013 contained a minimum of 1.35×10^{11} viable bacteria. A supplementary MaaT013 dose was authorized in case of relapse after D28 if CR/VGPR was achieved before D28.
The primary endpoint was GI-overall response rate (GI-ORR) at D28 assessed by an independent review committee. Secondary endpoints included ORR for GI-and all-organ at D28, D56 and Month3 (M3), overall survival (OS), and safety analysis.

Results: Sixty-six adult subjects with grade II-IV GI-aGvHD were enrolled and received at least one MaaT013 dose (median=3; range,1-4). Median age at informed consent was 55.5 years (range,24-76); 53% were male. Most subjects presented with grade III (58%) or IV (33%) aGvHD; 86% were steroid-resistant and 14% (n=9) steroid-dependent, all were resistant to ruxolitinib. 77% of patients had exclusive lower GI (LGI) involvement, 17% had LGI and skin involvement, 3% had LGI and liver involvement and 3% had LGI, skin and liver involvement.
The study met its primary endpoint, with a D28 GI-ORR of 62% (n=41, 95% CI, 0.49-0.74), significantly higher than the pre-established 22% threshold ($p<0.0001$). Most subjects achieved D28 GI-complete response (GI-CR:38%) or GI-VGPR (20%), while 5% achieved GI-partial response (PR). Responses for all-organ ORR were similarly frequent with D28 ORR of 64%, including 36% with CR and 18% with VGPR.
At D56 and M3, GI-ORR was maintained in 47% (95%CI, 0.35- 0.60) and 44% (95% CI, 0.32-0.57) subjects, respectively, with a prevalence of GI-CR (35% and 36%, respectively).
At the end of the study, the median OS was not reached. The OS was 59% at M6 and 54% at M12, exceeding the previously reported 12-month OS of 15% (Abedin, 2021)**.** Importantly, the OS was significantly higher in responders (achieving at least GI-PR at D28, n=41)

compared to non-responders (n=25): 76% versus 28% at M6; 68% versus 28% at M12, respectively (Log-rank p<0.0001)**.** The median OS of responders was not reached while it was 54 days in non-responders (95% CI, 24.0-116.0).
MaaT013 demonstrated an acceptable safety profile despite the vulnerability of subjects with refractory GI-aGvHD. 36 treatment-related adverse events (AEs) were reported in 19 (29%) subjects. Of these, 8 events in 7 subjects (11%) were considered serious. Out of 29 fatal AEs, one was deemed related to MaaT013 by the investigator.

Conclusions: Final ARES results demonstrate that MaaT013 induces frequent and deep responses translating into prolonged survival and acceptable safety profile in subjects with aGvHD who previously failed both systemic steroids and ruxolitinib, a population characterized by poor clinical outcomes with limited therapeutic options. These positive results support MaaT013 as the first microbiome-based therapy for the treatment of refractory aGvHD.

Background: Dysbiosis after allogeneic hematopoietic stem cell transplant (allo-HSCT) predisposes to acute gastrointestinal graft-versus-host disease (GI GVHD). We have

previously shown that human milk administration reduces peri-transplant dysbiosis by virtue of human milk oligosaccharides (HMO) that are known prebiotics (*Breastfeeding Medicine*, 2019). We have additionally conducted a phase I study of the most abundant HMO, 2'-fucosyllactose (2'-FL), and have demonstrated safety and established dosing. We hypothesized that peri-transplant oral 2'-FL administration would reduce dysbiosis and acute GI GVHD in children and young adult HSCT recipients.

Methods: We performed a prospective, single-center phase II study in which patients 0-34 years of age received oral, once daily 2'-FL from start of conditioning therapy until day +30 after HSCT. Patients were considered evaluable based on ≥60% compliance. Twenty-nine age- and prep-matched HSCT recipients with available samples in our institutional biorepository served as controls. Stool samples were evaluated for metabolomics by nuclear magnetic resonance (NMR) and for the microbiome by metagenomic shotgun sequencing before transplant (baseline) and days +7, +14, and +28 after HSCT. Urine 3-indoxyl sulfate (3-IS) was measured at baseline and day +7 as a surrogate of dysbiosis, with lower urine 3-IS levels suggesting greater dysbiosis (Weber et al., *Blood*, 2016). Plasma regulatory islet 3α (reg3α) and suppressor of tumorigenicity (ST2) levels were measured via enzyme-linked immunosorbent assay (ELISA) at baseline and day +7.

Results: Seventy patients, median age 8.8 years (range 0.5-33.5 years), were enrolled, of which 43 were evaluable based on compliance to 2'-FL (**Table 1**). Shannon diversity, a measure of species richness and abundance, was preserved in 2'-FL recipients longitudinally compared to a significant decline from baseline to day +28 in controls (p=0.04) (**Figure 1A**). Generalized linear mixed model (GLMM) analysis accounting for antibiotic exposure demonstrated significantly higher association of *Bifidobacteria* species and *Blautia* species with 2'-FL treatment (adjusted p<0.05), representing a favorable gut microbiome (**Figure 1B**). Urine 3-IS was higher at day +7 in 2'-FL recipients compared to controls (p=0.003), supporting reduced dysbiosis (**Figure 2**). Predominance of known anti-inflammatory fecal metabolites was observed in 2'-FL recipients at day +7, including higher aspartate (p=0.02), isoleucine (p=0.005), phosphocholine (p=0.007), taurine (p=0.04), and tyrosine (p=0.05) compared to controls (**Figure 3**). Median plasma reg3α levels were 5.5 ng/mL (range 0.02-46.8 ng/mL) in 2'-FL recipients and 9.9 ng/mL (range 0.02-99.5 ng/mL) in controls (p=0.05). Median ST2 levels were 18.1 ng/mL (range 7.8-200.0 ng/mL) in 2'-FL recipients and 37.5 ng/mL (range 20.5-200.0 ng/mL) in controls (p=0.038). Incidence of day +100 acute GI GVHD was 2% in 2'-FL recipients compared to 17% in controls (p=0.035). Adenovirus reactivation was 0% in 2'-FL recipients compared to 17% in controls (p=0.009), similar to our human milk study (**Table 1**). No increase in bloodstream infections was observed in 2'-FL recipients compared to controls, further confirming the 2'-FL safety profile.

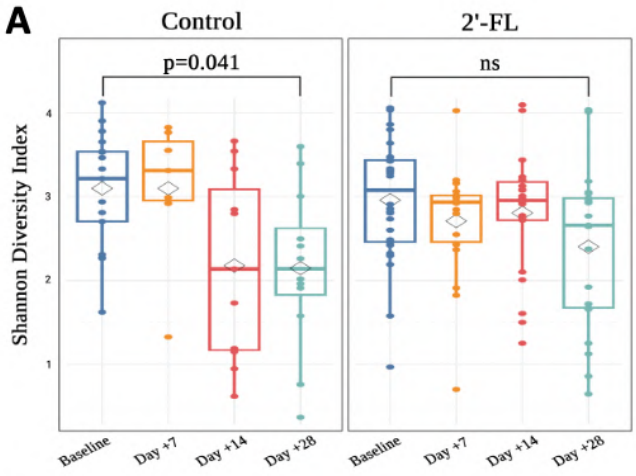
*Acute GVHD grading is based on modified Glucksberg criteria (Glucksberg, *Transplantation*, 1974).

P values obtained with Fisher's Exact test.



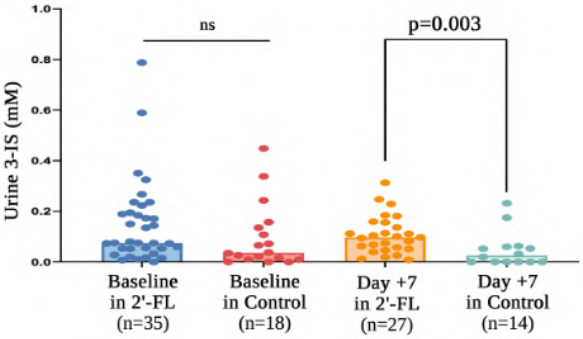


Figure 2. Urine 3-IS via NMR at day +7 in 2'-FL recipients and controls. Urine 3-IS was higher at day +7 in 2'-FL recipients compared to controls (p=0.003), supporting reduced dysbiosis in 2'-FL recipients.

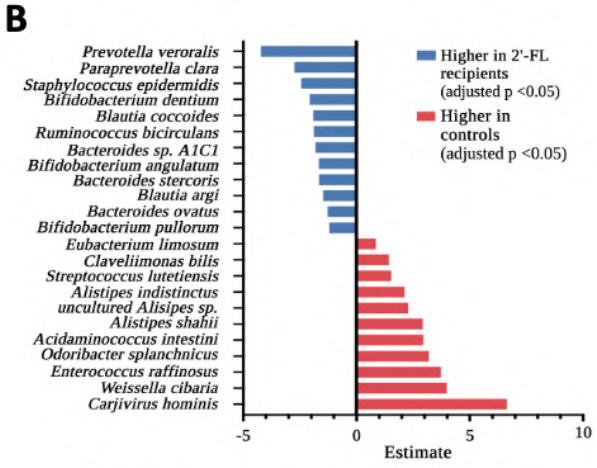

Figure 1. Metagenomic shotgun sequencing in 2'-FL recipients and controls. (A) Shannon diversity, a measure of species richness and abundance, is preserved longitudinally in 2'-FL recipients compared to a significant decline (p=0.041) in controls. **(B)** Generalized linear mixed model analysis from baseline to day +28 showing microbial species significantly associated with 2'-FL treatment (all with adjusted p <0.05). Higher *Bifidobacteria* and *Blautia* species were observed in 2'-FL recipients, representing a favorable microbiome. Time in the model is a fixed effect.

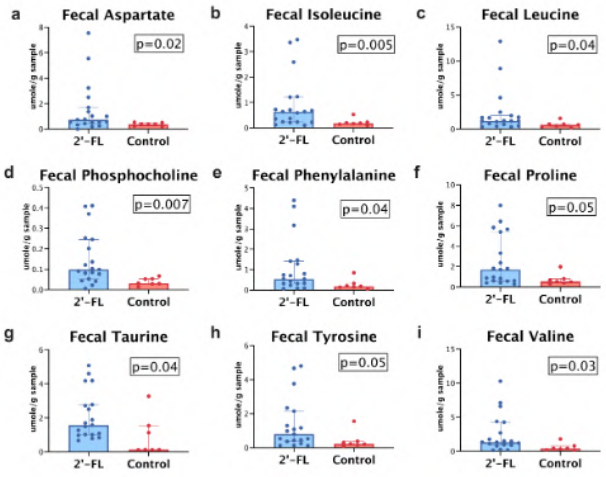

Figure 3. Fecal metabolites via NMR at day +7 in 2'-FL recipients and controls. Predominance of anti-inflammatory fecal metabolites was observed in 2'-FL recipients at day +7, including higher (**a**) aspartate (p=0.02), (**b**) isoleucine (p=0.005), (**d**) phosphocholine (p=0.007), (**g**) taurine (p=0.04), and (**h**) tyrosine (p=0.05) compared to controls.

Conclusions: Oral 2'-FL supplementation is safe and reduces peri-transplant dysbiosis and acute GI GVHD in children and young adult HSCT recipients.

ITACITINIB IN COMBINATION WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE AND TACROLIMUS (ICT) AS GVHD PROPHYLAXIS FOR REDUCED INTENSITY MATCHED DONOR HEMATOPOIETIC CELL TRANSPLANTATION (HCT): FINAL ANALYSIS

Monzr M. Al Malki[1], *Dongyun Yang*[1], *Sally Mokhtari*[1], *Anissa Bailey*[1], *Pooja Rajeevan*[1], *Rhiannon Imbeah*[1], *Salman Otoukesh*[1], *Brian Ball*[1], *Paul Koller*[1], *Vaibhav Agrawal*[1], *Yazeed Samara*[1], *Firoozeh Sahebi*[1], *Ibrahim Aldoss*[1], *Andrew Artz*[1], *Guido Marcucci*[1], *Stephen Forman*[1], *Ryotaro Nakamura*[1], *Haris Ali*[1]

Background: Post-transplant cyclophosphamide (PTCy) is a cornerstone of graft-versus-host disease (GvHD) prophylaxis in reduced intensity allogeneic hematopoietic cell transplant (HCT). Still, infection and GvHD remain significant challenges. Itacitinib, a selective JAK1 inhibitor, may reduce GvHD with less impact on hematopoietic recovery than other JAK inhibitors. We conducted a single-center study (NCT05364762) evaluating the safety of adding itacitinib to PTCy-based prophylaxis with tacrolimus, for 60 or 90 days, in patients undergoing matched related or unrelated peripheral blood stem cell (PBSC) HCT following fludarabine (25 mg/m^2: days -7 to -3) and melphalan (100 mg/m^2: day -2) conditioning.

Methods: GvHD prophylaxis was PTCy (50 mg/kg: days +3 and +4), itacitinib (200 mg daily, days +5–100), and tacrolimus (starting day +6). The primary objective was to assess safety of adding fixed-dose itacitinib to PTCy-based GvHD prophylaxis with 90 (cohort 1) or 60-day (cohort 2) tacrolimus. The primary safety event (PSE) was grade 3-4 acute GvHD (aGvHD) per MAGIC criteria. Observation continued from first PTCy dose until grade 3-4 aGVHD, competing risks (relapse, NRM, DLI or second HCT), or day +100 post-HCT.

Results: Twenty patients were enrolled. Median age was 63 years (range: 56–77), 55% were male, and 80% non-Hispanic. Most patients (80%) received unrelated donor HCT. KPS was 90-100 in 16 (80%) and HCT-CI ≥ 3 in 50% (n=10). Diagnoses included AML in CR1/2 (n=8; 40%), MDS (n=7; 35%), ALL in CR1/2 (n=2; 10%), CMML (n=2; 10%), or MF (n=1; 5%). All patients achieved engraftment with median neutrophil and platelet recovery at 16 days (range: 13-25) and 27 days (range: 17-137). Grade ≥3 adverse events (AEs) at least possibly related to itacitinib included anemia (n=14), febrile neutropenia (n=3), and sepsis (n=3). Grade ≥3 thrombocytopenia occurred in 18 patients, most within 6 weeks post-HCT, a median duration of 16 days (range: 8–102), resolving without significant bleeding. No unexpected safety signals or PSEs were observed with either tacrolimus schedule. Cytokine release syndrome (CRS) occurred in 3 patients (15%; all grade 1–2). During the first 100 days, bacterial infections occurred in 35% (grade 1: 10%, grade 2: 25%), and fungal/bacterial infections in 5% (grade 1) and 20% (grade 1: 5%, grade 2: 15%) of patients, respectively. No grade 3 infections were reported.
At the median follow-up duration of 366 days (range: 358-376) for 18 survivors, 1-year overall survival (OS) and relapse-free survival (RFS) were 90% (95% CI: 66–97) and 85% (95% CI: 60–95), respectively. One-year relapse and NRM were 15% (95% CI: 4–34.0) and 0%, respectively. Day 180 grade 2-4 and 3-4 aGvHD were 10% (n=2) and 0%, respectively.

One-year moderate-severe chronic GvHD was 5% (95% CI 0–2.1), and no patient required immunosuppression at 1 year. One-year GVHD-free, relapse-free survival (GRFS) was 75% (95% CI: 50–89).

Patient and Transplant Characteristics

ENDOTHELIAL DYSFUNCTION AND IMMUNE ACTIVATION INTERACT AND DETERMINE MORTALITY IN ACUTE GRAFT-VERSUS-HOST DISEASE

Thomas Luft[1], *Nicholas Schreck*[2], *Constantin Schwab*[3], *Aleksandar Radujkovic*[1], *Cryostem Consortium*[4], *Olaf Penack*[5], *Nils Englert*[3], *Ted Gooley*[6], *Carsten Müller-Tidow*[1], *Axel Benner*[7], *Peter Dreger*[1]

Medicine V, Heidelberg, Germany,* [2]*Faculty of Liberal Art and Sciences, University of Applied Sciences, Augsburg, Germany,* [3]*Institute of Pathology, University of Heidelberg, Heidelberg, Germany,* [4]*Association Cryostem, Marseille Innovation, Technopole de Chateau Gombert, Marseille, France,* [5]*Charité – Universitätsmedizin Berlin, Department of Hematology, Oncology and Tumorimmunology, Berlin, Germany,* [6]*Fred Hutchinson Cancer Research Center, Seattle, WA, USA; University of Washington, Seattle, United States of America (the),* [7]*Division of Biostatistics, German Cancer Research Center, Heidelberg, Germany*

Background: Severe acute graft-versus-host disease (aGVHD) is a life-threatening complication after allogeneic stem cell transplantation (alloSCT). We tested the hypothesis that simultaneous immune activation and endothelial dysfunction shape survival outcomes in aGVHD.

Methods: In the training cohort, 1,332 allografted patients provided informed consent; the cumulative incidence of any-grade aGVHD by day +180 was 43.4% (n = 512), grade 3–4 aGVHD 22.6% (n = 260), and steroid-refractory aGVHD 10% (n = 114). Cohort IA comprised 321 patients with serum for biomarker assessment obtained ≤14 days before aGVHD onset. In the training cohort IB, 537 patients had EASIX and CRP measured at onset. To validate our serum biomarker findings, cohort II included 125 independent patients with plasma at onset of aGVHD (CRYOSTEM/SFGM-TC); CRP and EASIX were not available. To validate the EASIX and CRP results, cohort III comprised 220 patients from Berlin and Seattle, with CRP/EASIX data at onset of GVHD; in subsets (n = 57, 61), values were also available on days +14 and +28.
Inflammatory biomarkers (Reg3a, TIM3, IL-18, CXCL9) and endothelial markers (ST2, angiopoietin-2, sCD141, CXCL8) were measured at aGVHD onset. Using random survival forests, we analyzed their association with non-relapse mortality (NRM) and overall survival

(OS) in two independent patient cohorts. In parallel, we evaluated the interdependency of C-reactive protein (CRP) as an inflammatory marker and the Endothelial Activation and Stress Index (EASIX) in a training cohort (n=537) and validated the findings in an independent cohort (n=220).

Results: Survival modeling showed that increasing inflammatory markers influenced outcome only when combined with increasing endothelial markers. This pattern was independently confirmed for IL-18 and CXCL9 when combined with any of the four endothelial markers. CRP and EASIX similarly displayed a synergistic effect on post-aGVHD outcomes. After intensified immunosuppression for severe aGVHD, endothelial markers rose between days 14–56 exclusively in patients who died within one year, but not in survivors. Patients with combined high EASIX and elevated CRP had markedly increased NRM risk in multivariable analyses in the training cohort, and this predictive power was confirmed in the validation cohort at aGVHD onset and days +14–56 after onset, both for continuous values and for pre-established cut offs (CRP>5 mg/dl, EASIX>3.57, both high: HR for NRM at aGVHD onset 7.03 (3.80-13.01, p<0.001). A direct link between endothelial and inflammatory pathology could be demonstrated by immune histology of gut biopsies from 25 severe aGVHD cases, where CRP deposition on endothelial surfaces was most pronounced in patients with high EASIX.

Conclusions: Mortality after aGVHD is driven by inflammation coupled with progressive endothelial injury. CRP binding to endothelial cells in the context of high EASIX provides a molecular explanation for the mutual enhancement of inflammatory and endothelial pathology during aGVHD.

VEDOLIZUMAB FOR TREATING STEROID-REFRACTORY LOWER GASTROINTESTINAL ACUTE GRAFT-VERSUS-HOST DISEASE: A SINGLE-CENTER REAL-WORLD STUDY

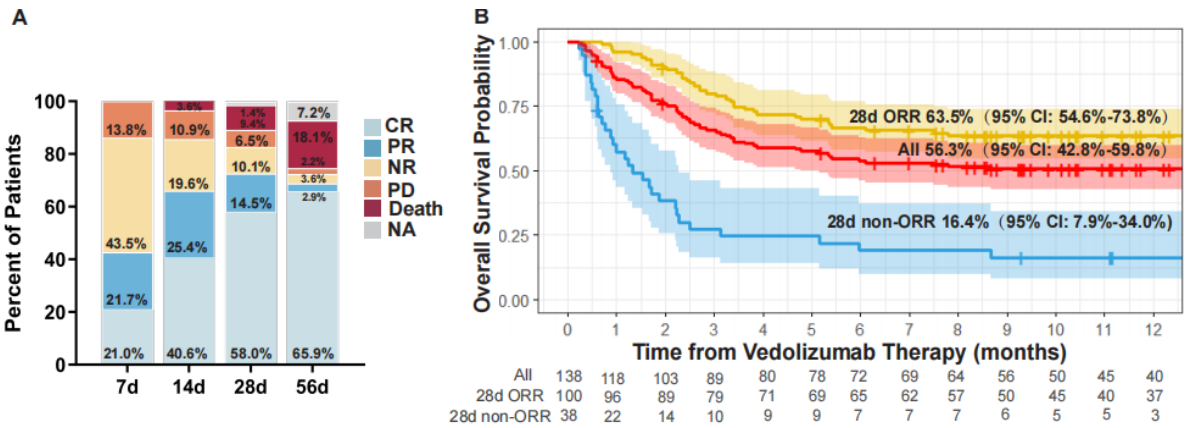
Jieya Luo[1], *Xinhui Zheng*[1], *Jingqi Li*[1], *Xin Chen*[1], *Erlie Jang*[1]
[1]*Institute of Hematology and Blood Diseases Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Tianjin, China*

Background: Steroid-refractory lower gastrointestinal acute graft-versus-host disease (SR-LGI-aGVHD) remains a life-threatening complication after allogeneic hematopoietic stem cell transplantation (allo-HSCT). Vedolizumab (VDZ), a gut-selective anti-integrin α4β7 monoclonal antibody, has shown preliminary efficacy in LGI-aGVHD by selectively inhibiting T-cell trafficking to the intestinal mucosa.

Methods: We retrospectively analyzed patients with SR-LGI-aGVHD treated with VDZ at the Institute of Hematology & Blood Diseases Hospital between January 2022 and December

2024. The primary endpoint was the lower gastrointestinal overall response rate (ORR) at day 28 after VDZ initiation. Secondary endpoints included 1-year overall survival (OS), steroid tapering, immune marker dynamics, treatment safety, and prognostic factors.

Results: A total of 138 patients received a median of two doses of intravenous VDZ (300 mg/dose). The median time from aGVHD onset to VDZ initiation was 7 days (IQR, 4-14). All patients received VDZ in combination with basiliximab, as second-line therapy in 42.8% and as third-line therapy in 57.2%. At treatment initiation, 65.2% had grade III-IV aGVHD, and 56.5% were classified as high-risk by Minnesota criteria.
The ORR at days 7, 14, 28, and 56 was 42.8% (CR 21.0%), 65.9% (CR 40.6%), 72.5% (CR 58.0%), and 68.6% (CR 65.9%), respectively. Median times to ORR and CR were 9 days (IQR, 6–14) and 19 days (IQR, 10.5-32). Sustained CR was achieved in 76.8% of patients (figure A).
Multivariable logistic regression identified older donor age (OR=2.443, 95% CI, 1.021-5.846, P =0.045), higher Minnesota risk grade at onset (OR=3.737, 95% CI, 1.026-13.613, P=0.046), and GVHD progression after VDZ initiation (OR=2.622, 95% CI, 1.017–6.757, P=0.046) as independent risk factors for failure to achieve ORR at day 28. A $CD34^+$ cell dose >3 × 10^6/kg was independently associated with a higher 28-day ORR (OR=0.300, 95% CI, 0.110-0.818, P=0.019).
After a median follow-up of 13.5 months (95% CI, 11.2-15.8), patients achieving ORR at day 28 had significantly higher 1-year OS (63.5% vs. 16.4%, P<0.001) (figure B), relapse-free survival (59.6% vs. 16.4%, P<0.001), and cumulative incidence of moderate-to-severe chronic GVHD (27.4% vs. 8.7%, P=0.049). The cumulative incidence of relapse did not differ significantly between groups (11.2% vs. 5.4%, P=0.315).
By day 28, 70.0% of patients achieved a ≥50% reduction in steroid dose from baseline (median 60 mg/day vs. 20 mg/day, P < 0.001). Compared with baseline (pre-VDZ), post-treatment peripheral blood samples showed decreased IL-5 levels (P=0.023), reduced proportions of NK cells (P=0.026) and Treg cells (P=0.019), and increased proportions of total T cells (P=0.011) and cytotoxic T lymphocytes (P=0.035).
No severe VDZ-related adverse events were observed within five half-lives (~4 months). Infections were the most common complications, including bacterial pneumonia (25.4%), gastrointestinal or urinary tract infections (21.0%), CMV viremia (18.8%) and EBV viremia (15.9%).



Conclusions: VDZ demonstrated substantial efficacy and a favorable safety profile as second- or third-line therapy for SR-LGI-aGVHD. Treatment response correlated more closely with baseline GVHD severity than the timing of intervention. VDZ was associated with a distinct immunological profile, leading to rapid and durable remission, improved survival, and reduced steroid dependence.

OS12-06

RISE OF CIRCULATING ENDOTHELIAL CELLS AT ENGRAFTMENT IS A HALLMARK OF STEROID-REFRACTORY GVHD

Polona Novak[1], *Katarina Klinar*[1], *Klara Šlajpah*[1], *Nika Kraljić*[1], *Ana Bošković*[1], *Matjaž Sever*[1,2], *Samo Zver*[1,2], *Helena Podgornik*[1,2]
[1]*UMC Ljubljana, Ljubljana, Slovenia,* [2]*University of Ljubljana, Ljubljana, Slovenia*

Background: Steroid-refractory acute graft-versus-host disease (SR-aGVHD) remains a major cause of transplant-related morbidity and mortality. Emerging evidence indicates that tissue injury in SR-aGVHD extends beyond classical target organs and reflects a systemic hyperinflammatory state. Rebound inflammation following corticosteroid withdrawal contributes further to bone marrow suppression and endothelial dysfunction, ultimately predisposing patients to severe infections and multiorgan damage. This early inflammatory cascade is predominantly driven by interferon-γ; however, the complexity of alloreactivity and the rapid expansion of immune effector cells result in a narrow therapeutic window for effective intervention. Given the central role of endothelial injury in this GVHD phenotype, we sought to characterize the temporal dynamics of circulating endothelial cells (CECs) in patients who develop SR-aGVHD.

Methods: Between July 2024 and November 2025, 54 adult patients undergoing allogeneic stem cell transplantation were prospectively analyzed. CECs were determined in peripheral blood samples at predefined time points: before conditioning, after conditioning, on day +7, at engraftment, on day +28, and at the onset of GVHD. All patients provided written informed consent. CECs were identified and quantified by flow cytometry. Changes in CECs over time were quantified using fold change (FC), defined as the ratio between CEC values measured at hematopoietic regeneration and day 0. FC values were summarized as medians with interquartile ranges (IQR). Comparisons between patients with SR-aGVHD and those without SR-aGVHD were performed using the Mann–Whitney U test (two-sided).

Results: 54 patients were included in the analysis; 19 (35%) were female, and the median age was 55 years. The median duration of follow-up was 9.7 months (interquartile range, 6.5–13.1 months). Twelve patients developed SR-aGVHD. Baseline characteristics were well balanced between patients with SR-aGVHD and those without, with no significant differences in disease-related variables, donor type, conditioning strategy, or the incidence of engraftment syndrome.
Median baseline CEC levels before conditioning were comparable between patients who later

developed SR-aGVHD (33.5/ml) and those who did not (29/ml). At day 0, median CEC counts were lower in patients with SR-aGVHD (37/ml) compared with patients without SR-aGVHD (68/ml).
At engraftment, patients with SR-aGVHD exhibited higher median CEC levels (167/ml vs. 127/ml) and a markedly greater relative increase from day 0 (4.5-fold vs. 1.8-fold). Following engraftment, patients without SR-aGVHD demonstrated a progressive decline in CECs, whereas patients with SR-aGVHD showed a continued rise. Although absolute CEC values were influenced by previous therapies, conditioning intensity, infectious complications, the dynamic increase at engraftment emerged as a distinctive feature of SR-aGVHD. Median fold change was higher in patients with SR-aGVHD compared with those without SR GVHD (SR: 2.85 [IQR 1.1–9.0], n=12; non-SR: 1.0 [IQR 0.5–2.0], n=42; Mann–Whitney U test, two-sided p≈0.01.

Conclusions: Our findings demonstrate that a pronounced rise in circulating endothelial cells at engraftment represents a robust biological hallmark of SR-aGVHD. This dynamic biomarker may allow preemptive identification of patients at risk for SR-aGVHD. Endothelial injury occurring before and after transplantation likely contributes to an endothelial-driven GVHD phenotype, supporting the need for refined disease classification and therapeutic strategies.

POST-TRANSPLANT CYCLOPHOSPHAMIDE DOSE REDUCTION WITHIN AN ENTIRELY CALCINEURIN AND MTOR INHIBITOR-FREE GVHD PROPHYLAXIS REGIMEN: INTERIM RESULTS OF THE ABC PHASE I-IIB TRIAL

A Samer Al-Homsi[1,2], *Stephanie Boisclair*[1,2], *Kelli Cole*[2], *Omar Marzouk*[2], *Angie Fleury*[2], *Farzaneh Mashayekhi*[2], *Mariam Daghestani*[2], *Saud Khalaf*[2], *Ruthee Bayer*[1,2], *Maher Abdul-Hay*[3], *Verona Abdelmeseh*[2], *Jaime Andres Suarez-Londono*[1,2]
[1]*Donald and Barbara Zucker School of Medicine at Hofstra University, Hempstead, United States of America (the),* [2]*Northwell Cancer Institute, New Hyde Park, United States of America (the),* [3]*NYU Langone Health and Grossman School of Medicine, New York, United States of America (the)*

Background: Optimal graft-versus-host disease (GvHD) prevention following allogeneic hematopoietic stem cell transplantation (AHSCT) should be effective, well tolerated, and of limited duration to allow timely immune reconstitution and, when appropriate, early introduction of maintenance therapy. As such, we evaluated a calcineurin- and mTOR inhibitor-free platform combining post-transplant cyclophosphamide (PTCy), bortezomib and abatacept. We herein report the interim results of the ABC phase I-II clinical trial.

Methods: Patients undergoing peripheral blood AHSCT for hematological malignancy were enrolled into 2 cohorts: matched (related or unrelated) and mismatched (7 out of 8) donor

transplants. Conditioning regimens consisted of fludarabine and busulfan (2 days) or fludarabine, busulfan (3 days) and thiotepa. rATG, 5mg/Kg total dose, split over days -4 to -2, was added in unrelated donor recipients. GvHD prophylaxis included PTCy (50mg/Kg, days +3 and +4), bortezomib (1.3mg/m², days 0 and +3) and abatacept 10mg/Kg. During phase I, abatacept was escalated in standard 3+3 design: 1 dose on day +5, 2 doses on days +5 and +14, and 3 doses on days +5, +14 and +28. No dose limiting toxicity occurred and the three-dose regimen was adopted for phase II. After the first 25 patients, the protocol was amended, decreasing PTCy to 37.5mg/Kg/dose. Survival outcomes were estimated by Kaplan–Meier analysis. Estimated cumulative incidence (ECI) was calculated using Gray's competing risk model.

Results: 58 patients have been enrolled with median follow-up of 13.2 months. Patient characteristics are summarized in Table 1. Median time to ANC and platelet engraftment was significantly shorter with reduced-dose PTCy compared with full-dose (15 vs 17 days, p=0.003 and 22 vs 25.5 days, p=0.04, respectively). Two patients have not achieved platelet engraftment. No primary or secondary graft failure occurred. Four patients, all receiving full-dose PTCy, experienced poor graft function; three requiring CD34+ boost. There were no differences in CD3+, CD4+, CD8+ or CD19+ cell recovery between the two PTCy groups (Figure 1a). Natural killer (NK) cell recovery was comparable at days +30 and +100. However, by day +180, NK cell count was higher for patients with full-dose PTCy (p=0.006). The incidence of *CMV, EBV and adenovirus reactivation requiring intervention were 31%, 17.2% and 3%, respectively.* Day +180 ECI of grade II-IV acute GvHD was 4% (0.26-17.3) and 12.8% (0.0392–0.2715), p=0.49) in full-dose and reduced PTCy groups, respectively. No grade III or IV events occurred. Additionally, the 1-year ECI of moderate and severe GvHD were 12% (2.9–28.1%) and 7.6% (1.3-22%) in full and reduced-dose groups, respectively, p=0.75. The ECI of relapse and treatment related mortality at 1-year were 18.6% (8.9-31.1%) and 4.1% (0.7-12.7%), respectively. At 1-year, estimated overall survival, progression-free survival and GvHD and relapse free survival were 89.3% (77.5-95%), 77.3% (61.5-86.5%) and 69.3% (53.4-80.1%).

Figure 1. Immune Reconstitution by PTCy Dose and Survival Outcomes

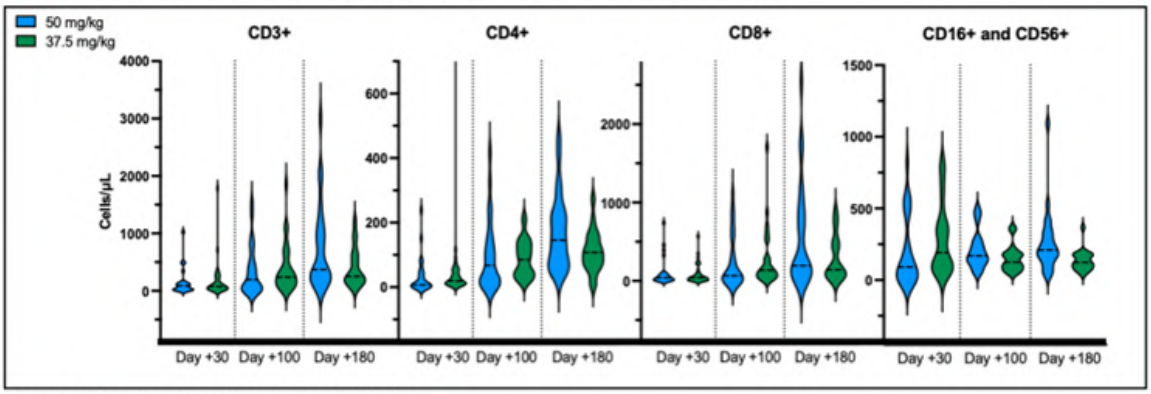

Figure 1a. Immune Reconstitution by PTCy Dose

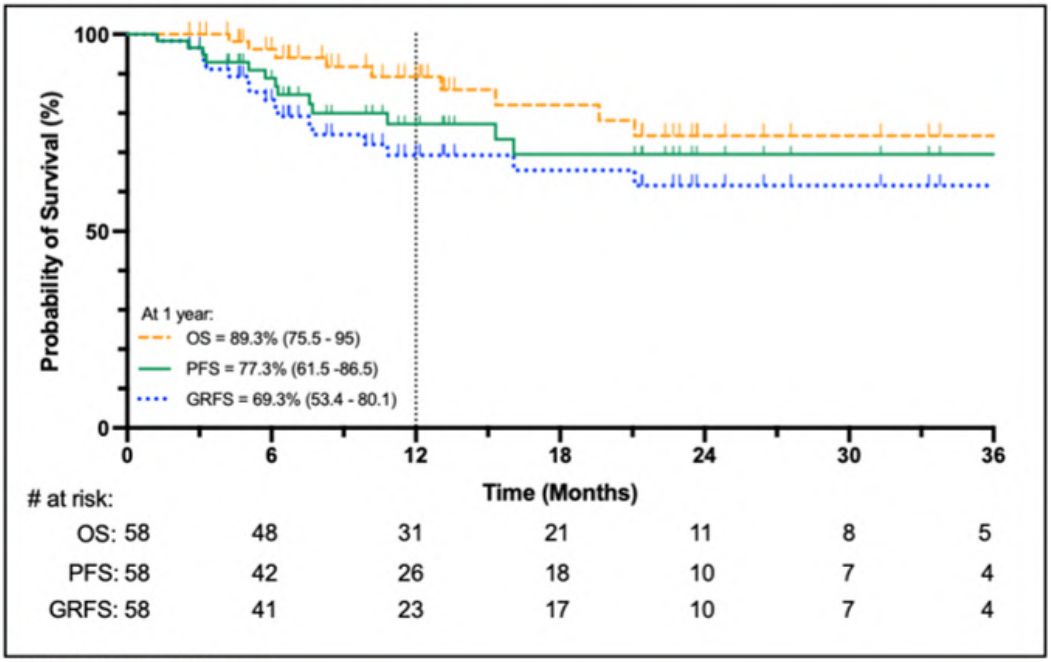

Figure 1b. Survival Outcomes

Conclusions: ABC is an effective, non-toxic and short-duration GvHD prevention that is entirely calcineurin- and mTOR inhibitor–free. Reducing the dose of PTCy resulted in faster engraftment without negatively affecting the incidence of acute or chronic GvHD. This did not translate into enhanced recovery of CD3+, CD4+, CD8+ and CD19+ lymphocyte subsets.

Clinical Trial Registry: NCT06681922

PREDICTIVE, TARGETABLE, SCALABLE: SIGNALING LYMPHOCYTE ACTIVATION MOLECULE FAMILY 7 (SLAMF7) IS DIFFERENTIALLY EXPRESSED AT SITES OF ACUTE GRAFT-VERSUS-HOST DISEASE AND CONFERS A FAVORABLE CLINICAL OUTCOME

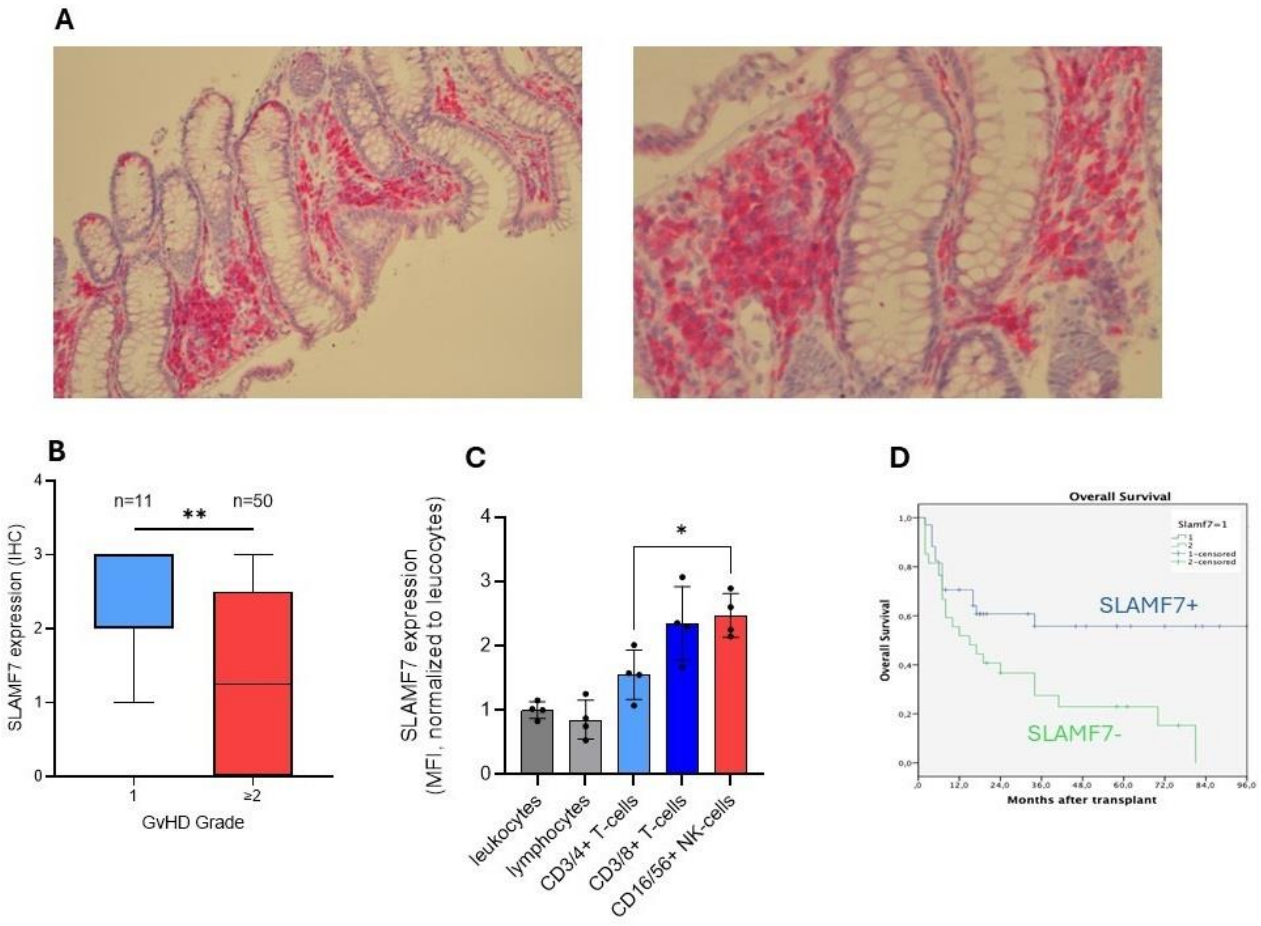
Simon Weisemann[1], *Viktoria Sophia Margarete Helena Mayer*[1,2], *Mathis Samuel Bittermann*[1], *Anju Singh*[1], *Yana Shikova*[1], *Susanne Harth*[1], *Sarah Loebel*[1], *Julia Meyne*[1], *Eva Karbaum*[1], *Anna Maxine Müller-de Ahna*[1], *Stefan Behrens*[1], *Ole Lindner*[1], *Verena Wörner*[1], *Maria Ziehm*[1], *Mathis Wehming*[1], *Natalie Lipinski*[1], *Jörg Mielke*[1], *Matthias Vierbuchen*[1], *Ahmet Elmaagacli*[1]
[1]*Asklepios Clinic St. Georg, Hamburg, Germany,* [2]*Asklepios Medical School, Semmelweis University, Hamburg, Germany*

Background: Graft-versus-host disease (GvHD) is a major barrier for therapeutic success after allogeneic hematopoietic stem cell transplantation (allo-HCT). The identification of potentially actionable targets and biomarkers to predict outcomes and provide personalized treatments for GvHD is still an unmet need. SLAMF7 belongs to a group of heterophilic cell surface receptors expressed in a wide range of immune cells, including B-, T-, NK- cells as well as monocytes and macrophages (Zhang, Z., et al., 2025). Here, to our knowledge for the first time, we investigate the role of SLAMF7 in acute GvHD (aGvHD).

Methods: We consecutively analyzed 61 HCT recipients with aGvHD transplanted at our institution between 2014 and 2024. SLAMF7 was stained using immunohistochemistry (IHC) on histological specimens from the most easily accessible aGvHD-involved organ and expression levels were graded by an expert pathologist on a scale from 0 (no expression) to 3 (ubiquitous expression). We further defined a SLAMF7-negative (expression score 0-1) as well as a SLAMF7-positive (expression score 2-3) subgroup and compared these subgroups with respect to histologic aGvHD grade, overall survival and potentially confounding variables. SLAMF7 expression was also measured in the peripheral blood cells using a flow-cytometry based assay. Therefore, peripheral blood mononuclear cells were stained for CD45, CD3, CD4, CD8, CD16, CD56 and SLAMF7 to determine differences in SLAMF7-expression among lymphocyte subsets.

Results: Of 61 patients, 34 patients were classified as having SLAMF7-positive and 27 as having SLAMF7-negative aGvHD using the above described IHC-based grading approach (figure 1A). Median recipient and donor age were well balanced between the two groups. There was a numerically predominance of male patients in both cohorts, but without statistically significant differences. No significant differences were observed with regard to the underlying hematologic disease, conditioning regimens, GvHD-prophylaxis, CMV-serostatus or donor-selection.
Comparing SLAMF7-expression with the respective GvHD grade revealed an inverse correlation, with lower SLAMF7-expression in histologically higher-grade GvHD. SLAMF7-expression in Lerner-grade I GvHD was significantly higher than in Lerner-grade II-IV (figure

1B). Flow-cytometry based analysis of peripheral blood samples from patients with SLAMF7-positive aGvHD revealed cytotoxic T- and NK-cells as main reservoir for SLAMF-7 expression (figure 1C). Caplan-Meyer analysis demonstrates a significant better 5-year overall survival of the SLAMF7 positive cohort (55,7 %± 9,2% compared to 22,9% ± 8,6% in patients with GVHD without SLAMF7 expression (p<0,014). Intriguingly, SLAMF7 negativity conferred a detrimental prognostic impact with a median overall survival of only 18 months and no long-term survivors (figure 1D).



Conclusions: SLAMF7 is expressed on inflammatory cells in a significant subset of patients with aGvHD. High SLAMF7 expression might limit tissue destruction as evidenced by a significant lower histological aGvHD grade in this subgroup. Expression of SLAMF7 might be considered as a new and independent prognostic factor and potential therapeutic target in patients with aGvHD.

OS16-01

BELUMOSUDIL FOR CHRONIC GRAFT-VERSUS-HOST DISEASE IN CHILDREN UNDER 12: A RETROSPECTIVE ANALYSIS OF EFFECTIVENESS AND SAFETY

*Jingtao Chen[1], **Jianyun Liao**[1], Jujian He[1], Weiwei Zhang[1], Wenqian Shi[1], Fang Wang[1], Yuqian Xia[1], Chunfu Li[1]*
[1]Nanfang-Chunfu Children's Institute of Hematology & Oncology, TaiXin Hospital Dongguan, Guangdong Province, Dongguan City, China

Background: Chronic graft-versus-host disease (cGVHD) in children occurs in 30% to 70% of cases after allogeneic hematopoietic stem cell transplantation (allo-HSCT), often involving multiple organs, leading to growth disorders and decreased quality of life. The traditional treatment regimen mainly consists of steroids combined with calcineurin inhibitors (CNIs), but about 50% of patients respond poorly, and long-term side effects are significant. Belumosudil, the first selective ROCK2 inhibitor, was approved by the FDA in 2021 for patients aged ≥12 years, but data for patients under 12 years old are scarce.

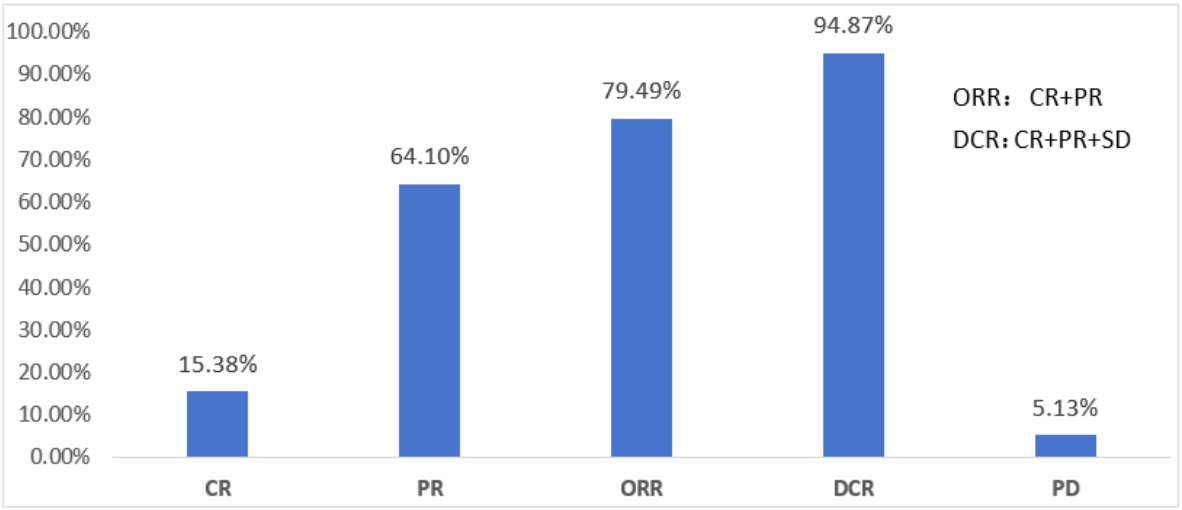
Methods: This study adopted a single-center retrospective observational design, including 39 children aged ≤12 years with cGVHD diagnosed according to the 2014 National Institutes of Health (NIH) consensus criteria and who had failed at least one line of systemic treatment. All children received Belumosudil Mesylate for at least 4 weeks, with the dose adjusted according to body weight (<30kg children received 100mg once daily, ≥30kg children received 200mg once daily). Immunosuppressive agents used in combination were tapered gradually after the onset of effect of Belumosudil.

Results:

Feature	**Data**
Total number of cases	39 cases
Median age	8 years (range: 3–12 years)
Gender ratio	Male: 28 cases (71.8%), Female: 11 cases (28.2%)
Primary disease	Thalassemia: 34 cases (87.2%), Aplastic anemia: 4 cases (10.3%), Pyruvate kinase deficiency: 1 case (2.6%)
Type of transplantation	Haploidentical: 29 cases (74.3%), Unrelated fully matched: 8 cases (20.5%), Sibling fully matched: 2 cases (5.1%)
Median time from transplantation to cGVHD diagnosis	12 months (range: 3–24 months)

Median number of organs involved	2 organs
Proportion of organ involvement	Skin (69.2%), Eye (46.2%), Liver (33.3%), Lung (33.3%), Oral cavity (30.8%), Nail (25.6%), Gastrointestinal tract (15.4%), Joint/fascia (12.8%)
Multorgan involvement (≥2 organs)	28 cases (71.8%)
Previous treatment failure	All patients had previously received at least one immunosuppressive agent (such as steroids, FK506, ruxolitinib, sirolimus, etc.) and failed or had poor response before using Belumosudil

Fig 1 Response Rates



1. Disease Patterns : Skin involvement (69.2%) was the most common, followed by pulmonary (33.3%), ocular (46.2%), and hepatic (33.3%) manifestations. 71.8% of patients had multi-organ involvement (≥2 organs).

2. Therapeutic Efficacy :

12. The overall response rate (ORR) was 79.5% (31/39) at 12 weeks and 84.6% (33/39) at 6 months. Organ-specific responses were heterogeneous:
13. Skin/Nail manifestations showed the highest response (80.0% at 12 weeks, improving to 85.7% by 6 months).
14. Pulmonary symptoms exhibited progressive improvement (from 60.0% to 80.0%).
15. Ocular and hepatic involvement had delayed responses (from 40.0% to 60.0% for ocular; from 33.3% to 50.0% for hepatic).

16. Notably, hepatic and articular responses required over 6 months for partial remission, underscoring the need for extended treatment patience.

3. Critical Modulators of Response : Early initiation of belumosudil (≤3 months post-cGVHD onset) achieved 90.0% efficacy versus 50.0% with delayed treatment (>3 months). The response rate of early intervention for lung symptoms was 100%, while only 20.0% of patients with delayed treatment responded.
4. Treatment Resistance : Four failures occurred in patients with advanced pulmonary disease (2 cases, 1 fatal), multi-organ involvement with late intervention (>12 months), or severe hepatic dysfunction (AST >200 U/L).
5. Mechanistic Implications : The rapid response in skin and lung symptoms may suggest an antifibrotic effect potentially associated with Th17-related pathways, while delayed hepatic remission could reflect slower pathological processes.

Conclusions: Belumosudil is a highly effective and safe therapeutic agent for children under 12 with difficult-to-treat cGVHD. It exhibits strong anti-fibrotic activity, leading to high response rates in the skin, joints, and other fibrotic tissues. Our findings strongly suggest that early intervention is a key determinant of success, especially for visceral cGVHD of the liver and lungs. Belumosudil represents a pivotal advancement and should be considered a preferred second-line option for this vulnerable patient population.

OS16-02

EFFICACY AND SAFETY OF AXATILIMAB IN JAPANESE PATIENTS WITH RECURRENT OR REFRACTORY CHRONIC GRAFT-VERSUS-HOST DISEASE AFTER AT LEAST 2 PRIOR LINES OF SYSTEMIC THERAPY

Yoshihiro Inamoto[1], *Noriko Doki*[2], *Tatsuo Ichinohe*[3], *Yoshiaki Ogawa*[4], *Shigeo Fuji*[5], *Koji Kato*[6], *Tatsunori Goto*[7], *Tadakazu Kondo*[8], *Toshiro Kawakita*[9], *Koichi Onodera*[10], *Koji Suzuki*[11], *Daisuke Tomizawa*[12], *Katsuyoshi Koh*[13], *Shintaro Ono*[14], *Kenzo Kinami*[14], *Naiyuan Zhang*[15], *Hideaki Fujiwara*[16]
[1]*Fujita Health University, Toyoake, Japan,* [2]*Tokyo Metropolitan Komagome Hospital, Tokyo, Japan,* [3]*Hiroshima University, Hiroshima, Japan,* [4]*Tokai University, Tokyo, Japan,* [5]*Osaka International Cancer Institute, Osaka, Japan,* [6]*Kyushu University, Fukuoka, Japan,* [7]*Japanese Red Cross Aichi Medical Center Nagoya Daiichi Hospital, Nagoya, Japan,* [8]*Kobe City Medical Center General Hospital, Kobe, Japan,* [9]*National Hospital Organization Kumamoto Medical Center, Kumamoto, Japan,* [10]*Tohoku University, Sendai, Japan,* [11]*University of Fukui, Fukui, Japan,* [12]*National Center for Child Health and Development, Tokyo, Japan,* [13]*Saitama Prefectural Children's Medical Center, Saitama, Japan,* [14]*Incyte Biosciences Japan GK, Tokyo, Japan,* [15]*Incyte Corporation, Wilmington, DE, United States of America (the),* [16]*Okayama University Hospital, Okayama, Japan*

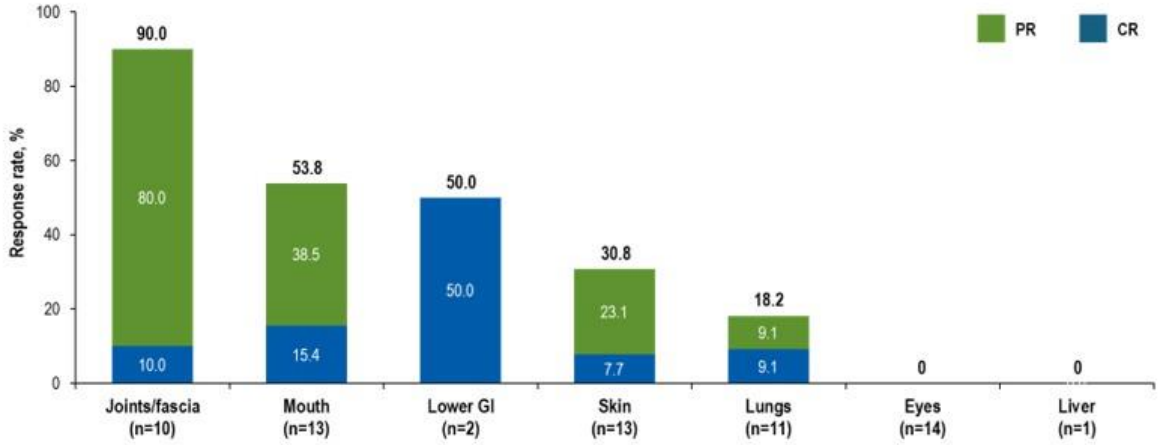
Background: Chronic graft-versus-host disease (cGVHD) is a major cause of morbidity and nonrelapse mortality among patients who undergo allogeneic hematopoietic stem cell

transplantation. Colony-stimulating factor 1 receptor (CSF-1R)–dependent monocytes and macrophages potentiate inflammation and fibrosis, contributing to multiorgan damage. Axatilimab is a high-affinity monoclonal antibody targeting CSF-1R. In the pivotal phase 2 AGAVE-201 study (NCT04710576), axatilimab 0.3 mg/kg every 2 weeks (Q2W) demonstrated clinical benefit and was generally well tolerated in patients with cGVHD. This analysis describes the results of a phase 3 study (NCT06263478) evaluating the efficacy and safety of axatilimab in Japanese patients with recurrent or refractory cGVHD.

Methods: In this phase 3, open-label, multicenter study, Japanese patients aged ≥6 years with recurrent or refractory cGVHD after ≥2 prior lines of therapy received intravenous axatilimab 0.3 mg/kg Q2W for ≤24 months. The primary endpoint was overall response rate (ORR) in the first 6 treatment cycles per the National Institutes of Health 2014 Consensus Criteria. Secondary endpoints included organ-specific responses, percent reduction in average daily dose of corticosteroids, symptom improvement (defined as a ≥7-point reduction in the modified Lee Symptom Scale [mLSS]), and safety and tolerability.

Results: Among the 21 patients enrolled, median (range) age and weight were 53.0 (7–63) years and 50.4 (19.0–75.5) kg, respectively; 61.9% of patients were male. Median (range) time from cGVHD diagnosis to Cycle 1 Day 1 was 33.0 (5.6–128.6) months. Patients received a median of 3 prior lines of therapy (range, 2–6); 19 (90.5%) were refractory to their last cGVHD therapy. Patients had a median (range) of 3.0 (1–5) involved organs at baseline, and 71.4% of patients had severe cGVHD at study entry. ORR (95% CI) in the first 6 cycles was 71.4% (47.8%–88.7%; all partial responses); at the analysis cutoff, no patients with a response had progressive disease, and all patients with a response were still on treatment. Median (range) time to first response was 1.9 (1.0–5.6) months. Among 20 patients with baseline mLSS assessments, 10 (50.0%) reported a ≥7-point improvement in their symptoms on study. Organ-specific responses in the first 6 cycles are reported in the Figure. Among 20 patients receiving corticosteroids at baseline, mean (SD) average daily dose was 21.4 (13.9) mg/d. Among the 18 patients receiving axatilimab and systemic corticosteroids up to Day 168, 11 patients (61.1%) reduced their average daily corticosteroid dose from baseline, and 1 patient (5.0%) tapered off corticosteroids by Day 140. Twenty patients (95.2%) experienced treatment-emergent adverse events (TEAEs); 8 (38.1%) had grade ≥3 TEAEs. Six patients (28.6%) had treatment-related TEAEs; all treatment-related TEAEs were grade 1/2 and not serious. No TEAEs led to dose reduction or treatment discontinuation. TEAEs of any grade occurring in >15% of patients were nasopharyngitis (n=7, 33.3%); influenza (n=5, 23.8%); and diarrhea, headache, peripheral edema, and pruritus (n=4 each, 19.0%).

Figure. Organ-Specific Responses* in the First 6 Cycles per 2014 NIH Consensus Criteria



CR, complete response; GI, gastrointestinal; NIH, National Institutes of Health; ORR, overall response rate; PR, partial response.
Denominators include patients with organ involvement in the first 6 treatment cycles. Differences in percentage totals are due to rounding.
* No patients had esophageal or upper GI involvement.

Conclusions: Axatilimab 0.3 mg/kg Q2W demonstrated clinical benefit and was well tolerated in Japanese patients with recurrent or refractory cGVHD.

IMPACT OF GRAFT-VERSUS-HOST DISEASE ON THE MAIN OUTCOMES FOLLOWING ALLOGENIC HEMATOPOIETIC STEM CELL TRANSPLANTATION BASED ON EX-VIVO ALPHA BETTA T CELL DEPLETION

Larisa Shelikhova[1], Maria Ilushina[1], Olga Molostova[1], Daria Shasheleva[1], Rimma Khismatullina[1], Sergey Blagov[1], Anna Bogoyavlenskaya[1], Maria Klimentova[1], Dmitriy Balashov[1], Yuliya Skvortsova[1], Elvira Sultanova[1], Svetlana Kozlovskaya[1], Irina Shipitsina[1], Elena Kurnikova[1], Alexei Maschan[1], ***Michael Maschan***[1]
[1]*Dmitry Rogachev Federal Research Centre of Pediatric Hematology, Oncology and Immunology, Moscow, Russian Federation (the)*

Background: Acute and chronic graft-versus-host disease (GVHD) directly or indirectly accounts for up to 40% of mortality after hematopoietic stem cell transplantation (HSCT) in hematological malignancies. One of the most promising methods for processing hematopoietic cell transplants to reduce the risk of GVHD is the depletion of TCRαβ T-lymphocytes. However, the impact of clinically significant GVHD on the main HSCT outcomes when TCRαβ depletion is used is not fully studied. To this end, we analyzed the impact of GVHD on overall and event-free survival, relapse risk, and transplant-related mortality in HSCT from unrelated and haploidentical donors using TCRαβ depletion as the primary GVHD prevention strategy.

Methods: The analysis included 438 patients (median age 8,7y) with ALL, n=236 and AML, n=202, who received their first allogeneic HSCT from an unrelated or haploidentical donor using TCRαβ depletion as the primary method for GVHD prevention from May 2012 to February 2022. The main characteristics of the group are presented in Table 1.
The median follow-up was 4.5 years (0.5 – 10). Landmark analysis (LA) was used to study the impact of GVHD on HSCT outcomes. The analysis included patients who survived to a specific point in time without significant events (relapse, transplant-associated death). For acute GVHD, the reference point was day +35, and for chronic GVHD, it was day +100. On day +35 - 414 patients were alive and leukemia-free, on day +100 336 patients were alive and leukemia-free.

Table 1 Clinical Characteristics of Patients

Remission status	CR1	181	41%
	>CR1	191	44%
	AD (all AML)	66	15%
Conditioning regimen	TBI	156	36%
	Treo	282	64%

Donor type	MUD	79	18%
	Haplo	359	82%
Serotherapy	ATG (+)	157	36%
	ATG (-)	281	64%

Results: Primary engraftment was achieved in 98% of patients with median time to engraftment of 13 days for neutrophils and 14 days for platelets. The CI of NRM was 8 % (95%CI:5-10), of relapse 34% (95%CI:29-39).EFS and OS were 57% (95% CI, 51 - 61) and 67% (95% CI, 60 - 71) respectively.
The CI of aGvHD grade I-IV was 49% (95% CI, 44 - 53), II-IV was 21% (95% CI, 17- 23), grade 3-4 was 6% (95% CI, 4 - 8) and chronic GvHD – 15% (95% CI: 12-19).
In the LA, the development of aGVHD stage 2-4 and stage 3-4 significantly increase the risk of transplant-related mortality 18% vs 3% and 35% vs 4% , p< 0,0001 with no significant effect on the relapse rate and event-free survival. The presence of grade 2–4 and 3–4 aGVHD were associated with lower overall survival (OS 70% vs 59%, p=0.04 and 69% vs 53%, p=0.03).
Patients with CGVHD had a significantly low relapse rate 7% vs 33% with p=<0.0001 and high rate of NRM 16% (p=0,006). EFS was higher in CGVHD group 82% vs 63% with p=0,003 without effect on OS 83% vs 75%, p=0,145.

Conclusions: HSCT performed using TCRαβ depletion reduces the risks of developing acute and chronic GVHD and transplant-related mortality.
However, despite the relatively low frequency, aGVHD stage 2-4 and stage 3-4 significantly increases transplant-related mortality and reduces overall survival. cGVHD affects the risk of transplant-related mortality, but reduces the risk of relapse, with no significant effect on overall survival.

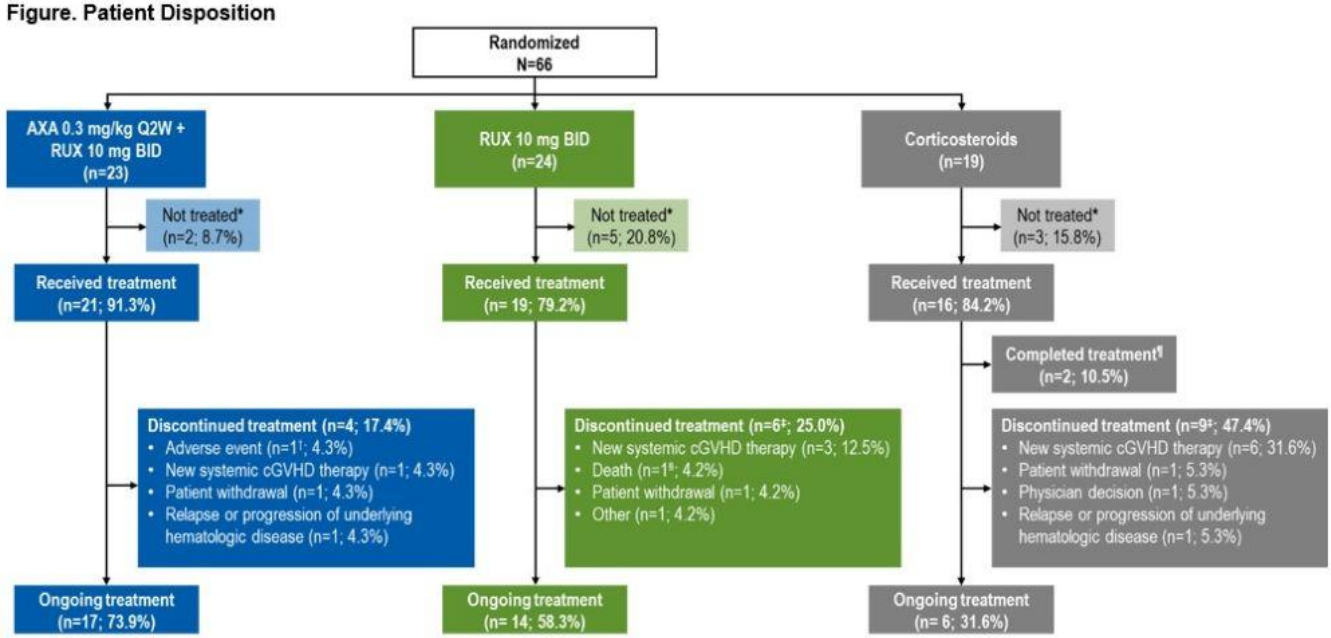
of America (the), [8]General University Hospital Gregorio Marañón, Institute of Health Research, Madrid, Spain, [9]Universidad Complutense de Madrid, Madrid, Spain, [10]Universidad de Salamanca, Salamanca, Spain, [11]AZ Sint-Jan Brugge, Brugge, Belgium, [12]Ghent University, Ghent, Belgium, [13]Incyte Corporation, Wilmington, DE, United States of America (the), [14]University of Pittsburgh, Pittsburgh, PA, United States of America (the)

Background: Chronic graft-versus-host disease (cGVHD) is a leading cause of morbidity and nonrelapse mortality following allogeneic hematopoietic stem cell transplantation. Axatilimab (AXA), a monoclonal antibody targeting colony-stimulating factor 1 receptor (CSF-1R), depletes the monocytes and macrophages that mediate fibrosis and end-organ damage in cGVHD. Ruxolitinib (RUX) is a selective inhibitor of Janus kinase (JAK)1/JAK2, which mediate cytokine signaling, T-cell activation, and inflammation in cGVHD. Both AXA and RUX have demonstrated clinically meaningful efficacy and were generally well tolerated as single agents in previously treated cGVHD. Owing to their distinct mechanisms of action, combining AXA and RUX may improve efficacy without overlapping safety concerns. The objective of this analysis is to report on the safety of AXA and RUX combined and of RUX alone among patients with newly diagnosed cGVHD.

Methods: In this ongoing, randomized, open-label, phase 2 study (NCT06388564), eligible patients were aged ≥12 years with new onset, moderate or severe cGVHD with no prior systemic cGVHD treatment. Patients were randomized to AXA 0.3 mg/kg every 2 weeks in combination with RUX 10 mg twice daily (BID; AXA+RUX), RUX 10 mg BID, or corticosteroids for up to 24 months; randomization was stratified by cGVHD severity and use of concomitant systemic immunosuppressants. The primary endpoint is overall response at 6 months in the absence of a new systemic cGVHD therapy. Safety assessments include treatment-emergent adverse events (TEAEs). A prespecified interim safety analysis occurred after ~30 patients received ≥1 cycle of treatment.

Results: As of the data cutoff (October 3, 2025), 66 patients were enrolled (AXA+RUX, n=23; RUX, n=24; corticosteroids, n=19), and 56 patients received treatment (AXA+RUX, n=21; RUX, n=19; corticosteroids, n=16; **Figure**). The median age of enrolled patients was 65.0 years (range, 16–77), and 35 patients (53.0%) were male. The median time from transplant to diagnosis of cGVHD was 7.6 months (range, 1.7–72.3), and 31 patients (47.0%) had severe cGVHD at enrollment per the National Institutes of Health consensus criteria. Commonly involved organs included the mouth (71.2%), eyes (65.2%), and skin (62.1%). Nineteen patients discontinued treatment (AXA+RUX, n=4; RUX, n=6; corticosteroids, n=9); 1 patient in the AXA+RUX group discontinued owing to concurrent TEAEs of fatigue and anxiety. Among all treated patients, 44 experienced TEAEs (AXA+RUX, n=15 [75.0%]; RUX, n=16 [84.2%]; corticosteroids, n=13 [81.3%]), and 11 experienced grade ≥3 TEAEs (AXA+RUX, n=5 [25.0%]; RUX, n=3 [15.8%]; corticosteroids, n=3 [18.8%]). TEAEs of any grade occurring in >2 patients in a group were anemia (n=4, 20.0%) in the AXA+RUX group; anemia, increased aspartate aminotransferase (both n=4, 21.1%), decreased platelet count, diarrhea, fatigue, increased amylase, increased alanine aminotransferase, peripheral edema, pyrexia, and upper respiratory tract infection (each n=3, 15.8%) in the RUX group; and insomnia (n=4, 25.0%) and constipation (n=3, 18.8%) in the corticosteroid group. Anemia was the only grade ≥3 TEAE that occurred in 2 patients (n=1 each in AXA+RUX and RUX).

Figure. Patient Disposition



AXA, axatilimab; BID, twice daily; cGVHD, chronic graft-versus-host disease; Q2W, every 2 weeks; RUX, ruxolitinib.
* The majority of the 10 untreated patients were randomized before the data cutoff date and therefore have no dosing information reported yet.
† Treatment-emergent adverse events leading to treatment discontinuation in 1 patient were concurrent fatigue and anxiety.
‡ For ruxolitinib 10 mg BID and corticosteroids, 1 patient in each group discontinued treatment prior to receiving the first dose.
§ Death due to bronchospastic crisis and considered unrelated to treatment.
¶ Treatment is considered complete if a patient achieves a complete or partial response and completes the study treatment taper.

Conclusions: In the updated safety analysis of this phase 2 trial, the combination of AXA+RUX was well tolerated and had a similar safety profile to RUX alone, with no evidence of additive toxicity.

Background: Chronic GvHD (cGvHD) is the most significant risk factor for late morbidity and mortality after allogeneic stem cell transplantation (alloSCT). There are no standard treatment options beyond firstline corticosteroids and second-line ruxolitinib. The selective ROCK-2 inhibitor belumosudil, a novel FDA-, but not yet EMA-approved agent, has shown efficacy in phase-2 trials and has recently been made available to German and Austrian patients within a managed-access program (MAP). In this study, we analyzed the clinical benefits of belumosudil within the MAP program in the German Austrian cohort.

Methods: This updated retrospective multicenter study will include 143 patients who received belumosudil in the MAP provided by Sanofi-Aventis. Seventeen German and one Austrian transplant center contributed data to this analysis. Patients could enter the MAP

after at least two and a maximum of five prior lines of treatment (LOT) for chronic GvHD, which had to include ruxolitinib if not intolerant. Organ scoring and response assessment were performed according to the NIH-consensus criteria before start, and at month 1, 3, 6 and 12 thereafter. Events defining failure-free survival (FFS) are relapse, death or start of a new immunosuppressive agent. Adverse events are reported according to the CTCAE criteria (version 5.0). The last-follow-up was on July 31th 2025.

Results: In total, 130 patients (60% male) with a median age of 61 years (range, 20 – 77) were included into the analysis by now. Initial cGvHD presentation was quiescent onset in 57%, progressive onset in 15%, and de novo onset in 28% of patients. The cohort had undergone a median of 3 prior LOT (range, 2 – 13). Ninety-three percent of patients were refractory to the previous treatment line. Patients had a history of ruxolitinib and ibrutinib pre-treatment in 95% and 13%, respectively. At belumosudil initiation, 81% of patients presented with severe cGvHD with a median of 3 NIH-defined organ manifestations (range, 1 – 7). Belumosudil was started at a median of 28 months after alloSCT (range, 2 – 243). The objective response at one and three months was partial remission or better in 48 and 61 patients (37% and 53%), respectively. Responses were observed across all organ systems. Median time to response was 3.1 months. At six months, 47 of 80 patients evaluable showed partial remission or better (59%). Belumosudil treatment was discontinued in 21 patients (19%) and a new immunosuppressive medication was commenced in 15 patients (13%) over the complete observation time. Forty-four percent of patients were treated with steroids at belumosudil start. Steroid dose reduction was achieved in 17 of these patients (34%). FFS was 82,7% and 65,3% at six and 12 months. One-year overall survival was 89,9%. Treatment-emergent adverse reactions CTCAE grade III-IV were mostly infectious complications and occurred in 28 patients (22%).

Conclusions: This retrospective analysis of a large real-world cohort demonstrates efficacy and safety of belumosudil in refractory chronic GvHD patients. Updated results on dynamics of organ response and belumosudil combinations of 143 patients will be presented. Further prospective trials are needed to determine the duration of response and the impact on GvHD-related mortality.

OS16-06

A COMPREHENSIVE ANALYSIS OF AXATILIMAB IN PATIENTS WITH CHRONIC GRAFT-VERSUS-HOST DISEASE AND RELATED BRONCHIOLITIS OBLITERANS SYNDROME: INTEGRATED ANALYSIS FROM 2 CLINICAL STUDIES

Zachariah DeFilipp[1], *Carrie L. Kitko*[2], *Iskra Pusic*[3], *Trent P. Wang*[4], *Britnie Thomas*[5], *Zhenyi Xue*[5], *Amandeep Salhotra*[6]
[1]*Hematopoietic Cell Transplant and Cellular Therapy Program, Massachusetts General Hospital, Boston, United States of America (the),* [2]*Vanderbilt University Medical Center, Nashville, United States of America (the),* [3]*Washington University School of Medicine, Saint Louis, United States of America (the),* [4]*Sylvester Comprehensive Cancer Center, University of Miami Miller School of Medicine, Miami, United States of America (the),* [5]*Incyte Corporation, Wilmington, United States of America (the),* [6]*City of Hope National Medical Center, Duarte, United States of America (the)*

Background: Lung manifestations of chronic graft-versus-host-disease (cGVHD), particularly bronchiolitis obliterans syndrome (BOS), are associated with high morbidity/mortality and poor responses to conventional treatment. Axatilimab treatment demonstrated clinical benefit in patients with pulmonary cGVHD in a phase 1/2 study (NCT03604692) and in the pivotal AGAVE-201 study (NCT04710576). The objective of this analysis was to describe clinical outcomes of axatilimab treatment in patients with cGVHD-BOS in 2 clinical studies.

Methods: In the phase 2 dose expansion study, intravenous (IV) axatilimab 1 mg/kg every 2 weeks (Q2W) was assessed. In the pivotal AGAVE-201 study, patients were randomized to IV axatilimab 0.3 mg/kg Q2W, 1 mg/kg Q2W, or 3 mg/kg every 4 weeks (Q4W). Responses were assessed by 2014 National Institutes of Health (NIH) cGVHD consensus criteria, which included forced expiratory volume in 1 second (FEV_1) and lung symptom score. This analysis evaluated lung-specific clinical responses by baseline FEV_1 and lung symptom score, as well as improvement in modified Lee Symptom Scale shortness of breath (SOB) scores among patients with cGVHD-BOS (obstructive lung defect with FEV_1 <75% predicted, FEV_1:vital capacity ratio <0.07, evidence of air trapping, and absence of infection). Logistic regression analysis was performed to investigate factors associated with NIH lung response.

Results: Of 117 patients with cGVHD-BOS at baseline, 84.6% had prior treatment with belumosudil, ibrutinib, and/or ruxolitinib, and the median (range) number of organs involved at baseline was 4 (1–9). The median (range) patient age was 55.0 (7–76) years; 69.2% of patients were male. The NIH lung response rate on study was 38.5%; the median (range) time to first response was 2.6 (1.0–14.8) months. Response rates were 37.1% and 40.5% for patients with baseline FEV_1 >39% and ≤39%, respectively, and were 37.0% and 40.2% for patients with baseline NIH lung scores of 3 and <3, respectively (**Table**). A ≥2-point improvement in SOB at rest or with exercise was observed regardless of NIH response. Based on univariate analysis, there was no significant association between baseline clinical features (eg, lung score, FEV_1, best response to last therapy) and lung response. The most common infections among patients with cGVHD-BOS were pneumonia (n=24; 20.5%), upper respiratory tract infection (n=22; 18.8%), and COVID-19 (n=19; 16.2%), which were grade ≥3 in 17 (14.5%), 2 (1.7%), and 7 (6.0%) patients, respectively.

Table. Efficacy Outcomes by Subgroup*

Outcome	**Axatilimab (n=117)**
NIH lung-specific response by baseline characteristics, n (%) [95% CI]	
Predicted FEV_1 >39% (n=62)†	23 (37.1) [25.2–50.3]
CR, n (%)	11 (17.7)
Predicted FEV_1 ≤39% (n=37)	15 (40.5) [24.8–57.9]
CR, n (%)	1 (2.7)
NIH lung score <3 (n=87)	35 (40.2) [29.9–51.3]
CR, n (%)	17 (19.5)
NIH lung score of 3 (n=27)	10 (37.0) [19.4–57.6]

Table. Efficacy Outcomes by Subgroup*

CR, n (%)	0
≥2-point improvement from baseline in mLSS SOB at rest,‡ n (%)	
NIH responder (n=26)	4 (15.4)
NIH nonresponder (n=37)	7 (18.9)
≥2-point improvement from baseline in mLSS SOB with exercise,‡ n (%)	
NIH responder (n=42)	17 (40.5)
NIH nonresponder (n=66)	15 (22.7)

CR, complete response; FEV_1, forced expiratory volume in 1 second; mLSS, modified Lee Symptom Scale; NIH, National Institutes of Health; PR, partial response; SOB, shortness of breath.
* Best response on study. † Patients with FEV_1 ≥75% at baseline were excluded. ‡ Score range, 0–4; patients with scores of 0 at baseline were excluded.

Conclusions: Axatilimab demonstrated clinical and symptom responses in patients with cGVHD-BOS across a spectrum of lung involvement, including those with FEV_1 ≤39% and NIH lung scores of 3. Symptom responses were observed in some patients who were NIH nonresponders. There were no statistically significant differences in NIH lung response among patients with different baseline characteristics, suggesting that a broad range of patients with BOS may respond to axatilimab.

CHRONIC GRAFT-VERSUS-HOST DISEASE: REAL-WORLD OUTCOMES AND EFFICACY OF RUXOLITINIB COMPARED WITH CONVENTIONAL TREATMENTS

*Garret Leung[1], Joycelyn Sim[1], **Thomas Chan**[1], Albert Lie[1], Yok-Lam Kwong[1], Harinder Gill[1]*
[1]The University of Hong Kong, Hong Kong, China

Background: Chronic graft-versus-host disease (cGVHD) remains a major challenge in allogeneic hematopoietic stem cell transplantation (HSCT), affecting 30–50% of recipients and leading to significant morbidity through multi-organ involvement. Approximately 50% of patients develop steroid-refractory disease requiring second-line treatment, but no standard therapy existed until the advent of ruxolitinib, a Janus kinase (JAK) inhibitor. While ruxolitinib demonstrated superior efficacy in the phase 3 REACH3 trial, real-world data comparing its effectiveness with conventional therapies in routine clinical practice settings remain limited.

Methods: We performed a single-centre retrospective analysis of 1,026 adult allogeneic HSCT recipients transplanted between January 2014 and December 2023. Among 374 patients who developed cGVHD requiring systemic treatment, 229 required second-line therapy. Response was assessed using National Institutes of Health criteria. To evaluate the real-world efficacy of ruxolitinib and account for baseline differences between treatment groups, we conducted a propensity score-matched (PSM) analysis comparing ruxolitinib with conventional second-line agents. Covariates matched included donor age, disease-risk index, graft source, conditioning intensity, GVHD prophylaxis, cGVHD severity, and prior glucocorticoid use in first-line therapy.

Results: Among 229 cGVHD patients requiring second-line treatment, 125 (55%) received ruxolitinib and 104 (45%) received conventional agents, primarily thalidomide (54%) and sirolimus (14%). For the whole cohort, severe cGVHD was associated with significantly inferior ORR (odds ratio, OR: 0.13; 95% confidence interval, CI: 0.05–0.30; P<0.001), while ruxolitinib treatment was associated with significantly superior ORR (OR: 4.09; 95% CI 2.26–7.52; P<0.001) (Figure 1A).
In the balanced PSM cohort, 66 patients were included in each of the conventional and ruxolitinib group (Table 1). Ruxolitinib, compared with conventional treatment, led to significantly higher ORR (68% versus 39%, P<0.001), superior failure-free survival (hazard ratio, HR: 0.37; 95% CI: 0.22–0.61; P<0.001) (Figure 1C), higher probability of achieving immunosuppression-free remission (HR: 1.81; 95% CI: 1.04–3.16; P=0.036) (Figure 1D), and decreased need of more than three sequential treatment lines (6% versus 20%, P<0.001).
Furthermore, ruxolitinib compared with conventional treatment showed better response in liver (77% versus 47%; P=0.013) and ocular involvement (68% versus 32%; P=0.021). However, however, pulmonary cGVHD remained poorly responsive (ruxolitinib: 22%; conventional: 13%) (Figure 1E). Grade 3 or higher infection rates were comparable and acceptable between ruxolitinib and conventional treatment (24% versus 23%; P=0.84) (Figure 1F). Overall survival was similar in both groups (HR: 0.90; P=0.78).

Table 1. Characteristics of Patients Receiving Second-line Chronic GVHD Treatment.

	Unmatched Cohort					
	Conventional (N=104)	**Ruxolitinib (N=125)**	**SMD**	**P-value**		**Conventi (N=66**
Age – no. (%)						
Recipient above 50 years	47 (45)	64 (51)	0.120	0.37		31 (47
Donor above 40 years	45 (43)	73 (58)	0.306	0.02		28 (42
Sex – no. (%)						
Male recipient	60 (58)	70 (56)	0.034	0.80		37 (56

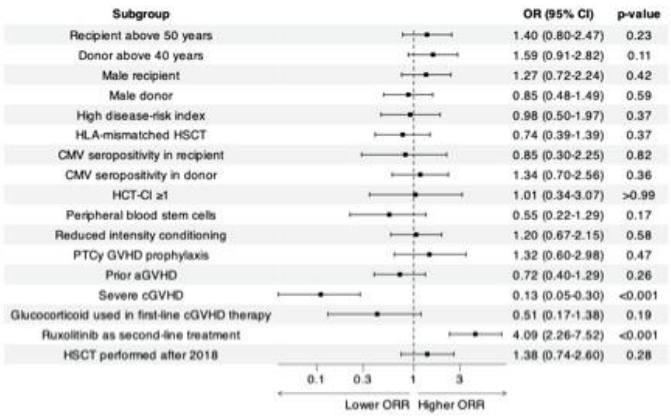
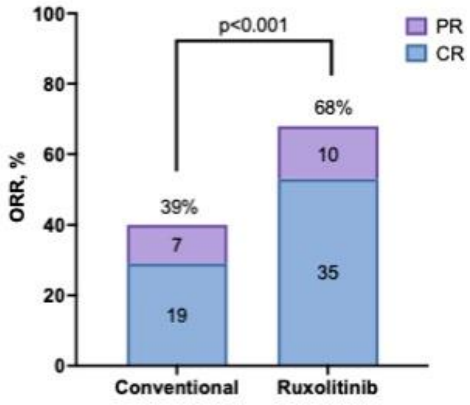
Prior grade II-IV aGVHD	42 (40)	39 (31)	0.192	0.15		27 (41
Severe cGVHD	35 (34)	8 (6)	0.724	<0.001		7 (11)
Glucocorticoid used in first-line therapy	100 (96)	103 (82)	0.456	0.001		62 (94

Figure 1.

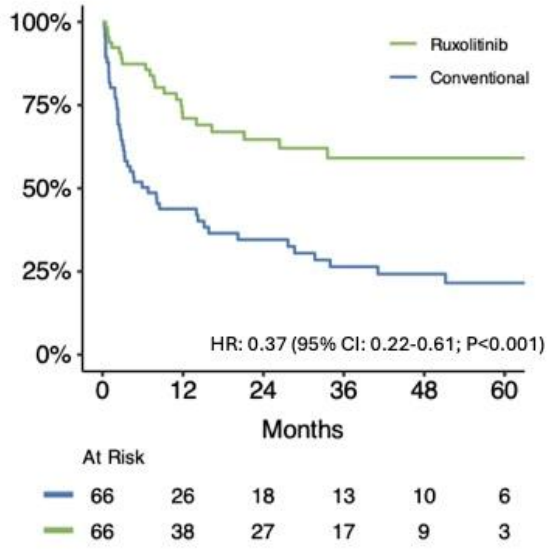
A. Odds Ratios of Overall Response in 2L cGVHD Treatment.



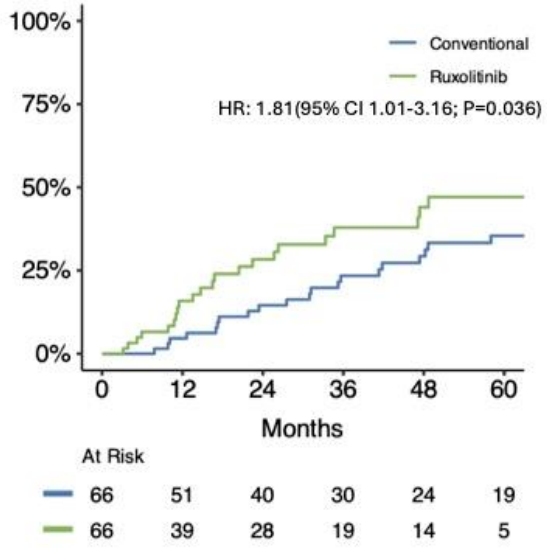
B. Overall Response Rates



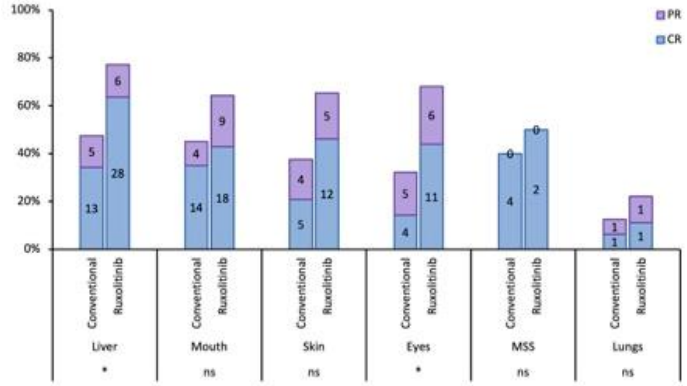
C. Failure-free Survival in PSM Cohorts.



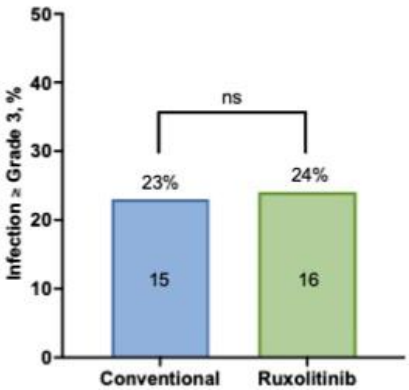
D. Probabilities of IST-free in PSM Cohorts.



E. Organ-specific Responses in PSM Cohorts.



F. Infection Risks in PSM Cohorts.



Conclusions: Our results showed that ruxolitinib was superior to conventional second-line agents for steroid-refractory cGVHD in ORR, failure-free survival, and successful immunosuppression tapering. These findings support ruxolitinib as the preferred second-line treatment for most patients with cGVHD. However, pulmonary GVHD remains an unmet clinical need, representing an important area for future therapeutic development and investigation.

Disclosure: Nothing to declare.

OS16-08

CHGVHD IMMUNE RECONSTITUTION-SCORE: INTEGRATING IMMUNOLOGICAL AND CLINICAL FEATURES TO PREDICT OUTCOMES IN CHRONIC GVHD

Maria Helena Parrinello[1,2], *Elisa Diral*[1], *Alessandro Bruno*[1], *Francesca Mazzocco*[1,2], *Raffaella Milani*[1], *Sarah Marktel*[1], *Raffaella Greco*[1], *Andrea Assanelli*[1], *Francesca Farina*[1], *Simona Piemontese*[1], *Sara Mastaglio*[1], *Lorenzo Lazzari*[1], *Annalisa Ruggeri*[1], *Consuelo Corti*[1], *Fabio Ciceri*[1,2], *Maria Teresa Lupo-Stanghellini*[1]
[1]*Haematology and Bone Marrow Transplantation Unit, IRCCS San Raffaele Scientific Institute, Milan, Italy,* [2]*Università Vita-Salute San Raffaele, Milan, Italy*

Background: Chronic-GvHD (chGvHD) is a frequent and clinically relevant late complication in long-term survivors of allogeneic HSCT, exerting a substantial impact on patients' quality of life as well as on overall morbidity and mortality. Previously, we demonstrated how a composite score based on post-transplant immune reconstitution (IR) and clinical parameters is effective in predicting chGvHD outcomes.

Methods: chGvHD IR-score was calculated according to previously published alghoritm (Figure 1A) evaluating CD3CD4, NK, IgA, IgM, platelets and Karnofsky performance status. Based on the chGvHD IR-score, patients were stratified into three risk categories: low-risk, intermediate-risk, and high-risk. We analyzed prospectively data from 180 patients who underwent allogenic HSCT at our Institute between 2016 and November 2023 and subsequently developed chGvHD; IR score was available in 166 patients, with a median follow up of 1132 days (range 386-2648). We then evaluated the correlation between the IR-score-defined risk and the probability of being alive, in remission, and free from active GvHD or the need for immunosuppressive therapy five years after the onset of chGvHD, in all the patients (from both the historical cohort – 127 patients - and contemporary cohort – 78 patients) with a potential follow-up period of five years (figure 1B).
Our objective was twofold: first, to validate the chGvHD IR-score in a contemporary cohort of patients; and second, to evaluate its ability to predict free survival from chGvHD and recurrence, 5 years after the onset of chGvHD itself.

Results: Among the 166 patients of the contemporary cohort, 65 patients were classified as low-risk, 73 as intermediate-risk, and 28 as high-risk at the time of chGvHD diagnosis. The 3 years-OS was 92%, 86%, and 60% for low-, intermediate-, and high-risk respectively

(p=0.0006), confirming the validity of chGvHD IR-score (Figure 1C).
Overall 127 patients in the historical cohort and 78 in the contemporary cohort were evaluable for the 5-year response. Eighty-nine patients (43%) were alive, in complete remission and off-immunosuppressive treatment, 76 patients (37%) were dead or relapsed while 40 patients (20%) were still under immunosuppressive treatment due to active chGvHD at 5 year after chGvHD onset. Probability of being alive, in complete remission and off-immunosuppressive treatment was higher among low-risk patients, while, high risk patients showed higher probability of death. This confirms the 5-year prognostic value of chGvHD IR-score (p<0.0001) (Figure 1D).

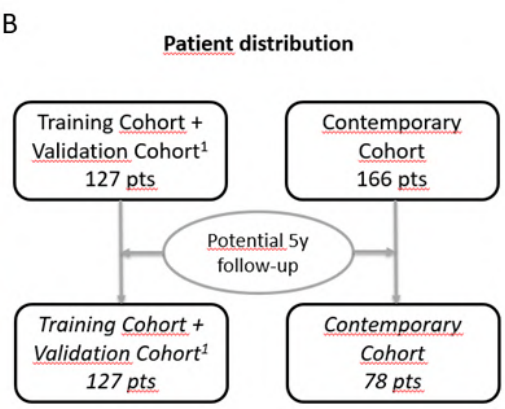
A

chGvHD IR-Score

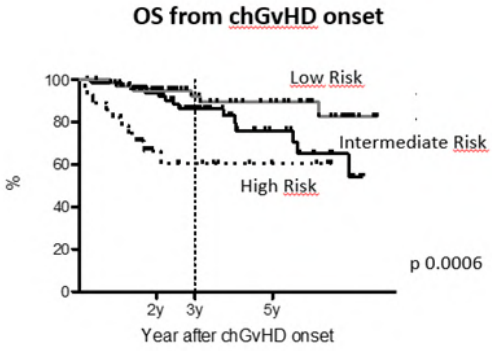
Parameters	Value of reference	B-coefficient
CD3CD4	>233/mcl	3.09
NK	<155/mcl	1.75
IgA	<0.43 g/L	1.47
IgM	<0.45 g/L	2.22
Platelets	<100x10^9/L	2.18
PS Karnofsky	<80%	5.05

Low Risk	Intermediate Risk	High Risk
<3.09	3.09-6.9	>6.9

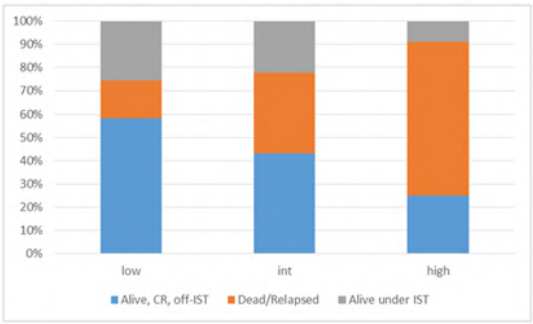
B



C



D



Conclusions: ChGvHD IR-score is a valid predictor tool of both short and long-term outcomes in chGvHD, effectively stratifying overall survival at 3 and regarding immunosuppressive therapy on long-term. Integration of immunological and clinical parameters into this composite score provides a practical and prognostic tool for a personalized, risk-adapted management strategy for cGvHD. Further multicentre confirmation is warranted.

Disclosure: Nothing to declare.

Background: Graft-versus-host disease (GVHD) prophylaxis in HSCT from 10/10 HLA-identical donors has improved with the use of PTCY, incorporating the same dose used in haploidentical HSCT. However, PTCY can add toxicity to conditioning regimens (cardiotoxicity, delayed engraftment, infection, etc.) and even increase the risk of alkylating agent-induced endothelial injury. For this reason, the GETH-TC (Spanish Group for HSCT and Cell Therapy) conducted a retrospective, multicentre study to evaluate the efficacy and safety of using reduced doses of PTCY (low-PTCY) in 10/10 HLA-identical donor HSCT (related – MRD, and unrelated – MUD).

Methods: Patients diagnosed with acute myeloid leukaemia and myelodysplastic syndrome who underwent their first allo-HSCT with peripheral blood stem cells (PBSC) from 10/10 HLA-identical donors in 2023 and 2024 were recruited. Primary endpoints included overall survival (OS), non-relapse mortality (NRM), and GVHD-free/relapse-free survival (GRFS). Secondary endpoints included cardiotoxicity, endothelial syndrome, and haemorrhagic cystitis.

Results: 276 patients met the study criteria, with a mean age of 61 years (range 18–75), of whom 65.6% received PBSC from MUD. Conditioning was reduced in 86.4% of patients. As GVHD prophylaxis, 167 patients received standard doses of 50 mg/kg/day on days +3 and +4 of PTCY (st-PTCY) and 109 received low-PTCY (defined as $\leq$40 mg/kg/day), mostly combined with calcineurin inhibitors ± mycophenolate. A HCT CI $\geq$ 3 was observed in 64.7%

of patients with st-PTCY and in 73.4% with low-PTCY, and 25.4% had active disease at HSCT (21% vs 32%, respectively) – see Table 1.
Engraftment was achieved in 97.8% of cases, with a median of 18 vs 17 days (p 0.007) for neutrophils, and 22 vs 15 days (p<0.001) for platelets in st-PTCY and low-PTCY, respectively. There were no differences in the incidence of endothelial syndrome or cardiotoxicity. 206 patients had some type of infection (74.6%), with a higher percentage observed in the st-PTCY group (47.8% vs 26.8%, p 0.027). Notably, BK virus haemorrhagic cystitis was more frequent with st-PTCY (cumulative incidence function (CIF) at day +100, 16.8% vs 2.8% p < 0.001). No patients with low-PTCY developed severe haemorrhagic cystitis.
No differences were found in CIF for grade II–IV aGVHD (18.6%, 95% CI: 13.1–24.8 vs 23.9%, 95% CI: 16.3–32.2) and III–IV up to day +100 (6.6%, 95% CI: 3.5–11 vs 11.9%, 95% CI 6.7-18.8) and also in moderate-severe cGVHD one year post-HSCT (19.8%, 95% CI: 13.9–26.6 vs 18.6%, 95% CI: 11.7-26.8). Estimated 2-year incidence of OS, relapse-free survival (RFS), NRM, relapse, and GRFS for both groups was 77.1% vs 78.1% (p 0.86), 70.6% vs 63.8% (p 0.51), 11.1% vs 9.4% (p 0.65), 26.8% vs 26.8% (p 0.26), and 48.5% vs 45.7% (p 0.84), respectively.

GRFS	Total	St-PTCY	Low-PTCY	P value
1-Year	51.8 (45.6-57.6)	51.3 (43.2-58.7)	52.8 (42.8-61.9)	0.84
2-Year	47.5 (40.6-54.1)	48.5 (39.9-56.5)	45.7 (33.5-57.1)	

Conclusions: In our experience, low-PTCY in MRD and MUD allo-HSCT do not increase the incidence of GVHD, offering survival results not inferior to st-PTCY doses. Low-PTCY appears to shorten time to engraftment and decrease the incidence of infections in general, particularly BK virus haemorrhagic cystitis. These findings should be explored in clinical trials evaluating whether there is an optimal PTCY dose that can improve HSCT outcomes in this context.

DECODING LONG-TERM IMMUNE SIGNATURE THROUGH AUTOANTIBODY EXPRESSION AS PERSISTENT IMMUNE SIGNALS IN POST-TRANSPLANT PAEDIATRIC ALL

Anita Lawitschka[1], *Leila Ronceray*[1], *Dorothea Bauer*[1], *Michael Rittenschober*[1], *Natalia Zubarovskaya*[1], *Winfried Pickl*[2], *Zoya Kuzmina*[3]
[1]*St. Anna Children's Hospital, Medical University of Vienna, Vienna, Austria,* [2]*Medical University of Vienna/Institute of Immunology, Vienna, Austria,* [3]*St. Anna Children's Cancer Research Institute, Vienna, Austria*

Background: Chronic graft-versus-host disease (cGvHD) following haematopoietic stem cell transplantation (HSCT) shares many similarities with *de novo* autoimmune disorders, being associated with the presence of autoantibodies. However, data on their implication in paediatric HSCT recipients are scarce. In this single-centre study of paediatric patients with ALL surviving longer than 3 months, our objectives were to evaluate autoantibody expression and investigate the correlation with cGvHD and immune reconstitution using serially monitored parameters.

Methods: We investigated circulating autoantibodies along with cellular and humoral parameters [T- and B-cell subsets, NK-cells, and immunoglobulin levels] in 440 samples from 74 patients serially during long-term follow-up (median 8 years, range 0.4-19.3). Evaluations comprised of patient and transplant characteristics, NIH-defined cGvHD details, and outcome such as relapse, overall survival (OS) and mortality, analysing these parameters for associations.

Results: Autoantibodies were detected in 65% of patients. Anti-nuclear antibodies were the most common, occurring in 75% of patients. When comparing demographic data and transplant characteristics, there were no significant differences between patients with and without autoantibody expression; 5-year OS was excellent, at 96%. Patients with autoantibodies showed significantly better immune reconstitution, with overall higher numbers of T cells, B cells, and serum immunoglobulins. In autoantibody-positive patients with cGvHD, autoantibody production positively correlated with significant expansion of CD56+ NK cells (p=0.023) and with signs of B-cell perturbation, higher $CD21^{low}$ B cells (p=0.044) in comparison to autoantibody-positive patients without cGvHD.
Furthermore, analysis of the association between autoantibody positivity and cGvHD activity at the time of evaluation demonstrated features of dysregulated B-cell homeostasis, evidenced by reduced $CD27^{+}$memory B cells (p = 0.028) and increased CD21^low B cells (p = 0.013) in patients with active cGvHD compared with those without cGvHD. We subsequently evaluated the potential role of autoantibody expression in the setting of increased CD21^low B cells (cutoff >7%), a well-established marker of cGvHD. Unexpectedly, a significantly higher prevalence of elevated CD21^low B cells associated with active cGvHD was observed in the autoantibody-negative group compared with the autoantibody-positive group (82% vs. 47%, p = 0.0053).
Analysis of immune parameters in the majority of survivors (89%) demonstrated normalization of the B-cell compartment, characterized by significantly increased levels of

class-switched CD27⁺IgD⁻ B cells ($p < 0.0001$) and immunoglobulin G4 ($p < 0.0001$). Overall mortality was significantly associated with elevated CD21^low B cells ($p = 0.039$) and CD56⁺ NK cells ($p = 0.019$). In multivariate analysis, improved overall survival was independently associated with lower CD56⁺ NK cell levels ($p = 0.041$) and higher CD27⁺ memory B-cell levels ($p = 0.014$).

Conclusions: Our findings indicate that autoantibody profiles are not reliable biomarkers for the diagnosis of cGvHD in children and adolescents, nor for predicting disease severity, clinical course, or outcomes. We identified a number of indicators of aberrant immune homeostasis associated with active cGvHD in paediatric ALL patients after HSCT. These findings confirm published results and suggest that candidate B cell subpopulations may serve as a surrogate measure for characterisation of cGvHD in paediatric HSCT for malignant diseases.

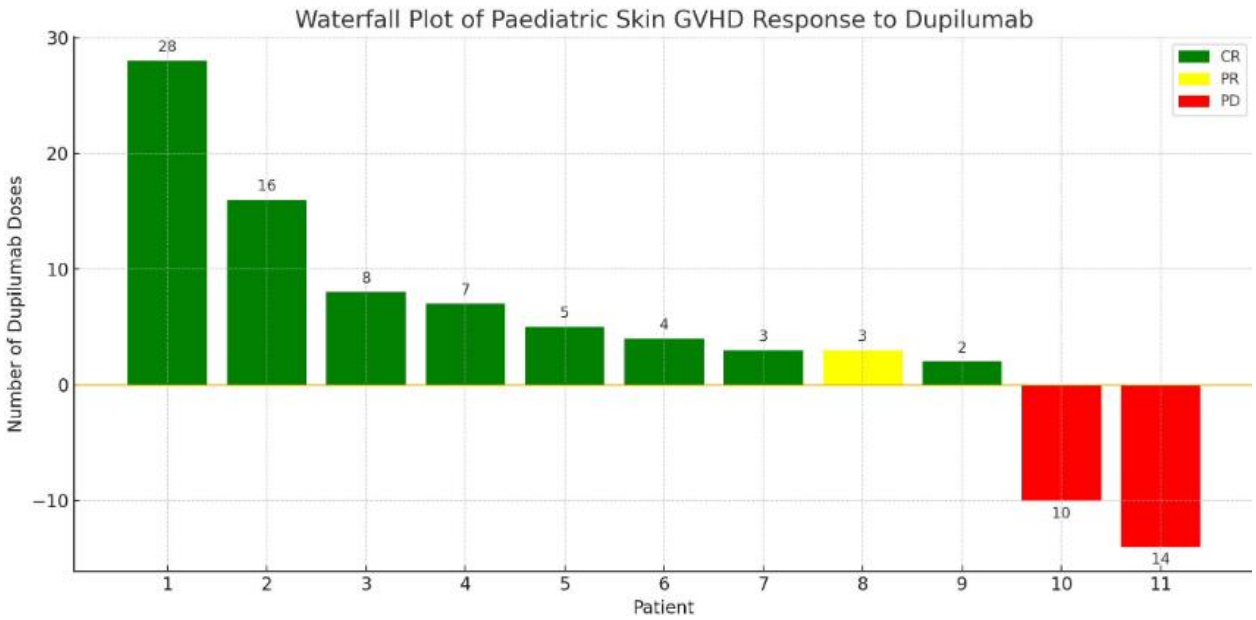
DUPILUMAB: EFFECTIVE AND SAFE ADDITION TO THE THERAPEUTIC ARMAMENTARIUM FOR PAEDIATRIC SKIN GVHD – A SINGLE CENTRE EXPERIENCE

Kalasekhar Vijaya Sekharan[1], *Sarah Brett*[1], *Ramya Nataraj*[1], *Claire Horgan*[1], *Oana Mirci-Danciar*[1], *Omima Mustafa*[1], *Robert Wynn*[1], *Srividhya Senthil*[1]
[1]*Royal Manchester Children Hospital, Manchester, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Skin graft versus host disease (GVHD) in children remains difficult to manage, particularly in steroid-dependent or refractory cases. Dupilumab, an IL-4Rα blocker, which targets Th2-driven pathways, improves cutaneous symptoms, and reduces steroid exposure, offering a promising therapeutic option.

Methods: We retrospectively reviewed paediatric patients receiving dupilumab for skin GVHD between January 2023 and October 2025. Severe acute(a) skin GVHD (stage III/IV) and chronic GVHD was treated with steroids and, steroid sparing second line agents, including dupilumab and others, such as, ruxolitinib, belumosudil, calcineurin inhibitors and extra corporeal photopheresis (ECP) when it was steroid dependent or refractory. Dupilumab was administered at 300 mg subcutaneously every two weeks until clinical improvement, then monthly until complete remission. Concomitant systemic therapies were tapered in responders, and additional interventions were used only if lesions progressed during dupilumab therapy.

Results: Eleven patients (median age 12 years, range 13 months–19 years; male-to-female ratio 2.6:1) received dupilumab post haematopoietic stem cell transplant (HSCT). Of them, eight (72%) underwent HSCT for non-malignant disorders. Nine patients (81%) received myeloablative conditioning, and eight received serotherapy (alemtuzumab, n=6; anti-thymocyte globulin, n=2). Donors included unrelated (n=8, HLA matched 4/8, HLA mismatched 4/8), matched sibling (n=2), haploidentical (n=1), with stem cell source being peripheral blood (n=5), bone marrow (n=2), and cord blood (n=4). Chronic, skin only GVHD was present in five (45%), skin aGVHD in two (19%), and overlap skin GVHD in four (36%) patients. All exhibited extensive eczematous type of skin GVHD (Stage-3/Grade-2: 10/11; Stage-4/Grade-4: 1/11). Nine (81%) were steroid-dependent and two (19%) steroid-refractory. Patients had a median of three prior systemic therapies (range 2–5). Overall response rate was 81% (eight complete response (CR), one partial response (PR)), with median time to improvement of 13 days (range: 5–40 days). Two patients had skin GVHD progression (PD) whilst on dupilumab (Figure-1). No significant adverse events were recorded.



Conclusions: Dupilumab is effective and well tolerated in steroid-dependent or refractory skin GVHD, demonstrating rapid clinical improvement and steroid-sparing potential. Early incorporation may further enhance outcomes in paediatric patients. Its use over other second line immunosuppressive agents may be considered, in particular, in malignant HSCT. However, larger prospective trials are needed to inspect its role in skin GVHD post HSCT.

Background: Chronic GVHD (cGVHD) is one of the most debilitating complications following allogeneic stem cell transplantation (SCT), resulting in increased mortality, morbidity and reduced quality of life. The first-line treatment still relies on steroids. Multiple new therapeutic options are capable of acting on inflammatory pathways responsible for cGVHD and are being used in subsequent therapeutic lines for patients with relapsed/refractory (r/r) cGvHD. Belumosudil is a selective ROCK2 inhibitor with immunomodulatory and anti-fibrotic properties. While the drug received approval in the United States in 2021 and in other

several Countries thereafter, it has not yet authorized in Europe and the only way to access the drug in Italy is through a compassionate use.

Methods: This observational, retrospective, multicentre study included 80 patients treated with belumosudil by 29 SCT centers in Italy between June 2023 and April 2025. The study aimed to evaluate the efficacy of belumosudil, accessed via compassionate use, in patients with r/r cGVHD, after failure of at least two systemic lines of therapy. Clinical data, encompassing baseline demographics, cGVHD severity, prior and concomitant treatments, NIH response, patient-reported outcomes (PROs), and adverse events (AEs) were collected from medical records. The cohort was characterized by a high proportion of patients with severe disease (86%), extensive prior treatment (median of 3 lines), and significant previous exposure to ruxolitinib (84%). Patients also presented with a prolonged history of cGVHD (median: 42.6 months). The median follow-up time from belumosudil treatment was 9.1 months (range: 1-20).

Results: The overall response rate (ORR) ORR at 3, 6, and 12 months was 52.6%, 57.6%, and 55.0%, respectively. The best overall response (BOR) was 62.5%, comprising 1.3% complete remission (CR) and 61.2% partial response (PR). Median time to response was 3 months, while duration of response was 83.4% at 12 months. Responses were observed across all organs evaluated, with the highest rates recorded in mouth, gastrointestinal tract, and liver, while for lung involvement only 10% of patients showed a NIH response. Failure-free survival was 89.1% and 67.5% at 6 and 12 months, respectively. Treatment was generally well tolerated: 28 non-infectious AEs were observed, with 36% being grade ≥3. Drug discontinuation due to any cause occurred in 26% of cases, with 11% due to AEs. Evaluation of the NIH Severity Index Score (SIS) was used as a tool to assess PROs: this demonstrated a significant improvement (≥ -2 points) in 33%, 36%, and 29% of patients at 3, 6, and 12 months, respectively. Moreover, NIH objective clinical responses showed a moderate concordance with the SIS ones (51.6%, 54.4%, and 46.1% at 3, 6, and 12 months, respectively).

Conclusions: The present real-world data confirm belumosudil as a valuable therapeutic option for patients, who were extensively pretreated, with moderate-to-severe forms of cGVHD. Our findings are consistent with those reported in previous clinical trials and real-world studies, thereby confirming the drug's efficacy and safety in advanced, heavily pretreated cGVHD patients.

Background: Treatment options for acute graft-versus-host disease (aGvHD) refractory to corticosteroids and ruxolitinib are poorly characterized, none being approved for this indication. CHRONOS study aimed to describe response rates, duration of response, and survival following third-line systemic therapy in this high-risk setting.

Methods: CHRONOS is a multicentre, non-interventional, retrospective cohort study including aGvHD adults with gastrointestinal (GI) symptoms who failed both corticosteroids and ruxolitinib, and who initiated a third-line systemic treatment between 30-May-2019 and 30-September-2024, in 22 European sites. Inclusion criteria were adult aGvHD patients with GI involvement, who only previously received corticosteroids and ruxolitinib. Main exclusion criteria were hyperacute GvHD, overlap chronic GvHD, relapsed malignancy, cytomegalovirus colitis, uncontrolled cardiac disease or significant respiratory disease. Data were collected via electronic case report forms with rigorous data curation ensuring highest standards of data quality and completeness. Primary endpoints were D28 (closest assessment date) all-organ

overall response rate (ORR) and GI-specific ORR (GI-ORR) after third-line treatment initiation, based on MAGIC criteria for aGvHD assessment. Secondary endpoints included D56 response (closest assessment date), duration of response (DOR), real-world progression-free survival (rwPFS) of the underlying malignancy, overall survival (OS), and incidence of events of special interest (Grade≥2 infectious events, Grade 3-4 neutropenia and thrombocytopenia) up to 12 months.

Results: Fifty-nine patients were included from 16 sites in Austria, Belgium, France, and Spain. Median age was 59 years (IQR, 49-64); 54% (n=32) were male. Most patients presented with Grade III/IV (93%, n=55) aGvHD; 97% (n=57) were steroid-resistant and 95% (n=56) resistant to ruxolitinib. Among the 13 third-line therapies used, the three most administered were extracorporeal photopheresis (n = 17), etanercept (n = 14), and vedolizumab (n = 10), with an overall median time from initial aGvHD diagnosis of 32 days (IQR: 20–53 days). At Day 28, ORR was 36% (21/59; 95% CI, 24%–49%), including 20% CR (n=12), 7% VGPR (n=4), and 9% PR (n=5). GI-ORR was 37% (22/59; 95% CI, 25%–51%), including 22% GI-CR (n=13), 10% GI-VGPR (n=6), and 5% GI-PR (n=3). Response rates declined by Day 56: all-organ ORR of 20% (12/59; 95% CI: 11%– 33%) and GI-ORR of 22% (13/59; 95% CI: 12%-35%). 29% (95% CI: 11%–49%) of D28-responders lost their all-organ response within the next 30 days, and 52% (95% CI: 29%–72%) within 90 days. Same results were observed for the GI-aGvHD-responders. Median rwPFS and OS were 86 days (95% CI: 54–128). Median OS was 186 days in responders (95% CI: 115 days-not reached) *versus* 45 days in non-responders (95% CI: 28–86 days). Up to M12, 41 patients died, mostly from aGvHD (n=25) and infectious complications (n=9). Grade≥2 infectious events occurred in 58% of patients, grade 3 to 4 thrombocytopenia and neutropenia in 64% and 32% respectively.

Conclusions: These findings illustrate the absence of standardization and the limited benefit of available third-line interventions, emphasizing the need for novel treatments. Survival outcomes were poor, particularly among non-responders, and infectious events were frequent. By establishing clear benchmarks, this study will facilitate the evaluation of novel therapeutic approaches.

Background: Acute graft-versus-host disease (aGVHD) is a major cause of morbidity and mortality after allogeneic stem cell transplantation; one year non-relapse mortality (NRM) following the diagnosis of grade II-IV GVHD is 25% (Holtan, *BMT*, 2022). Ann Arbor (AA) scores, derived from biomarkers associated with gastrointestinal damage, have been shown to correlate with resistance to standard therapy and increased non-relapse mortality; AA 2/3 scores are considered high-risk with 1-year NRM of 40% (Al Malki, *Blood Adv*, 2023). Extracorporeal photopheresis (ECP) is used for steroid-resistant GVHD, but prospective studies evaluating its efficacy as a first-line treatment for aGVHD are lacking.

Methods: We conducted a multicenter phase 2 trial combining ECP with standard corticosteroid therapy in patients with newly diagnosed aGVHD (clinical grade 2–4) and AA2/3. Patients were recruited from three centers in Germany and one center in Austria. ECP was administered (using the Therakos™ CELLEX™ Photopheresis System) three times per week in weeks 1–2, twice per week thereafter until Day 28, and once per week until Day 56. Methylprednisolone (2 mg/kg/day or equivalent) was given from Day 0 to Day 3, then tapered according to clinical response. Treatment per protocol lasted 2 months, with a follow-up period of 1 year. The primary endpoint was the rate of complete response (CR) at Day 28. Secondary endpoints included rates of NRM, relapse, and overall survival at 12 months. Results were compared with a contemporary matched control cohort (n=72) from the Mount Sinai Acute GVHD International Consortium (MAGIC) database.

Results: 52 patients were screened and 24 enrolled (n = 17 AA2; n = 7 AA3). Acute GVHD was grade II (17, 71%), III (6, 25%), and IV (1, 4%). Lower GI GVHD was present in 14 (58%) of patients. Median age was 59 years (range 44–63), and patients were transplanted

for acute leukemia (12, 50%), myelodysplastic or myeloproliferative neoplasms (9, 38%), and lymphoma or other malignancies (3, 12%). ECP treatment was well tolerated; adverse events of CTCAE grade ≥3 occurred in 19 patients (79%), mostly infections (15/19, 79%). One severe adverse event (port catheter infection) was considered related to ECP procedure. The addition of ECP to high dose methylprednisolone was more effective than methylprednisolone alone in comparative analyses performed after propensity score matching to achieve balance between groups for GVHD target organ involvement and severity, Ann Arbor score, and age: D28 OR (92% vs 63%, p=0.008); D28 complete response (88% vs 55%, p=0.009), 1y NRM (8% vs 35%, p=0.025) and 1y survival (88% vs 61%, p=0.018). One patient died from relapse and two from non-relapse causes.

Conclusions: The addition of ECP to standard corticosteroid first-line treatment in patients with GVHD that is high risk by biomarker score was feasible. Although the sample size was relatively small the excellent short-term patient outcomes such as Day 28 response rate translated into significantly improved long-term outcomes such as one-year NRM and survival when compared to a contemporary matched cohort as well as published NRM rates. A larger randomized controlled trial is warranted.

CLINICAL OUTCOMES AMONG PATIENTS WITH CHRONIC GRAFT-VERSUS-HOST DISEASE TREATED WITH AXATILIMAB: ANALYSIS OF AN EXPANDED ACCESS PROGRAM

*Leyla Shune[1], **Anthony Stein**[2], Damiano Rondelli[3], Laurie Davis[4], Shalini Shenoy[5], Britnie Thomas[6], Emily Andersen[6], Elizabeth Jordan[6], Karim Moftah[6], Zhenyi Xue[6], Hannah Choe[7]*
[1]University of Kansas Medical Center, Kansas City, KS, United States of America (the), [2]City of Hope National Medical Center, Duarte, CA, United States of America (the), [3]University of Illinois Chicago, Chicago, IL, United States of America (the), [4]Baylor College of Medicine, San Antonio, TX, United States of America (the), [5]Washington University in St. Louis, St. Louis, MO, United States of America (the), [6]Incyte Corporation, Wilmington, DE, United States of America (the), [7]The James Cancer Hospital Solove Research Institute and The Ohio State University Wexner Medical Center, Columbus, OH, United States of America (the)

Background: Chronic graft-versus-host disease (cGVHD) is associated with significant morbidity and nonrelapse mortality. Axatilimab, a monoclonal antibody targeting colony-stimulating factor 1 receptor (CSF-1R), depletes the CSF-1R–dependent monocytes and macrophages that potentiate inflammation and fibrosis in cGVHD. The US Food and Drug Administration (FDA) approved axatilimab 0.3 mg/kg every 2 weeks (Q2W) for patients with cGVHD after ≥2 prior lines of systemic therapy (LOT). Axatilimab was previously available through an expanded access program (EAP) in the US sponsored by Incyte Corporation (NCT05544032). This analysis evaluated the safety and clinical benefit of axatilimab among patients in the EAP.

Methods: Patients aged ≥6 years with refractory or recurrent cGVHD and ≥2 prior LOT received axatilimab 0.3 mg/kg Q2W until loss of benefit, withdrawal, or commercial availability of axatilimab. Concomitant cGVHD treatments were permitted. Clinician assessment of clinical benefit was evaluated in the EAP at each resupply (every two 28-day cycles of axatilimab 0.3 mg/kg Q2W). Treatment-emergent adverse events (TEAEs) were assessed until 30 days after treatment end or transition to commercial product. The first EAP site was activated on April 15, 2024, and the last patient stopped treatment in the EAP on July 11, 2025, following axatilimab commercial availability. The data cutoff was October 24, 2025.

Results: Of the 112 enrolled patients, 104 patients received axatilimab (**Figure**). Most treated patients (64.4%) had severe cGVHD, and 45.2% of patients had ≥4 organs involved at baseline (**Table**). Patients received a median of 4 prior LOT (range, 1–7), including belumosudil (80.8%), ruxolitinib (76.0%), and prednisone (74.0%). The most common concomitant cGVHD therapies were belumosudil (76.0%), prednisone (63.5%), and

ruxolitinib (54.8%); fewer patients received concomitant calcineurin inhibitors (21.2%) and sirolimus (16.3%). Prior to EAP closure, median (range) duration of axatilimab treatment in the EAP was 143 (19–372) days. Though most patients (73.1%) maintained stable cGVHD severity per National Institutes of Health 2014 criteria, clinicians reported clinical benefit in 90 patients (86.5%) from axatilimab during the EAP. At EAP closure, 70 patients (67.3%) transitioned to commercial product. Seventy-six patients (73.1%) experienced TEAEs of any severity, with 4 patients (3.8%) having infusion-related reactions. Thirty-seven patients (35.6%) had treatment-related TEAEs, most commonly (>3%) increased aspartate aminotransferase (n=12 [11.5%]), increased alanine aminotransferase (n=9 [8.7%]), fatigue (n=5 [4.8%]), and increased gamma-glutamyl transferase (n=4 [3.8%]). Fifteen patients (14.4%) had treatment-related serious TEAEs, most commonly pyrexia (n=2 [1.9%]). Three patients (2.9%) discontinued treatment due to unacceptable toxicity, and 2 patients (1.9%) discontinued treatment due to intolerance to axatilimab.

cGVHD, chronic graft-versus-host disease.

Conclusions: The US EAP represents the largest real-world experience of axatilimab treatment at the FDA-approved dose of 0.3 mg/kg Q2W in patients with cGVHD. Most patients (86.5%) experienced clinical benefit from axatilimab treatment per clinician assessment, and the majority (67.3%) transitioned to commercial product upon EAP closure, suggesting ongoing clinical benefit. Axatilimab safety was consistent with that observed in clinical trials, with no new or unexpected toxicities. Only 5 patients (4.8%) discontinued treatment due to unacceptable toxicity or intolerance to axatilimab. This analysis provides additional evidence of the real-world effectiveness and safety of axatilimab for cGVHD.

TWO-AGENT GRAFT-VERSUS-HOST DISEASE PROPHYLAXIS WITH CYCLOPHOSPHAMIDE AND RUXOLITINIB: EXPERIENCE BEYOND THE CLINICAL TRIALS

Ivan Moiseev[1], *Dmintrii Zhogolev*[1], *Maria Barabanshchikova*[1], *Daria Chernyshova*[1], *Tatyana Rudakova*[1], *Sergey Bondarenko*[1], *Elena Morozova*[1], *Yulia Vlasova*[1], *Anna Smirnova*[1], *Alexander Kulagin*[1]
[1]*RM Gorbacheva Research Institute, Pavlov University, Saint Petersburg, Russian Federation (the)*

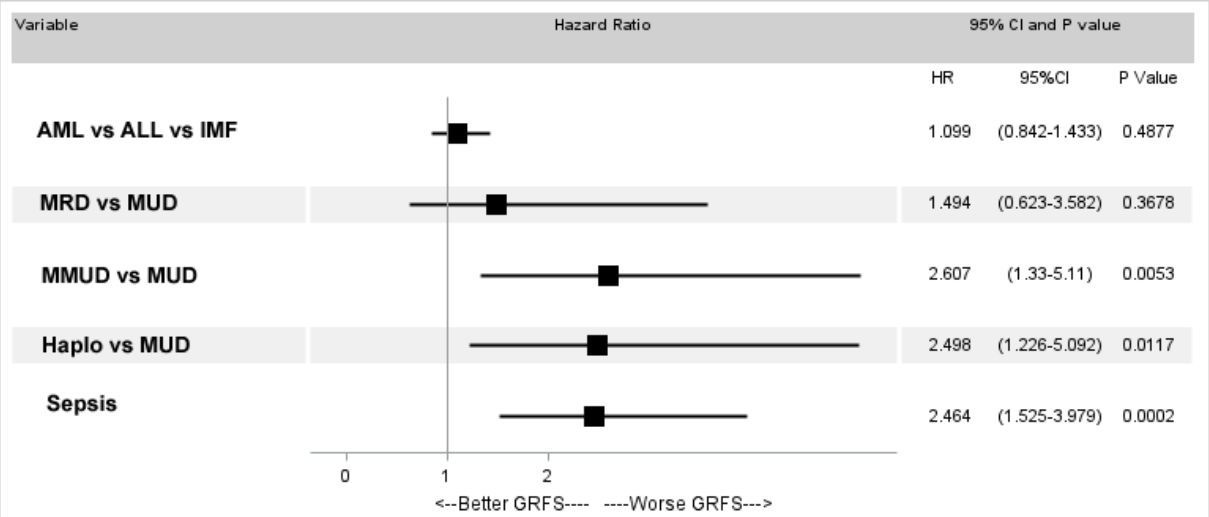
Background: We have previously reported promising efficacy and safety of calcineurin-free cyclophosphamide (PTCy) and ruxolitinib (PTCyRuxo) graft-versus-host disease (GVHD) prophylaxis in myelofibrosis (NCT02806375) and in acute leukemia (NCT04669210). Now we evaluated long-term results of this regimen in routine clinical practice.

Methods: The study comprised 225 standard risk adult recipients of hematopietic cell transplantation (HCT) with acute myeloid or lymphoblastic leukemia and myelofibrosis transplanted between 2015 and 2025. Disease characteristics are presented in the table. HCT was performed from a haploidentical donor in and unrelated donor in . Peripheral blood stem cells were a graft source in 97% of patients. All patients received FB2-FB4 conditioning with ruxolitinib 15-30 mg/day on days -7 to -2 and GVHD prophylaxis with PTCY 50 mg/kg on days +3,+4 and ruxolitinib 15 mg/day on days 5-21, and 10 mg/day on days 22-15. Median follow up was 17 months (range 1-117). Four-year outcomes are presented.

Parameter	Percent (n), Total n=225
Age, median (range), years	44 (18-75)

Males Females	50% (112) 50% (113)
Acute myeloid leukemia Primary myelofibrosis Acute lymphoblastic leukemia	53% (119) 29% (66) 18% (40)
Matched related donor (MRD) Mismatched related donor (Haplo) Matched unrelated donor (MUD) Mismatched unrelated donor (MMUD)	11% (24) 23% (53) 29% (65) 37% (83)
Graft CD34+ mln/kg, median (range)	6.4 (1.0-11.9)
PBSC BM	96% (216) 4% (9)
FB2 conditioning FB3 conditioning FB4 conditioning	17% (39) 76% (170) 7% (16)

Results: Cumulative incidence of engraftment was 93% (95%CI 90-97%) with a median of 18 days (range 12-229). Myelofibrosis negatively impacted engraftment and time to engraftment (89%, 34 days vs 96%, 17 days in acute leukemia, p<0.0001). Cumulative incidence of acute GVHD grade II-IV was 18% (95%CI 13-23%), grade III-IV 5% (95%CI 3-8%). Significant difference was observed in the incidence of grade II-IV acute GVHD according to the donor type: 8% MUD, 4% MRD, 21% Haplo, 28% MMUD, p=0.006. Incidence of moderate and severe chronic GVHD was 27% (95%CI 20-35%), while severe – 10% (95%CI 6-16%). No difference in the incidence of chronic GVHD was observed according to a donor type (p=0.20). Non-relapse mortality (NRM) was 19% (95%CI 13-26%), cumulative incidence of relapse (CIR) was 19% (95%CI 12-27%). NRM was lower in AML patients (10% vs 26%, p=0.02), while there was no differences in CIR (p=0.71). Overall survival was 71% (95%CI 61-78%), event-free survival 62% (95%CI 52-70%), GVHD-relapse-free survival (GRFS) 49% (95%CI 40-58%). The significant parameter for GRFS was the type of a donor, with best results in MUD HCT (69% vs 46% in MRD, 34% in MMUD, 44% in Haplo, p=0.01). After graft infusion 27% of patients had early cytokine release syndrome. Grade 3-4 toxicities included mucositis in 35%, hepatic toxicity in 6%, acute kidney injury 0.6%, bloodstream infections in 38%, sepsis in 23%, pneumonia in 28%, soft tissue infection in 8%. Veno-occlusive disease (VOD) was observed in 1.3%, transplant-associated microangiopathy in 0.6%. Cytomegalovirus reactivation was documented in 49%, herpes type 6 reactivation in 40%. Only sepsis had a negative impact on survival (p<0.0001). In the multivariate analysis MMUD (HR 2.6, 95%CI 1.2-5.1) and Haplo donors (HR 2.5, 95%CI 1.2-5.1) were associated with worse GRFS compared to MUD, while no differences were observed for MRD donors (HR 1.5, 95%CI 0.6-3.6).



Conclusions: Application of PTCy-ruxolitinib prophylaxis in the large patient cohort outside of clinical trials demonstrated reproducible results to the initial studies. We observed very low incidence of severe GVHD. The study also confirmed low incidence of VOD and TA-TMA as initially observed. Even with this effective prophylaxis there is an impact of 10/10-HLA compatibility on HCT outcomes.

Clinical Trial Registry: NCT02806375, NCT04669210

Disclosure: The study was supported by RSF grant №23-15-00327.

ABATACEPT REDUCES ACUTE GVHD INCIDENCE AND IMPROVES GRFS IN PEDIATRIC PATIENTS TRANSPLANTED FROM AN HLA-MISMATCHED DONOR: A REAL-WORLD, MULTICENTER, RETROSPECTIVE STUDY

Francesco Quagliarella[1], Mattia Algeri[1,2], Emillia Boccieri[1], Marco Zecca[3], Maura Faraci[4], Manuela Tumino[5], Giovanna Lucchini[6], Riccardo Masetti[7,8], Jochen Buechner[9], Marco Becilli[1], Francesca Del Bufalo[1], Daria Pagliara[1], Roberto Carta[1], Tiziana Corsetti[1], Barbarella Lucarelli[1], Chiara Rosignoli[1], Matteo Becci[1], Federica Galaverna[1], ***Pietro Merli***[1,10]*, Franco Locatelli[1,11]*

[1]IRCCS Ospedale Pediatrico Bambino Gesù, Rome, Italy, [2]Magna Graecia University, Catanzaro, Italy, [3]Fondazione IRCCS Policlinico San Matteo, Pavia, Italy, [4]IRCCS Istituto Giannina Gaslini, Genova, Italy, [5]Azienda Ospedaliera Università di Padova, Padova, Italy, [6]Fondazione IRCCS San Gerardo dei Tintori, Monza, Italy, [7]IRCCS Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy, [8]University of Bologna, Bologna, Italy, [9]Oslo University Hospital, Oslo, Norway, [10]UniCamillus, Rome, Italy, [11]Catholic University of the Sacred Heart, Rome, Italy

Background: The use of HLA-mismatched donors has been associated with an increased risk of both acute and chronic GvHD (respectively 30-60% and 29-70%), resulting in higher TRM (20-28%) (Jagasia, Blood 2012; Kröger, NEJM 2016)
New promising strategies for prevention of GvHD involve modulation of interactions between T-cells and antigen-presenting cells (APCs). In this regard, abatacept (ABA, CTLA4-IgG1) is a fusion protein that selectively inhibits T-cell co-stimulation by binding ligands CD80 and CD86 on APCs, thus blocking CD28-mediated signaling.

Methods: We retrospectively collected data from 8 pediatric centers from Italy and Norway on all consecutive patients transplanted from an HLA-mismatched donor who received abatacept during the transplant period. ABA was added, on an off-label basis, to standard GvHD pharmacological prophylaxis following EBMT guidelines (CSA, MTX, ATLG) at the dose of 10 mg/kg (max 750 mg/dose). Besides the classical administration schedule (day -1,+5,+14,+28), extended administration with additional doses was performed in many patients.
Classical clinical outcomes (GvHD, TRM, relapse, OS, EFS and GFRFS) were calculated, and compared to a historical cohort of acute leukemia patients receiving a transplant from a MMUD donor (Bertaina, Blood 2018).

Results: Between February 2021 and January 2025, ABA was administered to 100 pediatric/young adult patients undergoing unmanipulated HSCT from mismatched donors (91 MMUD and 9 PTCy haploidentical transplants). Twenty-eight patients received 4 doses of ABA, while 72 >4 (median 6 doses, range 5-13). Most patients, except 23 with non-malignant diseases, received a myeloablative conditioning regimen. Details on patients and transplants characteristics are reported in Table 1.
With a median follow-up for surviving patients of 19 months (range, 3-50), cumulative incidence of grade II-IV and grade III-IV aGvHD for MMUD transplants were 24.4% (95% CI 16.6-35.0) and 6.9% (95% CI 3.1-14.8), respectively. Cumulative incidence of grade II-IV aGvHD was higher in patients who received only four doses of abatacept (38.1% vs 18.7%, p=0.05). Twenty-three patients out of the 92 at risk, developed mild to moderate cGvHD (no cases of severe cGvHD were recorded), the cumulative incidence being 29.3% (95% CI 20-41.8), with no difference according to the number of doses of ABA received.
In malignant diseases, both TRM and relapse incidence were lower in patients receiving extended-course ABA (4.9 vs 15.3%, p=0.19, and 7.1% vs 39.7%, p=0.009), this resulting into an improved 3-yr EFS as compared to patients receiving 4 doses of the drug (88.2% vs 44.9%, p=0.001). Compared to the historical controls, patients receiving ABA showed an improved 3-yr GRFS (59.3% vs 31.9%, p=0.006, Fig.1).
OS and EFS of non-malignant patients were 95.8% and 92.9%, respectively.
Regarding safety, we did not observe an increased incidence of infections, with the only exception of increased EBV reactivation, 24 patients requiring treatment with rituximab. However, no cases of PTLD were recorded.

	N	% - range
Age at HSCT (years, range)	8.5	(1-23.0)

Diagnosis		
ALL	30	30
AML	17	17

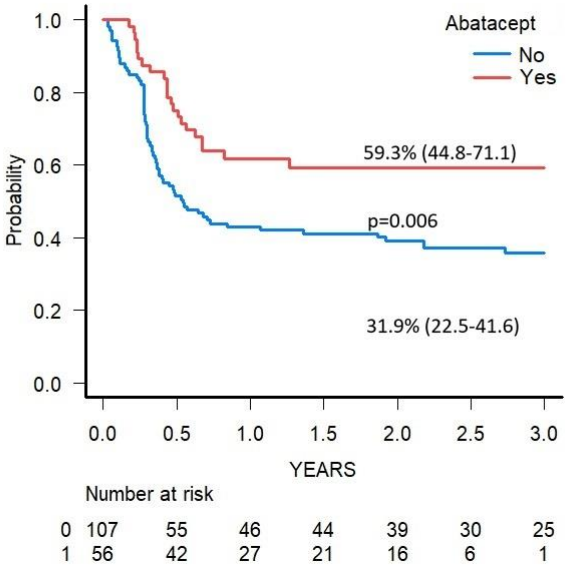
BM	64	64
PBSC	36	36
Table I. Patients and transplant characteristics		



Conclusions: Our data indicate that ABA, added to a standard GvHD prophylaxis (including serotherapy), is a safe and effective approach for preventing acute GvHD in pediatric patients undergoing mismatched HSCT for both malignant and non-malignant diseases, especially if administered up to day + 60, without increased risk of relapse or TRM.

Kingdom of Great Britain and Northern Ireland (the), [5]Heartlands Hospital, University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom of Great Britain and Northern Ireland (the), [6]Royal Manchester Children's Hospital, Manchester University NHS Foundation Trust, Manchester, United Kingdom of Great Britain and Northern Ireland (the), [7]American Hospital Dubai, Dubai, United Arab Emirates (the)

Background: Graft-versus-host disease (GVHD) is a major complication of allogeneic stem cell transplantation (allo-SCT). Reduced-intensity conditioning (RIC) and GVHD prophylaxis with in vivo T-cell depleting agents such as alemtuzumab or ATG have broadened access to allo-SCT for older or co-morbid patients with high-risk haematological malignancies. The role of ATG in RIC allografts is not well characterised and comparative studies with alemtuzumab remain pertinent. The primary aim of this study was to assess 2-year GVHD-free, relapse-free survival (GRFS) in patients who received alemtuzumab compared with ATG during RIC allo-SCT. Secondary endpoints include cumulative incidence (CI) of acute grade III/IV GVHD (aGVHD), CI of moderate and severe chronic GVHD (cGVHD), CI of non-relapse mortality (NRM), CI of relapse (CIR), overall survival (OS) and progression-free survival (PFS).

Methods: Retrospective multicentre study of 399 patients from five centres who underwent RIC allo-SCT for haematological malignancy and received either alemtuzumab (n=261) or ATG (n=138). The median age was 60.25 years (range 16.5-76.9), with 57.6% males. Disease lineage was either myeloid (n=300), lymphoid (n=97), mixed phenotype (n=1) or undifferentiated (n=1). Donor types included unrelated (n=318) and sibling (n=81). Median follow-up estimated using the reverse Kaplan-Meier method was 37.9 months. PFS and OS were calculated using univariate and multivariate Cox proportional hazards models. CIR, NRM and CI of GVHD were assessed with Fine-Gray competing-risks regression for both univariate and multivariate analyses. Multivariable models adjusted for age, sex, disease lineage, cytogenetic risk, cytomegalovirus serostatus, donor type, conditioning regimen and centre.

Results: In univariate analysis, choice of GVHD prophylaxis had no significant effect on GRFS, PFS, NRM, CIR or CI of moderate/severe cGVHD. ATG use was associated with better OS (HR 0.69, 95% CI 0.5-0.95, p=0.024) but more grade III/IV aGVHD (HR 3.5, p=0.0073) when compared with alemtuzumab.
In multivariate analysis, choice of GVHD prophylaxis had no effect on GRFS, PFS, OS, CIR, NRM or CI of moderate/severe cGVHD. ATG was associated with more grade III/IV aGVHD when compared with alemtuzumab (HR 6.24, 95% CI 1.28-30.4, p=0.024). Age and cytogenetic risk were significant co-variates for GRFS, PFS, OS and NRM.

Conclusions: Alemtuzumab-based GVHD prophylaxis is associated with lower incidence of grade III/IV aGVHD compared with ATG in RIC allo-SCT. No differences were observed in GRFS, PFS, OS, CIR or NRM after adjustment for confounding covariates. These findings support the continued use of alemtuzumab in RIC allo-SCT.

Disclosure: Nothing to declare.

B012

RESULTS OF ABATACEPT ADDITION TO POST TRANSPLANT CYCLOPHOSPHAMIDE-BASED GVHD PROPHYLAXYS IN ALLOGENEIC HEMATOPOYETIC STEM CELL TRANSPLANTATION

Lucia Castilla-Garcia[1], *Maria del Pilar Montero Anton*[1], *Rebeca Bailen-Almorox*[1], *Ignacio Alberto Gomez Centurión Luna*[1], *María Jose Llácer Ferrandis*[1], *Paula Fernandez Caldas*[1], *Cristina Villanueva Bueno*[1], *Jose Luis Revuelta Herrero*[1], *Vicente Escudero Vilaplana*[1], *María Sanjurjo Sáez*[1], *Cristina Muñoz Martínez*[1], *Santiago Sabell Stewart-Howie*[1], *Ramón García Sanz*[1], *Mi Kwon*[1]
[1]*Hospital General Universitario Gregorio Marañón, Madrid, Spain*

Background: Graft-versus-host disease (GVHD) remains a leading cause of morbidity and mortality.Abatacept (ABA) inhibits T-cell activation and has recently been approved by the FDA for GVHD prophylaxis in combination with MTX and a calcineurin inhibitor. However, clinical data on its use alongside high-dose post-transplant cyclophosphamide (PTCY) regimens remain limited. Since February 2020, our center has incorporated ABA in patients undergoing HSCT with high risk GVHD (female donor, mismatched donor) and presenting HCT-CI score ≥3 and/or age ≥55 years. Initially, three doses of abatacept were administered on days +5, +14, and +28. Following an interim analysis, a fourth dose was added on day+56, based on existing literature, in an effort to reduce the incidence of chronic GVHD.

Methods: In this single center, retrospective analysis, 45 consecutive patients who underwent allo-HSCT between February 2020 and March 2025 were included. ABA was administered intravenously at a dose of 10mg/kg on days +5, +14, and +28. A subset of patients received an additional dose on day +56. Patients were stratified into two cohorts based on the administration of the day +56 dose: +56 cohort (n=17) and non+56 cohort (n=28).

Results:

Variable	+56 cohort	Non +56 cohort	p
Median age, years (IQR)	63 (57–65.5)	63 (57–65.5)	–
HCT-CI, median (range)	4 (0–13)	4 (0–13)	–
Graft source	PB (100%)	PB (100%)	–
GVHD prophylaxis	ABA+PTCY+TAC+MMF	ABA+PTCY+TAC+MMF	–
AML diagnosis	47.1%	56.3%	–
CR pre-HSCT	58.8%	50%	–
CR MRD+ AML	23.6%	11.8%	–
High/very high risk	23.5%	10.7%	0.3
Haplo donor	82.4%	85.7%	0.2
Reduced-intensity conditioning	88.2%	93.4%	0.5
Outcomes (overall cohort)			
Median follow-up, months (range)	15.7 (7.4–31.1)		
1-year PFS	66% (95% CI 0.5–0.7)		
1-year OS	72% (95% CI 0.5–0.8)		
1-year relapse CI	16.6% (95% CI 0.07–0.2)		
1-year NRM	23.3% (95% CI 0.12–0.3)		
GVHD outcomes			
aGVHD II–IV day +100	11.7%	10.7%	0.4
aGVHD II–IV day +180	18.5%	32.1%	0.4
Mod–sev cGVHD at 1 year	13.3%	28.9%	0.3
Immunosuppression stopped by day +100	47.1%	7.7%	0.007

The median age of the study population was 63 years (IQR 57–65.5), with a median HCT-CI of 4 (range 0–13). Baseline characteristics were generally balanced between cohorts, although a higher proportion of patients with high or very high disease risk were included in the +56 cohort. All patients received PBSC grafts and uniform GVHD prophylaxis including ABA. Haploidentical donors predominated, and reduced-intensity conditioning regimens were used in the majority of cases. Two patients in the +56 cohort received clofarabine–melphalan due to persistent disease prior to transplant. With a median follow-up of 15.7 months, estimated 1-year progression-free survival and overall survival in the overall cohort were 66% and 72%, respectively. The 1-year cumulative incidence (CI) of relapse was 16.6%, and non-relapse mortality was 23.3% (Table 1). The CI of grade II–IV acute GVHD at day +100 and day +180 was 11.7% vs 10.7% and 18.5% vs 32.1% in the +56 vs non+56 cohorts, respectively, without statistically significant differences. Grade III–IV acute GVHD incidence across the entire cohort was low (2.2% at day +100 and 6.9% at day +180). The CI of chronic GVHD at day +180 and day +365 was 13.3% vs 14.3% and 20.6% vs 28.5% in the +56 vs non+56 cohorts, respectively. Moderate-to-severe chronic GVHD at one year was numerically lower in the +56 cohort. Notably, immunosuppression discontinuation by day +100 was significantly more frequent in the +56 cohort (47.1% vs 7.7%, p=0.007). No ABA-

related adverse events were observed, and neutrophil and platelet engraftment were comparable between cohorts.

Conclusions: In this real-world PBSC allo-HSCT cohort receiving PTCY-based GVHD prophylaxis, the addition of abatacept was associated with low rates of acute and chronic GVHD and favorable overall outcomes. Administration of an additional ABA dose at day +56 enabled earlier immunosuppression discontinuation without an apparent increase in GVHD incidence. These findings support the feasibility of ABA incorporation into PTCY-based platforms and warrant prospective validation.

BELUMOSUDIL FOR ACUTE AND CHRONIC GRAFT-VERSUS-HOST DISEASE: A SINGLE-CENTER REAL-WORLD STUDY OF EFFICACY AND SAFETY

Zhaodong Zhong[1], Yaogong Wu[1], ***Heng Mei***[1]
[1]*Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China*

Background: Graft-versus-host disease (GVHD) remains a serious complication following allogeneic hematopoietic stem cell transplantation. Although corticosteroids serve as the cornerstone of first-line therapy, a considerable proportion of patients require additional treatment due to inadequate response, steroid dependence, intolerance, or the need to preserve graft-versus-leukemia (GVL) effects in high-risk settings. Belumosudil, a selective ROCK2 inhibitor approved for chronic GVHD (cGVHD), promotes immune homeostasis by rebalancing effector and regulatory T-cell responses. Importantly, preclinical studies indicate that inhibition of the ROCK1/2 pathway mitigates acute GVHD (aGVHD) by downregulating dendritic cell costimulation and T-cell trafficking, while notably preserving GVL activity. This mechanistic insight provides a strong rationale for evaluating belumosudil in aGVHD. However, real-world evidence regarding its use in aGVHD, as well as across different lines of therapy for cGVHD, remains limited. This study aimed to assess the real-world effectiveness of belumosudil in a heterogeneous cohort of patients with GVHD.

Methods: In this retrospective study, patients receiving belumosudil for GVHD after allo-HSCT were identified. Data on baseline characteristics, treatment history, clinical outcomes, and safety were collected.

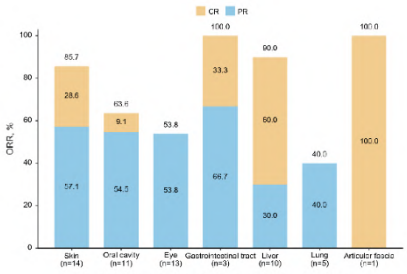

Figure 1. ORR by organ system in the cGVHD population

Results: A total of 32 patients with GVHD were analyzed, with a median follow-up of 9.2 months. The aGVHD cohort (n=8) had high-grade disease (62.5% grade III-IV) with universal gastrointestinal involvement.The cGVHD cohort (n=24) included 15 patients receiving belumosudil as second-line therapy (one prior treatment line) and 9 patients treated in later lines (≥2 prior lines), the latter group exhibiting a higher disease burden (33.3% vs. 20.0% severe cGVHD; median of 3 vs. 2 organs involved). In the aGVHD group, the day-28 overall response rate (ORR) was 100%, with 75% achieving complete response (CR) and a median time to response of 13.5 days; responses were maintained through day 56 in all surviving patients (5/5 CR). 7/8 patients responded in GI-GVHD. Among cGVHD patients, the best overall response rate reached 95.8%, including a CR rate of 16.7%. Notably, response rates were higher in the second-line therapy group (ORR 100%) compared to later-line therapy (ORR 88.9%). Responses deepened over time, with ORR increasing from 90.5% at 3 months to 95.8% at 6 months, and reaching 100% at 9 months among evaluable patients, reflecting sustained therapeutic benefit. All affected organs showed response(figure 1).Median time to response was 21 days, and median duration of response was 220 days (range 120–519). Immunosuppressant dose reductions were achieved in 79.1% of patients. Five fatal events occurred (four in aGVHD and one in cGVHD), all judged unrelated to belumosudil. No grade≥3 treatment-related adverse events were observed.

Conclusions: This study provides the first real-world evidence of belumosudil's efficacy in aGVHD, demonstrating promising therapeutic potential with a 100% day-28 ORR.The findings in cGVHD further validate its robust clinical activity, particularly when used in earlier treatment lines, supported by high response rates and a favorable steroid-sparing profile. The results support that belumosudil is highly effective and well-tolerated in the management of GVHD.

Disclosure: We have no potential conflict of interest and source of funding.

REAL-WORLD SINGLE-CENTER EXPERIENCE OF ANTI-THYMOCYTE/ ANTI-T-LYMPHOCYTE GLOBULINS IN POST-TRANSPLANT CYCLOPHOSPHAMIDE CONDITIONINGS OF HAPLOIDENTICAL AND UNRELATED ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION: SAFETY, EFFICACY, AND ENDOTHELIAL INJURY PROFILE

Eleni Gavriilaki[1,2], *Christos Demosthenous*[1], *Anna Vardi*[1], *Panagiotis Dolgyras*[1], *Paschalis Evangelidis*[2], *Ioannis Papadopoulos*[1], *Ioannis Batsis*[1], *Kyra Panteliadou*[1], *Georgios Karavalakis*[1], *Apostolia Papalexandri*[1], *Grigorios Salvaras*[1], *Nikolaos Spyridis*[1], *Zoi Bousiou*[1], *Ioanna Sakellari*[1]
[1]*George Papanikolaou Hospital, Thessaloniki, Greece,* [2]*Aristotle University of Thessaloniki, Thessaloniki, Greece*

Background: Different types of globulins, such as thymoglobulin (ATG) and Grafalon (ATLG), in combination with post-transplant cyclophosphamide (PTCY), have been incorporated into graft-versus-host disease (GvHD) prophylaxis regimens for haploidentical and unrelated allogeneic hematopoietic cell transplantation (allo-HCT) over the last few years. Nevertheless, no studies have compared the safety and efficacy of ATLG to ATG combined with PTCY in allo-HCT recipients. Moreover, the differential impact of these two agents on endothelial injury markers, such as soluble C5b-9, following HCT remains unexplored.

Methods: Therefore, we prospectively studied consecutive adult patients who underwent allo-HCT from a haploidentical or unrelated donor at our JACIE-accredited centre and received either ATLG (15 mg/kg for 3 days) or ATG (5 mg/kg for 2 days) along with PCTY as GvHD prophylaxis. The following parameters were analyzed: GvHD prophylaxis (ATLG or ATG), age, gender, HCT indication, disease risk index, donor type, endothelial activation and stress index (EASIX) score on the day of HCT, acute (aGvHD) and chronic (cGvHD) development, overall survival (OS), progression-free-survival (PFS), transplant-related mortality (TRM), and GvHD, relapse-free survival (GRFS). Patients' samples for sC5b-9 measurement were collected and stored before ATLG/ ATG administration and post-allo-HCT, and the difference between post and pre-HCT values was compared within the two arms.

Results: We studied 34 allo-HCT recipients (ATLG: 17, ATG: 17). The main indication for HCT in both groups was acute myeloid leukemia [41.2% versus (vs) 41.2%, p=0.66]. ATLG patients were older [median age interquartile range (IQR): 58 (48-63) vs 45 (27-55), p=0.006] and had higher baseline EASIX scores [6.25 (2.8-12.3) vs 1.3 (0.8-1.9), p<0.01]. The remaining clinical pre-HCT characteristics were comparable between the two groups. The 90-day cumulative incidence of aGvHD was 20% [95% confidence interval (95% CI): 0-41] for those treated with ATLG and 29.4% (7–51.8) for ATG patients (p=0.39, Figure 1A). Similarly, the 90-day cumulative incidence of grade≥ II aGvHD was comparable between the two groups [ATLG: 13.3% (0-31.1) vs ATG: 17.6% (0-36.4), p=0.62, 1B]. Regarding cGvHD, the 1-year cumulative incidence was 27.8% (3.6–52) in the ATLG arm and 48.4% (20.2-76.6) in ATG (p=0.37, 1C). Importantly, all cGvHD cases were classified as mild, whereas cGvHD development was correlated with prior aGvHD (p<0.001). Furthermore, we observed

zero prevalence of graft failure. With a median follow-up of 9.7 (6.8-16.2) months [ATLG: 8.5 (6.7-10.3) vs ATG: 15.4 (7.2-23.6), p=0.04], 12-month OS was not statistically different among the two groups (ATLG: 75% (95% CI: 53.5-100) vs ATG: 92.3 % (78.9-100), HR: 2.23, p=0.38, 1D). Similarly, 12-month PFS was comparable (ATLG: 75% (53.5-100) vs ATG: 80.1 (62.2-100), HR: 0.97, p=0.97, 1E). Additionally, the 24-month cumulative incidence of TRM was 7.1% (95% CI: 0-21.1) in the ATLG group and 20% (0–59.2) in ATG (p=0.285, 1F). GRFS was found to be 52.8% (29.8-93.6) in the ATLG cohort and 58.8% (39.5-87.5) in ATG (p=0.66, 1G). The mean sC5b-9 difference was comparable between the two groups [ATLG: 161.4 ($\pm$308) vs ATG: 57.2 ($\pm$152), p=0.54, 1H].

Conclusions: Endothelial injury markers and clinical outcomes were similar between ATLG/ ATG and PCTY, with an excellent survival and safety profile.

ASSOCIATION BETWEEN ORAL CHRONIC GRAFT-VERSUS-HOST DISEASE AND THE GRAFT-VERSUS-LEUKEMIA EFFECT AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION: A PROSPECTIVE, SINGLE-CENTER OBSERVATIONAL STUDY

Nicolas Labrue[1], Ghada Abichou[2], Sami Benachour[2], Rinzine Sammut[2], Thomas Cluzeau[2], Christine Voha[2], ***Michael Loschi***[2]
[1]Institute of Oral and Dental Medicine, Nice, France, [2]Hopital l'Archet, Nice, France

Background: Oral cGVHD compromises quality of life but may reflect the Graft-versus-Leukemia (GVL) effect due to shared T-cell mechanisms. We hypothesized that oral involvement serves as a clinical surrogate for beneficial immune surveillance and improved disease control.Consequently, the study aims to determine if oral cGVHD correlates with improved post-transplant outcomes, such as Overall Survival, Disease-Free Survival and Non-Relapse Mortal.

Methods: We conducted a prospective monocentric study including 54 consecutive patients who underwent allo-HSCT between October 2023 and May 2025. Oral evaluations were performed at pre-transplantation visit and at month +1, +3 +6, and +12 post-transplant. Oral cGVHD was graded according to the NIH Modified Oral Mucosal rating Scale (M-OMRS) consensus criteria by a dental practitioner. Clinical outcomes were compared between patients with and without oral cGVHD. Univariate and multivariate analyses were conducted using standard statistical methods with SPSS 2018 software. To focus on the impact of oral cGVHD, the following patient exclusions occurred post-transplant:frailty, early death, and patient withdrawal/refusal. These exclusions primarily concerned patients who were either too frail to develop sustained chronic GVHD or who did not survive long enough to reach the cGVHD assessment points.

Results:

Graft characteristics	Number (%)
Disease comorbidity	45 (83)
Complete Chimerism	50 (96,2)
Stem cell source Peripheral blood	51 (94,44)

Graft characteristics	Number (%)
Stem cell source cord blood	2 (3,70)
Stem cell source Bone marrow	1 (1,85)
CMV Donor-/recipient+ mismatch	17 (31,44)
Relationship to recipient unrelated	36 (66,66)
Relationship to recipient related	18 (34,34)
MAC	13 (24,07)
RIC	41 (75,99)

Among the 54 patients (median age 57,6 years, sex ratio 1/1) with a median follow up of 15,11 months, 52 (96,3%) developed aGVHD, and 46 (85%) cGVHD, including oral involvement in 35 cases (76%). two cases of oral cGVHD weren't associated with a systemic form. Oral cGVHD scores were mild in 35,1% of the cases, moderate and severe equal at 31,4% of the cases according to the NIH M-OMRS assessment.The most frequency underlying disease was AML in 20 cases and Myelofibrosis in 12 cases. Twenty-four patients were in RC1 state while 15 were RC2, 2 were RC3 and 1 RC4. One patient with myelofibrosis was in partial remission and 11 had a stable disease. At 15 months OS was significantly higher in patients with oral cGVHD compared to those without (100% vs 66%, p=0.01). DFS was also significantly improved (98% vs. 48%, p=0.003). Importantly, oral cGVHD was not associated with increased NRM, at 15 months it was significantly lower in patients with oral cGVHD compared to those without (0% vs. 24%, p=0.002), indicating a strong negative correlation between the presence of oral cGVHD and the incidence of NRM.

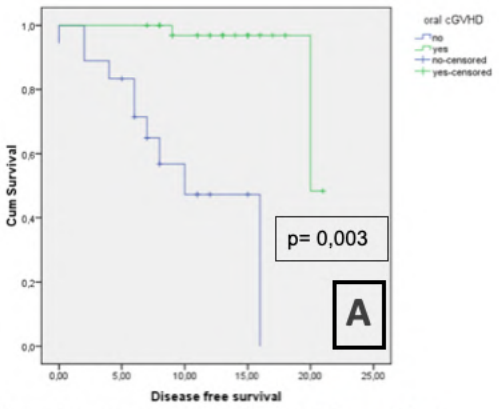

Figure A : Impact of oral cGVHD on Disesase Free Survival

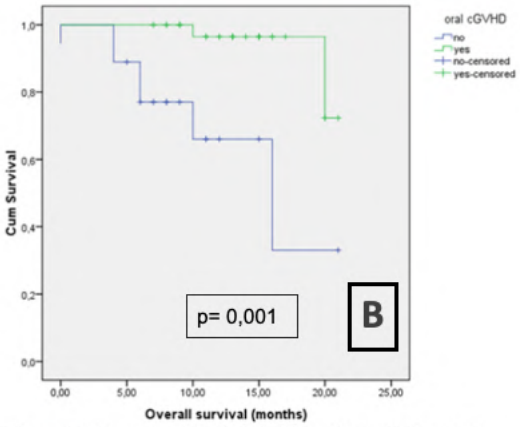

Figure B : Impact of oral cGVHD on Overall Survival

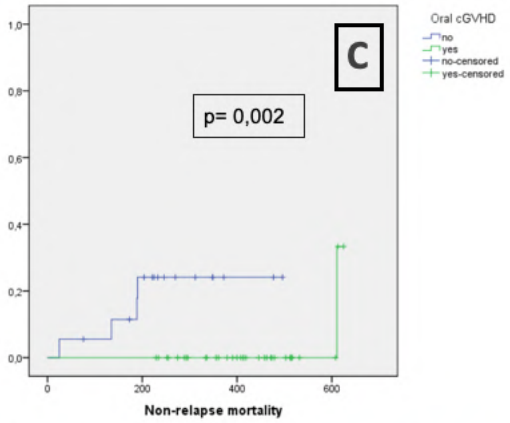

Figure C : Impact of oral cGVHD on Non Relapse Mortality

Conclusions: This prospective study identifies oral cGVHD as a promising proxy for the GVL effect. Crucially, the presence of oral cGVHD correlated with significantly improved OS and DFS, without increasing NRM. these results suggest that mild to moderate oral cGVHD indicates a favorable balanced immune state. This methodology likely contributed to the high incidence of acute GVHD (96.3%) and chronic GVHD (85%) observed in the final cohort, as patients with early, non-relapse mortality (often without established cGVHD) were disproportionately excluded from the primary outcome analysis. The short median follow-up of 15.11 months is a primary limitation of the current data, which requires further validation. Ongoing analyses, including salivary biomarkers and long-term data updates, aim to validate early diagnostic tools and optimize post-transplantmanagement strategies.

THE COMBINATION OF RUXOLITINIB AND EXTRACORPOREAL PHOTOPHERESIS IS A HIGHLY EFFECTIVE SECOND LINE TREATMENT FOR CHRONIC GRAFT-VERSUS-HOST DISEASE

Andrea Varkonyi[1], Marienn Reti[1], Agnes Kiraly[1], Krisztina Jeszenszky[1], Melinda Paksi[1], Viktor Lakatos[1], Alexandra Raska[1], Eva Torbagyi[1], Janos Fabian[1], Laszlo Gopcsa[1], Peter Remenyi[1], ***Nikolett Wohner***[1]
[1]*Central Hospital of Southern-Pest, National Institute of Hematology and Infectious Diseases, Budapest, Hungary*

Background: Allogeneic hematopoietic stem cell transplantation (allo-HSCT) is potentially curative for hematologic malignancies, but its success is limited by graft-versus-host disease (GVHD). Chronic GVHD (cGVHD) affects one third to half of long-term survivors and is a major cause of late non-relapse morbidity and mortality. Standard first-line therapy with prolonged glucocorticoids frequently leads to steroid-refractory (SR) or steroid-dependent (SD) disease and long-tem toxicity. Ruxolitinib is an established second-line agent in SR cGVHD, while extracorporeal photopheresis (ECP) is an effective immunomodulatory option with a relative lack of toxicity and immunosuppression. Both are recommended as preferred second-line therapies, but data on their combined use in larger, well-characterized cGVHD cohorts remain limited. We therefore evaluated the efficacy and safety of combined ECP and ruxolitinib (RUX+ECP) treatment and explored clinical predictors of response.

Methods: We performed a single-center retrospective study of 80 patients with SR or SD cGVHD, treated between 2017 and 2025 at Central Hospital of Southern-Pest, National Institute of Hematology and Infectious Diseases, Department of Hematology and Stem Cell Transplantation, Innovative Cell Therapy Center, Budapest, Hungary. SR cGVHD was defined as progression despite ≥1mg/kg/day prednisone for 1–2 weeks or lack of improvement on ≥0.5mg/kg/day for 1–2 months, SD cGVHD as flare when tapering prednisone below 0.25mg/kg/day. All patients received ruxolitinib 5–10 mg twice daily combined with ECP, initiated twice weekly and then tapered individually. Responses were assessed by NIH consensus criteria as complete response (CR), partial response (PR), or no response (NR). Statistical analyses were performed using GraphPad Prism 10.6.1.

Results: Median age at start of treatment was 45.5 years (IQR 31.25–53). Underlying diseases were predominantly AML (38/80,47.5%) and B/T-ALL (19/80,23.8%). Myeloablative conditioning was used in 59 patients (73.8%) and reduced-intensity conditioning in 21 (26.2%). Donor types included matched unrelated donors in 32 patients (40.0%), HLA-identical related donors in 27 (33.8%), and haploidentical related donors in 21 (26.2%). Overall, 32 patients (40.0%) achieved CR and 36 (45.0%) PR, yielding an overall response rate of 68/80 (85.0%), 12 patients (15.0%) were non-responders. Median time to response was 30 days (IQR 21–60). Neither baseline cGVHD severity (χ^2=0.62, df=2, p=0.73) nor

donor type (χ^2=1.7, df=2, p=0.42) significantly influenced response to RUX+ECP. A prior history of acute GVHD (aGvHD) likewise had no statistically significant impact on response (92.3% vs 81.4% responders without vs with prior aGVHD; χ^2=1.61, df=1, p=0.20; Fisher's exact test p=0.31).

Conclusions: Here we report the largest cohort to date to evaluate the efficacy and safety of RUX+ECP in cGVHD. In this SR or SD cGVHD population, we observed an overall response rate of 85%, which compares favorably with historical cohorts treated with ruxolitinib monotherapy (60–75%). Response rates were consistently high across the patient population, independent of donor types, baseline cGVHD severity or the history of aGVHD, suggesting that the benefit of this combination extends across clinically diverse risk groups. No relevant safety signal emerged. These findings support RUX+ECP as a highly active and broadly applicable second-line strategy in cGVHD and warrant confirmation in prospective, controlled studies.

OUTCOMES IN TCRAB-DEPLETED HAPLOIDENTICAL TRANSPLANTATION WITH UPFRONT CD45RA-DEPLETED MEMORY T-CELL ADD-BACK: ANALYSIS OF 127 ADULTS WITH HEMATOLOGICAL MALIGNANCIES TREATED AT NATIONAL UNIVERSITY CANCER INSTITUTE, SINGAPORE

Victor Wei Teik Ling[1], *Boo Yang Liang*[1,2], *Michelle Limei Poon*[1], *Lip Kun Tan*[1], *Joanne Lee*[1,3], *Evelyn Aun*[1], *Ian Wu*[1,4], *Balamurugan Vellayappan*[1], *Teck Guan Soh*[1,5], *Christopher Thow*[1], *Jamie Chew*[1], *Yin Jie Koh*[1], *Liang Piu Koh*[1]
[1]*National University Cancer Institute, Singapore, Singapore,* [2]*Hospital Sultanah Aminah, Johor Bharu, Malaysia,* [3]*Center for Clinical Haematology, Mount Elizabeth Novena Medical Center, Singapore, Singapore,* [4]*Sengkang General Hospital, Singapore, Singapore,* [5]*KK Women's and Children's Hospital, Singapore, Singapore*

Background: In haploidentical hematopoietic cell transplantation (haplo-HCT), effective prevention of graft-versus-host disease (GVHD) through T-cell depletion (TCD) must be balanced against increased risks of infection and relapse. We hypothesised that combining a TCRαβ-depleted allograft with upfront infusion of CD45RA-depleted memory T cells (αβTCD+T_MDLI) could improve GVHD-free, relapse-free survival (GRFS).

Methods: Mobilized peripheral blood stem cells (PBSC) were separated into two fractions (8-9:1-2 ratio) and depleted using the CliniMACS device (Miltenyi Biotec) with TCRαβ and CD45RA reagents, respectively. Most patients (n=119) received reduced-intensity conditioning comprising fludarabine, thiotepa, and melphalan combined with either total lymphoid irradiation (TLI 6-7.5 Gy; n=22), low-dose total body irradiation (TBI 2 Gy; n=105), or anti-thymocyte globulin (ATG; n=1). Eight patients received alternative

conditioning regimens. GVHD prophylaxis (tacrolimus n=117; sirolimus n=2; MMF n=4) was administered for 30 days post-transplant.

Results: Between 2017-2025, 127 patients (median age 56 years, range 18-75) with high-risk malignancies underwent αβTCD+TMDLI: AML (n=67, 53%), ALL (n=22, 17%), MDS/MPN (n=15, 12%), lymphoproliferative disorders/others (n=23, 18%). The grafts contained median 7.33×10^6 $CD34^+$ cells/kg, 2.06×10^6 $CD3^+CD45RO^+$ memory T cells/kg, 8.2×10^6 $TCR\gamma\delta^+$ cells/kg, with negligible $TCR\alpha\beta^+$ and $CD3^+CD45RA^+$ naïve T cells. Engraftment was robust with median neutrophil and platelet recovery at days 12 (range 7-22) and 11 (range 7-43), respectively. No primary graft failure occurred; two secondary graft failures after day +90 (COVID-19 vaccine-related and sepsis-induced) were successfully rescued with second transplants from different donors. Five patients with high-level donor-specific antibodies achieved successful engraftment after desensitization.
Cumulative incidence (CI) of grade II-IV and III-IV acute GVHD at 180 days was 27.0% (95% CI 19.6-34.9) and 5.5% (95% CI 2.4-10.5), respectively. Two-year CI of chronic GVHD was 6.8% (95% CI 2.9-12.8). At 2 years, non-relapse mortality (NRM) was 18.5% (95% CI 11.9-26.2) and relapse was 15.8% (95% CI 9.3-23.8). With median follow-up of 22 months, the 3-year overall survival, event-free survival, and GRFS were 68% (95% CI 56.9-77.1), 66% (95% CI 55.9-74.3) and 58% (95% CI 47.8-67.0), respectively.
Multivariate analysis identified low/intermediate disease risk index (DRI) and the use of TBI 2Gy as independent prognostic factors associated with superior OS, EFS, GRFS, and lower NRM. Relapse was influenced solely by DRI. Letermovir prophylaxis correlated with improved outcomes in univariate, but not multivariate analysis. Outcomes significantly improved in transplants performed after 2020, coinciding with universal adoption of TBI 2Gy and letermovir prophylaxis.

Conclusions: RIC haplo-HCT using TCRαβ-depleted grafts with upfront CD45RA-depleted memory T-cell achieves reliable engraftment, remarkably low rates of severe acute and chronic GVHD, translating into promising GRFS. Optimal outcomes occur in patients with low/intermediate-risk DRI receiving TBI 2Gy conditioning.

MESENCHYMAL STROMAL CELLS FOR THE TREATMENT STEROID REFRACTORY GRAFT-VERSUS-HOST DISEASE IN CHILDREN

Krzysztof Czyzewski[1], *Joanna Cisek*[1], *Monika Richert-Przygonska*[1], *Robert Debski*[1], *Katarzyna Peszynska-Zelazny*[1], *Lukasz Ledzinski*[2], *Anna Klarkowska*[2], *Jan Styczynski*[1]

Background: Corticosteroids remain the first-line therapy for both acute and chronic graft-versus-host disease (GVHD). However, approximately 50% of patients with acute GVHD are

refractory to high-dose corticosteroids, and 50–60% of patients with moderate to severe chronic GVHD require steroid-sparing treatment strategies. Mesenchymal stromal cells (MSCs) derived from Wharton's jelly represent a therapeutic option for subsequent lines of treatment in steroid-refractory (SR) GVHD. MSCs are multipotent, non-hematopoietic stromal cells with immunoregulatory and immunosuppressive properties mediated through the secretion of cytokines, chemokines, and extracellular vesicles. MSC therapy is generally safe, with a low incidence of adverse events. The aim of this study was to evaluate the safety and efficacy of MSC therapy in pediatric patients with steroid-refractory GVHD based on a single-center experience.

Methods: We performed a retrospective analysis of pediatric patients with steroid-refractory graft-versus-host disease (SR-GVHD) following allogeneic hematopoietic stem cell transplantation (allo-HSCT) who received cryopreserved, commercially available, third-party donor Wharton's jelly–derived mesenchymal stromal cells (WJ-MSCs).

Results: Twenty children (13 boys, 7 girls) with median age 5.3 years (age range 3 months - 16.7 years), diagnosed for ALL (n=6), primary immunodeficiencies (n=6), AML (n=3), MDS (n=1), BMF (n=4: SAA n=2, BDA n=1, FA n=1) recipients of allo-HSCT (10 MUD-PB, 7 MUD-BM, 2 MSD-PB, 1 MSD-BM) were included into the study. In all patients SR-GVHD was diagnosed (15 acute GVHD, grade 2-4: 6-skin+gastro-intestinal, 4-skin, 2-gastro-intestinal, 1-lungs+skin, 1-hepatic+gastro-intestinal, 1-skin+hepatic+gastro-intestinal; 5 chronic GVHD, grade moderate-severe: 2-skin, 1-sclerodermatous, 1-skin+eye, 1 lungs+skin+gastro-intestinal). The total number of 85 MSCs intravenous infusions were performed (median: 3, range: 1-10). The median number of infused MSCs was $1.36x10^6$/kg b.w. (range 0.85-2.99) in 1-4 weeks intervals. In 19/20 patients before MSC administration combined therapy with corticosteroids was performed including 1-3 agent/therapy (ciclosporine, tacrolimus, mycophenolate mofetil, vedolizumab, ruxolitinib, basiliximab, extracorporeal photophereses). The median time from GVHD diagnosis to first infusion of MSC was 96 days (range 15-305 days); 75% (15/20) achieved a response (55% complete response, 20% partial response), while 25% (5/20, all acute GVHD) did not respond to MSC therapy. Overall, 80% (12/15) of patients with complete/partial response are alive (2 patient died due to leukemic relapse, 1 due to infection). Among 5 non-responding patients, 3 died due to GVHD progression, 1 due to infection and 1 due to toxic encephalopathy. In two patients, mild abdominal pain occurred 1-2 days after infusion (not after all infusions). No other adverse events were observed in the other patients.

Conclusions: Cryopreserved Wharton's jelly mesenchymal stromal cells area safe and effective therapeutic option in pediatric patients with steroid refractory acute or chronic GVHD. Overall, 75% of patients achieved clinical response.

BEYOND STATIC SNAPSHOTS: A DYNAMIC PREDICTION MODEL FOR ACUTE GRAFT-VERSUS-HOST DISEASE INTEGRATING SERIAL MEASUREMENTS OF SIX INFLAMMATORY BIOMARKERS

Xiaoyu Zhang[1], *Weihua Zhai*[1], *Qiaoling Ma*[1], *Donglin Yang*[1], *Aiming Pang*[1], *Yi He*[1], *Erlie Jiang*[1], *Mingzhe Han*[1]
[1]*Institute of Hematology & Blood Diseases Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College, Tianjin, China*

Background: Acute graft-versus-host disease (aGVHD) is a life-threatening complication following allogeneic hematopoietic cell transplantation (allo-HSCT), with non-relapse mortality (NRM) rates exceeding 50% in severe cases. This high mortality underscores the urgent need for accurate and timely predictions to guide risk-adapted therapies. Although several prognostic models exist, including clinical grading and biomarker-based tools, they have notable limitations. Therefore, we propose a dynamic prediction model that integrates distinct pathophysiological signals from multiple biomarkers measured serially after transplantation.

Methods: This single-center, retrospective cohort study enrolled patients undergoing HID-HSCT at the Stem Cell Transplantation Center, Institute of Hematology and Blood Diseases Hospital, Chinese Academy of Medical Sciences, between January 2019 and January 2025. Six inflammatory biomarkers—IL-6, IL-8, TNFR1, ST2, REG3α, and Elafin—were measured at three time points: on the day of stem cell infusion (day 0) and on days +7 and +14 post-infusion. The dataset was randomly divided into training and testing sets at a 7:3 ratio. Machine learning (ML) models were developed based on the six biomarkers at different time points, and their performance was assessed. We evaluated a total of twelve ML classifiers, optimizing them via 10-fold cross-validation repeated ten times and grid search. Model performance was assessed using the area under the ROC curve (AUC), accuracy, sensitivity, specificity, and F1-score. Interpretability of the optimal "black-box" model was achieved using SHapley Additive exPlanations (SHAP) to determine global feature importance and provide local explanations for individual predictions.

Results: This retrospective study included 1,278 patients who underwent HID-HSCT and completed biomarker testing. Ultimately, 951 patients were enrolled and completed follow-up. Among the algorithms tested, logistic regression demonstrated the most robust and consistent performance. Predictive accuracy varied over time, with the highest discriminative ability observed on day +7 (AUC=0.78), compared to day 0 (AUC=0.62) and day +14 (AUC=0.51). SHAP analysis revealed distinct, time-dependent biomarker importance: at day 0, REG3α, ST2, and Elafin (reflective of initial tissue damage) were most influential; by day +7, TNFR1, IL-6, and Elafin (indicating systemic inflammation) dominated; and at day +14, IL-8, Elafin, and ST2 (GVHD-associated tissue injury and adaptive immune responses) became primary contributors. This shift underscores the evolving biological processes post-

transplant.

Conclusions: Our study validated a dynamic, time-aware machine learning model for predicting Grade II–IV aGVHD following HID-HSCT using six classic inflammatory biomarkers—IL-6, IL-8, TNFR1, ST2, REG3α, and Elafin—measured at multiple post-transplant time points. By establishing a time-aware modeling framework, this study demonstrates how dynamic biomarker importance reflects physiological transitions after transplantation—from initial tissue injury to subsequent immune activation. Such an approach enables earlier identification of patients at risk, providing clinicians with actionable insights for timely and individualized intervention.

Background: ATG has been reported to improve GRFS in HLA-mismatched unrelated PBSCT; however, its role in BMT remains unclear. We conducted a prospective, randomized, multicenter phase III trial to evaluate the efficacy of adding ATG-Thymoglobulin (ATG-T) to standard GVHD prophylaxis with tacrolimus and methotrexate.

Methods: Patients with hematologic malignancies scheduled to undergo HLA one-locus mismatched unrelated BMT were enrolled. Patients were randomly assigned in a 1:1 ratio to receive standard GVHD prophylaxis with or without ATG-T at a dose of 2.5 mg/kg. The target enrollment was 130 patients; however, only 102 were enrolled, and 97 were eligible for analysis (47 in the ATG-T group and 50 in the control group). The primary endpoint was GRFS.

Results: At one year, GRFS was 42.6% (95% CI, 28.3–57.8) in the ATG-T group and 36.0% (95% CI, 22.9–50.8) in the control group, with no significant difference (P=0.509, Figure 1). The incidence of grade III–IV acute GVHD was 10.6% in the ATG-T group and 12.0% in the control group (P=0.833). The incidence of severe or steroid-requiring moderate chronic GVHD was 14.9% and 14.0%, respectively (P=0.900). The relapse rate was 34.0% (95% CI, 20.9–49.3) in the ATG-T group versus 28.0% in the control group (P=0.520). Overall survival was 78.7% in the ATG-T group and 68.0% in the control group (P=0.233), with no significant difference observed.

Conclusions: Although the target enrollment was not met, limiting the strength of the conclusions, the addition of ATG-T to standard GVHD prophylaxis did not demonstrate improvement in one-year GRFS. No significant differences were observed in secondary endpoints either, suggesting that the impact of low-dose ATG in HLA one-locus mismatched unrelated BMT may be limited.

Background: Calcineurin inhibitor (CNI) based prophylaxis combined with an antimetabolite has been the historical standard for preventing graft-versus-host disease (GVHD) after allogeneic hematopoietic stem cell transplantation (allo-HSCT). Post-transplant cyclophosphamide (PTCy) has reshaped this paradigm decreasing acute and chronic GVHD without impairing overall survival (OS). In parallel, sirolimus has emerged as an effective alternative to CNIs, lowering aGVHD and improving survival outcomes. Therefore, PTCy-

based strategies incorporating sirolimus instead of tacrolimus have generated meaningful interest.

Methods: A multicenter, retrospective study included 445 adult patients undergoing reduced-intensity conditioning allo-HSCT between September`19 and December`22 was performed to compare 3 GVHD-prophylaxis regimens based on: tacrolimus-sirolimus-MMF (G1, n=158), PTCy-CNI-MMF (G2, n=193), and PTCy-sirolimus-MMF (G3, n=94). Outcomes evaluated included overall survival (OS), GVHD-free relapse-free survival (GRFS), incidence of acute and cGVHD, relapse, transplant-related mortality (TRM), and CMV reactivation. To quantify differences for the different outcomes, Cox proportional hazards models were fitted with G1 as reference group. We accounted transplant centre as a clustering factor. Hazard ratios (HRs) therefore represent population-averaged effects with standard errors corrected for intra-centre correlation. Results are reported as HRs with 95% confidence intervals (CI) and two-sided p-values.

Results:

Baseline characteristics were balanced *(Table 1)*, although G3 contained the highest proportion of HCT-CI = 0, and G1 the highest percentage of high/very-high DRI.
Cumulative incidence (CI) of grades II-IV aGVHD were 31% for G1, 27% [HR 0.73 (95% CI 0.60–0.88) p=0.001] for G2 and 28% [HR 0.77 (95% CI 0.53–1.11) p=0.20] for G3. By contrast, no significant diferentes were observed for grades III-IV aGvHD between the different groups with a CI of 14, 15 and 14%, respectively. Similarly, no significant differences were observed in terms of mod/severe cGvHD, with CI of 40% for G1, 37% [HR 1.33 (95% CI 0.81–2.17) p=0.30] for G2 and 28% [HR 0.86 (95% CI 0.69–1.07) p=0.20] for G3. Significantly lower rates of mucositis, CMV reactivation, and hemorrhagic cystitis were observed among patients included in G1.
OS at 3 years was 64% for G1, 67% [HR 0.80 (95% CI 0.59–1.07) p=0.13] for G2 and 62% [HR 0.97 (95% CI 0.72–1.32) p=0.90] for G3, while GRFS at 3 years was 32% for G1, 37% [HR 0.90 (95% CI 0.74–1.09) p=0.30] for G2 and 39% [HR 0.77 (95% IC 0.71–0.84) p<0.001] for G3.
In multivariate analysis, age [HR 1.03 (95% CI 1.01-1.04), p<0.001], HLA mismatched [HR 1.4 (95% CI 1.12-1.74), p=0.003] and unrelated donor [HR 1.31 (95% CI 1.14-1.5), p<0.001] significantly influenced on OS while GvHD prophylaxis: for G2 [HR 0.79 (95% CI 0.76-0.94, p=0.007] and for G3 [HR 0.81 (95% CI 0.70-0.94), p=0.004] together with age [HR 1.01 (95% CI 1.0-1.02), p<0.046], HLA mismatched [HR 1.62 (95% CI 1.15-2.27), p=0.006] and unrelated donor [HR 1.28 (95% CI 1.04-1.56), p<0.017] significantly influenced on GRFS.

Conclusions: As compared to tacrolimus-sirolimus-MMF, the use of PTCy-CNI-MMF and PTCy-sirolimus-MMF decreases the risk of GRFS while increases the risk of mucositis, CMV reactivation, and hemorrhagic cistitis. No differences in terms of survival are observed between these strategies to prevent GvHD.

Disclosure: Nothing to declare

B022

ST2 AND REG3A IN GRAFT VERSUS HOST DISEASE

Dan Le[1], *Joanne Tan*[1,2], *Sridurga Mithraprabhu*[2], *Tiffany Khong*[2], *Andrew Spencer*[1,2]
[1]*Alfred Health, Melbourne, Australia,* [2]*Australian Centre for Blood Diseases, Monash University, Melbourne, Australia*

Background: Serological biomarkers offer a non-invasive way to predict chronic graft-versus-host-disease (cGvHD) occurrence/outcomes. Suppression of tumorigenicity (ST2) and Regenerating islet-derived protein 3-alpha (REG3a) have been shown to predict onset of acute graft-versus-host disease (aGvHD) and correlate with gastrointestinal cGvHD severity at onset. There is little published evidence of their role in predicting cGvHD. ST2 is a member of the interleukin family (IL)-1 receptor family, binding to IL-33 with capacity to regulate its function.1 REG3a is a c-type lectin secreted by Paneth cells, and a biomarker of GI GvHD.2 Our study aims to evaluate the association of ST2/REG3a levels with aGvHD/cGvHD incidence.

Methods: Consecutive patients who underwent elective alloSCT between January 2022 to 2024 were included in this study and were followed up regularly to evaluate for aGvHD/cGVHD. Patient serum was collected on day (D)100 following allogeneic stem cell transplant (alloSCT); ST2/REG3a concentrations were measured using enzyme-linked immunosorbent assay (ELISA). GvHD severity was graded according to Mount Sinai Acute GVHD International Consortium (MAGIC) criteria for aGVHD and National Institutes of Health (NIH) criteria for cGVHD. Data was compared using 2-tailed Welch's t-test and analysed using GraphPad.

Results: 101 patients were analysed during this study period. Table 1 shows patient characterstics. The median follow-up period was 23.8 months. Median time of onset for aGvHD and cGvHD were 51 and 204 days respectively.
ST2 levels at D100 post-alloSCT were elevated in patients with Grade II-IV aGvHD compared to patients with Grade I or less (52682 pg/L versus 37181 pg/L; p=0.004). Therefore, patients with grade II–IV aGVHD were excluded from subsequent analyses of cGVHD outcomes to avoid confounding (n=32). There was no significant difference in D100 ST2 levels between patients with cGVHD and those without cGVHD (33059 pg/L versus 38619 pg/L; p=0.25). D100 ST2 levels were not significantly different between patients with moderate-severe cGVHD and patients unaffected by cGVHD (37221 pg/L versus 38619 pg/L; p=0.84) and those with and without involvement of the gastrointestinal (GI) tract (60532 pg/L; 33399 pg/L; p=0.11).

REG3a levels at D100 did not differ between patients with and without grade II–IV aGVHD (23 ng/L versus 30 ng/L; p=0.27) or between those with and without cGVHD (34 ng/L versus 28.4 ng/L; p=0.61), and were not associated with cGVHD severity (37 ng/L versus 28 ng/L; p=0.55) or gastrointestinal involvement (23 ng/L versus 32.8 ng/L; p=0.45).

	Patients (N)	**Percentage (%)**

Male sex, n, %	70	69.3
Diagnosis, n, %		
Acute leukaemia	60	59.4
Myelodysplastic syndrome	13	12.9
Myeloproliferative neoplasm	13	12.9
Lymphoma	10	9.9
Others	5	5
GVHD prophylaxis, n, %		
Post transplant cyclophosphamide	84	83.2
Methotrexate	9	8.9
Alemtuzumab	5	5
Others	3	3
Acute GVHD, n, %		
Grade 2-4	32	31.7
Chronic GVHD, n, %	23	22.8
Chronic GVHD NIH grade, n, %		
Mild	8	8
Moderate	12	11.9
Severe	3	3

Conclusions: In our study, ST2 and REG3a levels are not associated with subsequent development of cGVHD regardless of GI tract involvement. ST2 in the early-post transplant period correlates with aGVHD in alloSCT recipients, reaffirming it as a credible biomarker in this setting. This could be explained by aGVHD/cGVHD being mediated by different pathophysiology - tissue damage, inflammatory cytokine release and T-cell autoinflammatory activity in aGVHD; tissue fibrosis/sclerosis from self-tolerance loss and autoreactive Th17/B cells activity in cGVHD.3,4
While associations between ST2 and REG3a with cGvHD occurrence were not demonstrated, this may be limited by cohort size. Future studies examining potential linkages between ST2, REG3a and cGVHD should consider the impact of prior aGVHD.

Disclosure: Nothing to declare.

GRAFT-VERSUS-HOST DISEASE IN THE CENTRAL NERVOUS SYSTEM - EMERGING PROBLEM OF MODERN HSCT TECHNOLOGY

Natalia Bronina[1], *Pavel Vlasov*[2], *Maria Natrusova*[1], *Djamila Polatova*[3], *Gleb Bronin*[3]
[1]*Morozov Children's Hospital, Moscow, Russian Federation (the),* [2]*Russian University of Medicine, Moscow, Russian Federation (the),* [3]*Scientific and Practical Medical Center for Pediatric Oncology, Hematology and Immunology, Tashkent, Uzbekistan*

Background: Hematopoietic stem cell transplantation (HSCT) and CAR-T cell therapy are increasingly being used to treat both oncological and non-oncological diseases. The early and late complications of these treatments are also being studied. One important aspect is the recognition of the existence of acute and chronic graft-versus-host disease (GVHD) in the central nervous system (CNS). The aim of this study is to describe and systematize the immune neurological complications of cell therapy in children.

Methods: Retrospective analysis of 444 patient records after HSCT and 21 after CAR-T cell therapy over a 7-year period. The results of clinical, laboratory, and instrumental examinations were reviewed. The study revealed 11 patients with immune neurological complications, aged 2 to 18 years.

Results: Eight patients developed neurological immune complications after HSCT: five before day 100 (45 ± 12.8), which were considered "possible acute CNS-GVHD," and three after day 100 (200 ± 47), considered "chronic CNS-GVHD." The average age of the children was 10.4 ± 2.4; there were five boys and three girls. Two children developed complications after the second HSCT, and one - three months after CAR-T therapy. Six children underwent haploidentical HSCT, one from a matched related donor, and one - from a matched unrelated donor. All patients experienced neurological disorders: seizures (3/8), impaired consciousness (3/8), mental disorders (3/8), focal symptoms (5/8), and eye pain as the only symptom in one child. 6/8 patients had changes in magnetic resonance imaging of the CNS, 3/8 had albuminocytologic dissociation, 5/8 had macrophage activation syndrome, 1/8 had thrombotic microangiopathy, and 1/8 had mixed chimerism. 7/8 children had GVHD affected

organs outside the CNS, grades 2-4. All patients met the criteria for "possible CNS-GVHD". All patients received many lines of immunosuppression for the treatment of CNS-GVHD. Thus, 4/8 patients underwent plasmapheresis, 5/8 received high-dose (2g/kg) intravenous immunoglobulin (IVIG), 5/8 - rituximab and cyclophosphamide, 1 child - etanercept. Three out of eight patients received mycophenolic acid for the long maintenance therapy, one child received IVIG, and one received ruxolitinib. Three patients experienced complete regression of neurological symptoms, while two experienced partial regression. Three patients died: one from non-CNS involvement of GVHD, one from sudden unexpected death in epilepsy (SUDEP), and one from complications of CNS-GVHD. Two patients developed grade 1 immune effector cell-associated neurotoxicity syndrome (ICANS) early after CAR-T therapy, but they had a good clinical response to anti-cytokine therapy. Two children experienced late complications: one developed demyelinating disease (an undulating course, with a partial response to immunosuppressive therapy) after CAR-T and subsequent HSCT; the other developed toxic encephalopathy grade 4 (the child died from complications).

Conclusions: Immune-mediated neurological complications are possible after cell therapy. They significantly worsen outcomes, leading to persistent neurological deficits and, through the need for increased immunosuppressive therapy, indirectly affecting the course of the underlying disease and secondary complications (including infectious ones). Further study of these complications and the development of optimal therapeutic strategies are needed.

Clinical Trial Registry: Not applicable.

Disclosure: No conflict of interest.

Background: The 2014 National Institutes of Health (NIH) criteria for therapeutic response in chronic graft-versus-host disease (cGVHD) assess cutaneous responses using the NIH skin score based on percent body surface area involved and gross changes in sclerotic features.

Clinical or functional improvements in sclerotic skin features following cGVHD treatment may not be captured by the current 2014 NIH criteria for patients with deep sclerosis. In the pivotal, phase 2 AGAVE-201 trial (NCT04710576), axatilimab, a monoclonal antibody targeting colony-stimulating factor 1 receptor, was evaluated among patients with cGVHD after ≥2 prior lines of therapy. Overall efficacy and safety results of the trial were previously reported. The objective of this analysis was to assess improvements in sclerotic skin and associated symptoms after 6 months of axatilimab treatment in AGAVE-201 among patients who would not be considered clinical skin responders per the 2014 NIH criteria.

Methods: This analysis included patients in AGAVE-201 with an NIH skin feature score of 3, documented percent body surface area of sclerosis/fasciitis (sBSA), and clinician-rated 0–10 skin/joint tightening score at baseline and Cycle 7 Day 1 (C7D1). Modified response criteria were developed by the NIH Skin Taskforce (unpublished). Partial response (PR) was defined as ≥20% improvement in current sBSA with ≥10% absolute improvement (or resolution to 0%) and ≥2-point improvement from baseline in skin/joint tightening. Progression was defined as >20% worsening in current sBSA with >10% absolute worsening or ≥2-point worsening from baseline in skin/joint tightening. Stable disease was defined as not meeting response or progression criteria.

Results: In AGAVE-201, 180/193 patients (93.3%) with skin involvement at baseline had sclerotic features and 149 of these patients (82.8%) had a skin feature score of 3, indicating a high degree of sclerotic skin involvement. For this analysis, improvements per the modified response criteria were assessed at C7D1 in all 69 patients who met the inclusion criteria (**Table**). PR per the modified criteria occurred in 5 patients (7.2%), progression in 2 patients (2.9%), and stable disease in 62 patients (89.9%). Assessment of individual response criteria within the PR composite definition demonstrated additional clinical benefit. Improvement of ≥20% in sBSA occurred in 15 patients (21.7%), with ≥10% absolute improvement (or resolution) in 10 patients (14.5%). Improvement of ≥1 point and ≥2 points in skin/joint tightening occurred in 41 patients (59.4%) and 24 patients (34.8%), respectively.

Table. Responses per Modified Criteria and Individual Disease Assessments

Response, n (%)	**Axatilimab 0.3 mg/kg Q2W (n=24)**	**Axatilimab 1 mg/kg Q2W (n=23)**	**Axatilimab 3 mg/kg Q4W (n=22)**	**Axatilimab all doses (N=69)**
Partial response	4 (16.7)	1 (4.3)	0	5 (7.2)
Stable disease	19 (79.2)	21 (91.3)	22 (100)	62 (89.9)
≥20% improvement in sBSA	7 (29.2)	3 (13.0)	5 (22.7)	15 (21.7)

Table. Responses per Modified Criteria and Individual Disease Assessments

≥10% absolute improvement in % sBSA, or resolution	7 (29.2)	1 (4.3)	2 (9.1)	10 (14.5)
≥2-point improvement in skin/joint tightening	10 (41.7)	9 (39.1)	5 (22.7)	24 (34.8)
≥1-point improvement in skin/joint tightening	18 (75.0)	13 (56.5)	10 (45.5)	41 (59.4)
Progression	1 (4.2)	1 (4.3)	0	2 (2.9)

Q2W, every 2 weeks; Q4W, every 4 weeks; sBSA, percent body surface area of sclerosis/fasciitis.

Conclusions: These data demonstrate that axatilimab was associated with sBSA and skin/joint tightening improvement at C7D1 in a subset of patients with sclerotic cGVHD who had a skin feature score of 3 and would not have met the 2014 NIH criteria for clinical response. These data highlight the need for additional, sensitive assessments of treatment benefit in clinical trials for patients with sclerotic cutaneous involvement.

B028

A MODIFIED PEDIATRIC DAY 100 SCORE TO PREDICT MODERATE TO SEVERE CGVHD, TRANSPLANT-RELATED MORTALITY, AND OUTCOME AFTER HEMATOPOIETIC CELL TRANSPLANTATION

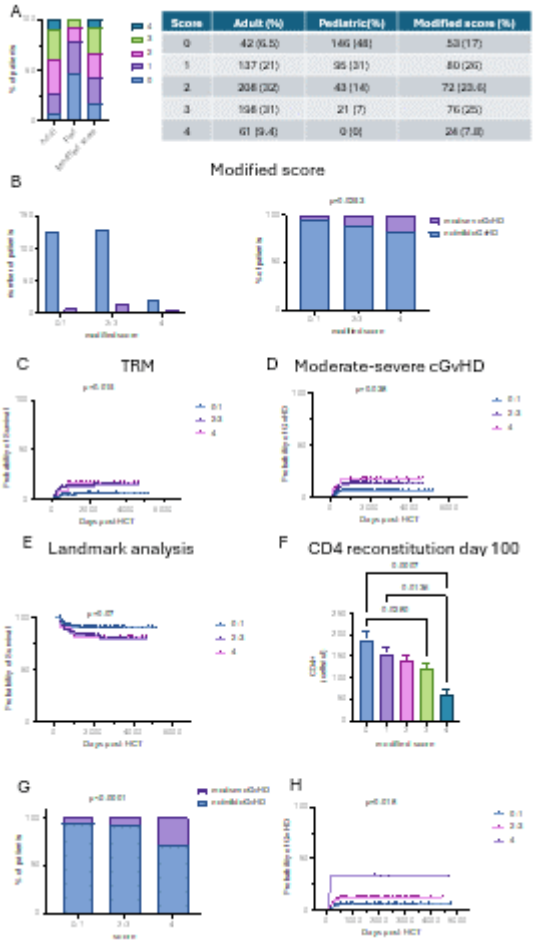
*Silvia Nucera[1], Umberto Gasperoni[2], Violante Gustuti[2], Anita Toso[2], **Sonia Bonanomi**[1], Adriana Balduzzi[1,2], Giovanna Lucchini[1]*
[1]Fondazione IRCCS San Gerardo dei Tintori, Monza, Italy, [2]University Milano Bicocca, Monza, Italy

Background: Chronic graft-versus-host disease (cGVHD) is one of the most devastating complications following HCT in pediatric patients, as it has a profound impact on mortality and long-term quality of life. Classical predictors of cGVHD include HLA matching, donor–recipient age, use of peripheral blood as the stem cell source. However, no patient-specific predictive tool currently exists to estimate the individual risk of developing cGVHD in children. In the adult setting, Metafuni et al. in 2022 validated a simple and practical score that can predict the likelihood of moderate/severe cGVHD at day +100 post-HSCT. This score is based on 4 readouts: gamma-glutamyl transferase (GGT) >75 UI/l, creatinine >1 mg/dl, cholinesterase <4576 UI/l, and albumin <4 g/dl and stratifies patients according to the score: 0-1 low risk; 2-3 intermediate risk; 4 high risk of cGvHD.
We developed a pediatric score derived from the adult model to assess its feasibility and its ability to predict the risk of chronic GVHD in individual pediatric patients.

Methods: We retrospectively studied a cohort of 305 pediatric patients who underwent HCT at Fondazione IRCCS San Gerardo dei Tintori from 2011 to 2025. Composition of the cohort is shown in Table1. To establish the cut-off of albumin, GGT, creatinine and cholinesterase in the pediatric population we used ROC curves as done by Metafuni and colleagues. We exploited the new cut-offs to calculate the score. Patients' outcomes and cGvHD data were then correlated with the score.

Characteristic	Number of patients
Indication for HCT: **-ALL:** **-AML** **-other malignancies**	 -128 -57 -42

-hemoglobinopathies	-25
-metabolic diseases	-20
-aplastic anemia/Fanconi anemia	-23
-other non malignant diseases	-10
Age (median)	9 years (6mo-21 years)
Donor:	
-MSD	-76
-MRD	-8
-MUD 10/10	-107
-MUD 9/10	-62
-MMD	-43
Source:	
-BM	-262
-PB	-39
-CB	-4
Conditioning:	
-Busulfan based	-80
-Fludarabin based	-34
-TBI	-103
-Treosulfan based	-85
GvHD prophylaxis:	
-CSA + MTX	-201
-CSA + MTX + MMF	-24
-CSA + MTX + Rituximab	-26
-CSA, MMF, PTCy	-43
T cell depletion:	
-ATG-G	-89
-ATLG	-118



Results: We first applied the adult score to the pediatric population (Fig1A) but the distribution of the patients was significantly different from the adult cohort. We exploited ROC curves to estimate the proper cut-offs for our cohort: GGT >39 UI/l (AUC 0.54, specificity 0.55 sensitivity 0.55), creatinine >0.55 mg/dl (AUC 0.52, specificity 0.57 sensitivity 0.43), cholinesterase <6225 UI/l (AUC 0.53, specificity 0.53 sensitivity 0.53, and albumin <4 g/dl (AUC 0.46, specificity 0.41 sensitivity 0.53) and with the modified score the distribution of patients is similar to the adult cohort (Fig1A). We then compared the number and percentage of patients that developed moderate/severe cGvHD and we observed that patients with score>2 have a significant increase in cGvHD (Fig1B). Importantly, a score>2 predicts a higher transplant-related mortality (Fig1C) and higher cumulative incidence of cGvHD (Fig1D). In landmark survival analysis (cut-off 225 days, median onset of cGvHD) we observe a trend towards worse overall survival for score >2 (Fig1E). We also observe a significant delay in CD4 T cell reconstitution in patients with score >2 (Fig1F). Finally, we observe that in patients wothout aGvHD (grade 0-1), the score is even more predictive (Fig1G-H).

Conclusions: We demonstrated that this score, appropriately adapted for the pediatric population, reliably identifies patients who, at day +100 post-HSCT, are at higher risk of developing cGVHD and consequently face an increased risk of mortality. This seems

particularly true for patients who do not have prior aGvHD. These results need validation in a larger pediatric cohort. This score could support the implementation of targeted preventive interventions from day +100 for high-risk patients, to mitigate progression to cGVHD.

SERUM CHOLINESTERASE AS A LOW-COST, ROUTINELY AVAILABLE BIOMARKER FOR ACUTE INTESTINAL GRAFT-VERSUS-HOST DISEASE IN CHILDREN

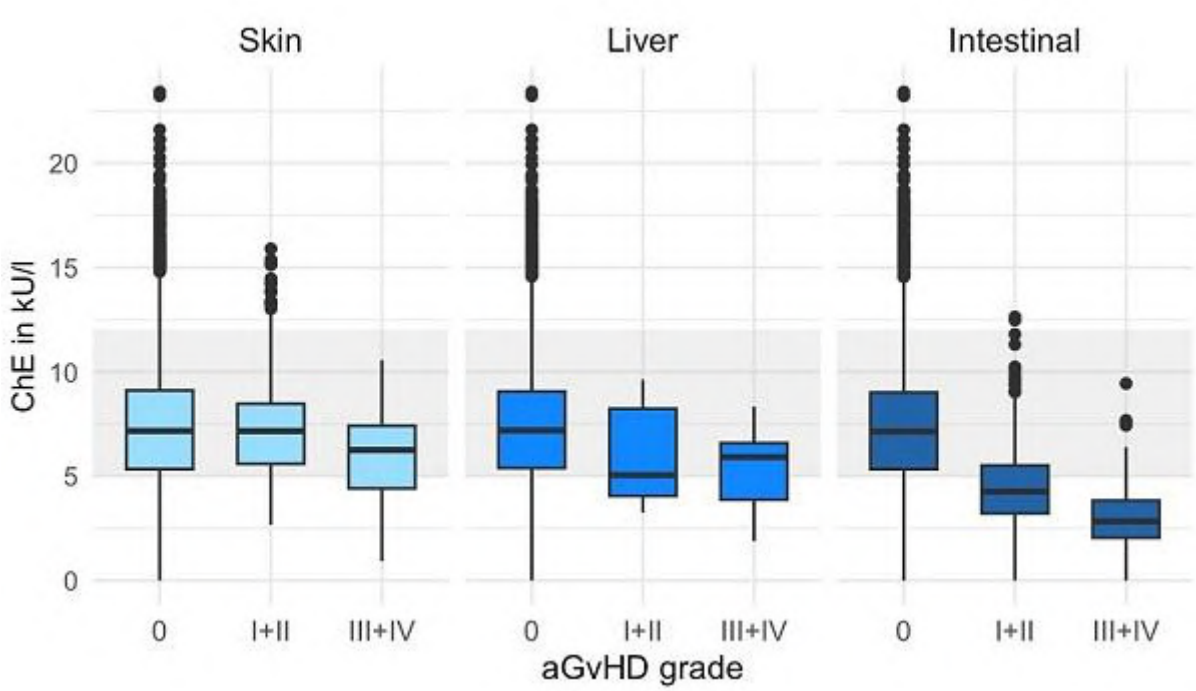
*Katja Gerber[1], **Wiebke Jünemann**[1], Luca Marie Beermann[1], Helena Clara Lichtenfeld[1], Ysabel Alessa Schwietzer[1], Johanna Schrum[1], Ingo Müller[1], Manon Queudeville[1]*
[1]University Medical Centre Hamburg-Eppendorf, Hamburg, Germany

Background: Acute graft-versus-host disease (aGvHD) of the intestine is a dreaded complication following allogeneic stem cell transplantation. Currently, disease severity is determined by stool frequency or volume, parameters that are often difficult to measure in pediatric patients. Early diagnosis and accurate staging are crucial for initiation of therapy, response assessment and timely adjustment of treatment intensity. To support clinical decision making, we sought for a cheap and readily-available biomarker reflecting disease severity in aGvHD of the intestine.

Methods: We evaluated all patients who developed aGvHD after receiving an allogeneic stem cell transplantation at our center between January 2014 and December 2023. Serum levels of albumin, immunoglobulin G (IgG) and cholinesterase (ChE) were measured at least twice a week and the GvHD stages were prospectively documented in the electronic patient records. Files were retrospectively analyzed and the correlation of serum protein values and the severity of aGvHD was analyzed using a cumulative link mixed model as part of a mixed ordinal logistic regression analysis.

Results: In total, 139 patients (32%) developed grade I-IV aGvHD, 33 of whom suffered from intestinal aGvHD. 9756 assessments of GvHD severity were identified in the patient charts and correlated with 7818 measurements of ChE. Patients with intestinal aGvHD displayed a relevant stage-dependent decrease in ChE-levels. Almost all ChE levels of patients with severe intestinal aGvHD were out of normal range, while ChE levels remained largely constant in patients suffering skin or liver aGvHD (Fig. 1). Two other serum proteins, albumin and IgG, showed only a limited decline, as they are supplemented regularly based on predefined thresholds.
The odds of reaching a higher intestinal aGvHD stage was decreased by more than 50% with each rise of ChE by one unit, demonstrating the significant association of a higher ChE-value with a lower score for intestinal aGvHD, with a coefficient in odds of 0.468 (confidence interval 0.444 – 0.493, $p < 0.0001$).

Patients with steroid-responsive intestinal aGvHD showed a rapid increase in ChE concentration after treatment initiation, while patients with steroid-refractory aGvHD continued to show below-normal serum ChE concentration levels for weeks.



Conclusions: We see a correlation between serum ChE levels and the clinical severity of intestinal aGvHD. With every rise in ChE-unit, patients have a significantly reduced risk of being scored into a higher stage of intestinal aGvHD. In patients with response to steroids, ChE levels rapidly normalized under treatment demonstrating that ChE is a potential indicator for treatment response in intestinal aGvHD.
ChE is a commonly available and inexpensive parameter with a short turnaround time. The course of individual ChE levels could be particularly valuable for assessing disease severity changes under treatment in pediatric patients and helpful in deciding whether early therapeutic escalation is necessary or de-escalation possible.
These findings need to be corroborated prospectively by including ChE measurements in a prospective multicenter trial with a pediatric patient cohort at risk for intestinal GvHD, thus validating consecutive ChE measurements as a useful marker for the course of disease in aGvHD.

HUMANIZED ANTI-CD25 MONOCLONAL ANTIBODY FOR GVHD PROPHYLAXIS IN ELDERLY HAPLOIDENTICAL ALLOGENEIC STEM CELL TRANSPLANTATION: A PHASE II STUDY

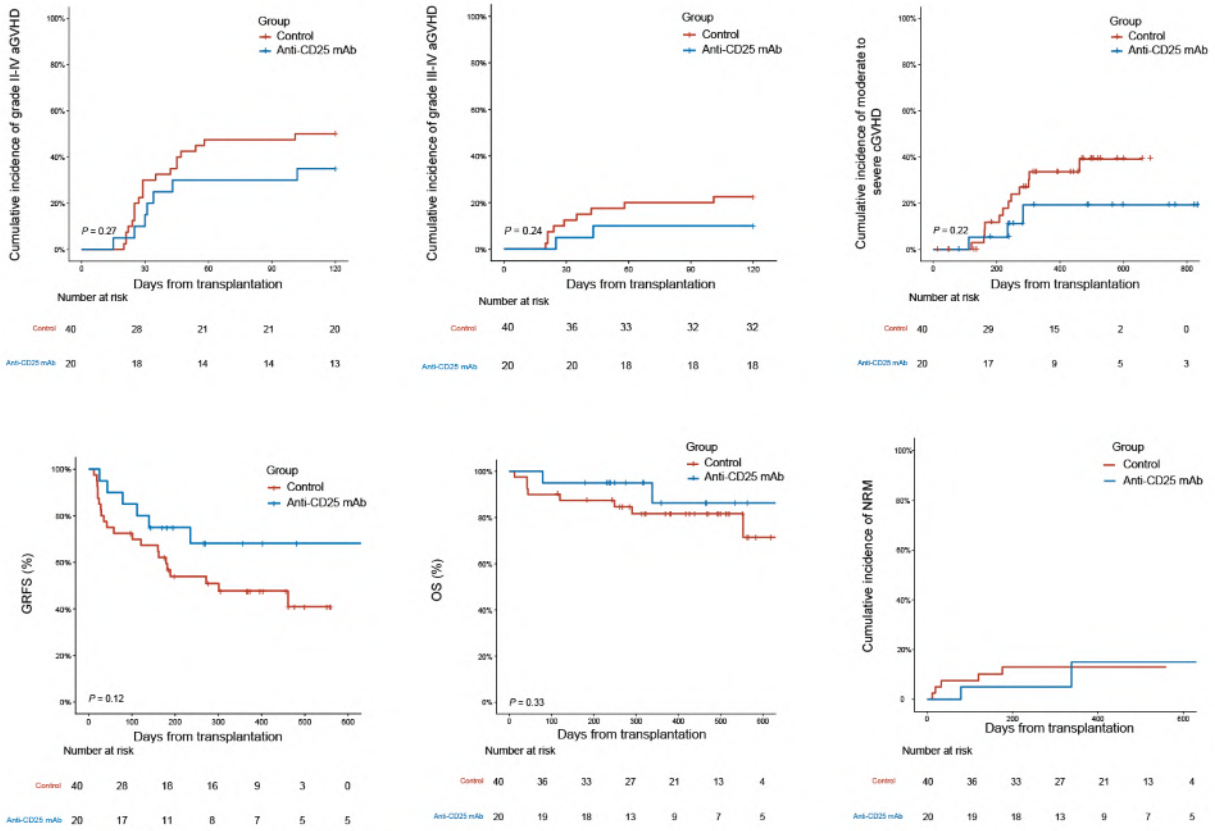
*Runzhi Ma[1], **Xiaoyu Zhang**[1], Qiaoling Ma[1], Weihua Zhai[1], Donglin Yang[1], Aiming Pang[1], Sizhou Feng[1], Mingzhe Han[1], Yi He[1], Erlie Jiang[1]*
[1]Institute of Hematology & Blood Diseases Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College, Tianjin, China

Background: Older age was associated with high risk of aGVHD after allogeneic HSCT, morbidity and mortality attributed to aGVHD was even higher. Optimization of GVHD prophylaxis is essential in elderly haploidentical HSCT. Anti-CD25 monoclonal antibody (mAb) was safe and effective in treating steroid-refractory GVHD. In this prospective, phase II clinical trial, we aim to investigate the efficacy and safety of addition of humanized anti-CD25 mAb in ATG-based GVHD prophylaxis system in elderly patients undergoing haploidentical HSCT (NCT05923814).

Methods: Eligible patients were over 50 years old and undergoing haploidentical allogenic HCT between 2023–2025. A historical control group was established from patients in the same center. Institutional Review Board approval was obtained in accordance with the Declaration of Helsinki. The standard GVHD prophylaxis protocol includes rATG+CNI+short-term MTX+mycophenolate mofetil. Patients in experimental group received humanized anti-CD25 mAb (50 mg/day, +1d, +4d) and reduced rATG (8mg/kg, Thymoglobuline). The control group was administered a standard rATG dose (10mg/kg). The primary endpoint was the cumulative incidence of grade 2–4 acute GVHD by day 100 post-HCT and cumulative incidence of chronic GVHD. Acute GVHD were diagnosed and graded based on MAGIC algorithm. Chronic GVHD were scored based on NIH criteria.

Results: We enrolled 20 patients in CD25 group and 40 patients in control group. Baseline characteristics were balanced between the two groups. The median age was 58 years (range, 50-67) in CD25 group and 56 years (range, 50-66) in control group. Neutrophil engraftment occurred at a median of 14 days vs 16 days respectively, and no adverse effect of early-used CD25 mAb on engraftment was documented. The cumulative incidence of grade 2–4 acute GVHD was 30% for CD25 group and 47.5% for control group (P=0.27). Even no statistical significance was observed, CD25 group showed 17.5% advantage in reducing aGVHD. Furthermore, addition of anti-CD25 reduced the severe grade 3-4 aGVHD incidence by **12.5% (10% vs 22.5%, P=0.24)**. Anti-CD25 prophylaxis group also exhibited lower rate in chronic GVHD requiring systemic immunosuppression (19.3% vs 33.6%, P=0.21). Otherwise, no significant differences were observed in post-HSCT infectious complications, including pneumonia, sepsis, invasive fungal infection, respiratory viral infection, CMV viremia, and EBV viremia. At a median follow-up of 467 days (range:382-519), no patient died of aGVHD in CD25 group, and two patients (10%) died of infection. The causes of deaths in control group was relapse (4/8, 50%), infection (2/8, 25%), acute GVHD (1/8, 12.5%), and hemorrhagic stroke (1/8, 12.5%). The CD25 group showed potentially improved one-year GRFS **(**68.2**% vs 40.9%)** with a **27.3%** advantage. No significant

difference was observed in one-year OS (86.4% vs 81.7%), one-year NRM (15% vs 13%) and one-year relapse incidence (5% vs 9%).



Conclusions: Our study revealed that the addition of short-course anti-CD25 prophylaxis (day +1, +4) in the rATG system proved feasible and safe. However, we did not observe its significant advantage in reducing severe acute or chronic GVHD. The benefit of extensive administration of anti-CD25 mAb warrants further investigation.

[1]*Department of Stem Cell Transplantation, University Medical Center Hamburg-Eppendorf, Hamburg, Germany,* [2]*Dipartimento di Scienze Mediche e Chirurgiche, Università di Bologna, Bologna, Italy,* [3]*IRCCS Azienda Ospedaliero-Universitaria di Bologna, Istituto di Ematologia "Seràgnoli", Bologna, Italy*

Background: Allogeneic stem cell transplantation (allo-SCT) is a curative strategy for hematological malignancies but remains limited by graft-versus-host disease (GVHD). In matched unrelated donor (MUD) transplantation, in vivo T-cell depletion with anti-thymocyte globulin (ATG; Thymoglobulin®) or anti-T-lymphocyte globulin (ATLG; Grafalon®) is widely used for GVHD prophylaxis, although optimal dosing strategies remain undefined. While several studies have demonstrated that recipient absolute lymphocyte count (ALC) influences ATG exposure and clinical outcomes, corresponding data for ATLG are lacking. We therefore evaluated the prognostic impact of ALC at ATLG initiation in two independent cohorts receiving a fixed ATLG dose.

Methods: This retrospective two-center study included 368 adult patients undergoing first 10/10 MUD peripheral blood stem cell transplantation, comprising a University Medical Center Hamburg-Eppendorf (UKE) cohort (n=251) and a University Hospital of Bologna cohort (n=117). All patients received a fixed cumulative ATLG dose of 30 mg/kg (Grafalon®), administered according to center-specific schedules (UKE: test dose on day -4 followed by fractionated dosing until day -1; Bologna: five equal doses from day -6 to day -2). Patients were stratified into low- and high-ALC groups based on the median ALC at the first ATLG dose; ALC was also analyzed as a continuous variable. Endpoints included acute and chronic GVHD, non-relapse mortality (NRM), relapse, overall survival (OS), progression-free survival (PFS), and GVHD-free, relapse-free survival (GRFS).

Results: Median ALC at ATLG initiation differed significantly between centers (UKE: 0.23 × 10^9/L; Bologna: 0.70 × 10^9/L). ALC was not associated with the incidence of acute or chronic GVHD or with GRFS in either cohort and showed no consistent association with OS, PFS, or NRM. In the UKE cohort, 1-year acute GVHD grades II–IV incidence was 33% versus 38% (p=0.40), and 1-year GRFS was 37% versus 36% (p=0.59) for low versus high ALC, respectively. Corresponding values in the Bologna cohort were 19% versus 14% for acute GVHD (p=0.80) and 58% versus 59% for GRFS (p=0.69). Divergent associations were

observed for relapse: in the UKE cohort, higher continuous ALC was associated with increased relapse incidence (sHR 1.20, p=0.034), whereas in the Bologna cohort, higher categorical ALC was associated with a lower 1-year relapse incidence (7% vs. 23%, p=0.03).

Conclusions: ALC on the first day of ATLG administration does not represent a consistent prognostic biomarker across centers when a fixed cumulative dose of 30 mg/kg is used. In the Bologna cohort, the association between higher ALC and lower relapse incidence is biologically plausible and compatible with a pharmacodynamic model in which higher recipient lymphocyte counts bind more ATLG, resulting in reduced effective immunosuppression and preserved graft-versus-leukemia activity. In contrast, the opposite association observed in the UKE cohort appears more likely influenced by center-specific factors and residual confounding. Nevertheless, the biological rationale for ALC-guided and schedule-optimized ATLG dosing remains compelling, and earlier administration when lymphocyte counts are higher may optimize exposure. Prospective studies integrating pharmacokinetic monitoring with harmonized administration schedules are required to define optimal ATLG dosing strategies.

B033

SAFETY AND FEASIBILITY OF 0.6 MG/KG EVERY 4 WEEKS DOSING OF AXATILIMAB IN PATIENTS TREATED IN THE AGAVE-201 STUDY

*Nosha Farhadfar[1], **María Sola Soto**[2], Saurabh Chhabra[3], Valkal Bhatt[4], Emily Andersen[4], Zhenyi Xue[4], Zachariah DeFilipp[5]*
[1]Sarah Cannon Transplant & Cellular Therapy Program, Methodist Hospital, San Antonio, TX, United States of America (the), [2]Hospital Universitario Vall d'Hebron, Barcelona, Spain, [3]Mayo Clinic College of Medicine and Science, Phoenix, AZ, United States of America (the), [4]Incyte Corporation, Wilmington, DE, United States of America (the), [5]Hematopoietic Cell Transplant and Cellular Therapy Program, Massachusetts General Hospital, Boston, MA, United States of America (the)

Background: Axatilimab, a monoclonal antibody targeting colony-stimulating factor 1 receptor, is approved by the US Food and Drug Administration at a dose of 0.3 mg/kg (up to a maximum dose of 35 mg) every 2 weeks (Q2W) for patients with chronic graft-versus-host disease (cGVHD) after ≥2 prior lines of therapy, based on results from the pivotal AGAVE-201 study (NCT04710576). Patients treated with axatilimab 0.3 mg/kg Q2W in AGAVE-201 were able to transition to 0.6 mg/kg every 4 weeks (Q4W) dosing based on the investigator's discretion and per study protocol criteria. The objective of this analysis was to describe the safety and feasibility of transition from axatilimab 0.3 mg/kg Q2W to 0.6 mg/kg Q4W dosing in AGAVE-201.

Methods: Patients treated with axatilimab 0.3 mg/kg Q2W in AGAVE-201 who had their Cycle 7 assessment and achieved a partial or complete response per National Institutes of

Health criteria that was sustained for ≥20 weeks or had not progressed were able to change their dosing schedule to 0.6 mg/kg Q4W (without dose capping) per the study protocol and investigator discretion. Patients who received additional systemic therapies were excluded from this post hoc analysis. The data cutoff was March 30, 2025.

Results: In the first 6 treatment cycles, 59 of the 80 patients (73.8%) randomized to axatilimab 0.3 mg/kg Q2W had a response to treatment, 19 of whom (32.2%) transitioned to 0.6 mg/kg Q4W dosing. Overall response rate in the first 6 treatment cycles among the 19 patients who switched to 0.6 mg/kg Q4W was 94.7% (95% CI, 74.0%–99.9%); 1 patient with stable disease was eligible to switch, per investigator discretion. Patients were on treatment for a median (range) of 20.9 (2–32) months after switching doses, and 16 of 19 patients (84.2%) maintained the 0.6 mg/kg Q4W dose. The safety with axatilimab was generally similar before and after the dosing change. With 0.6 mg/kg Q4W, 10 patients (52.6%) had grade ≥3 treatment-emergent adverse events (TEAEs); pneumonia was the only grade ≥3 TEAE reported in >1 patient (n=2). TEAEs led to treatment interruptions in 4 patients (21.1%) and discontinuations in 3 patients (15.8%) after switching. The most common TEAEs after switching were fatigue and upper respiratory tract infection (each n=5 [26.3%]); 1 patient (5.3%) had an infusion-related reaction (rash). Incidences of on-target TEAEs were generally similar before and after the switch, including elevations in alanine aminotransferase (n=3 before, n=1 after) and amylase (n=0 before, n=1 after).

Conclusions: Transition to 0.6 mg/kg Q4W (without dose capping) is feasible and well tolerated in patients treated with axatilimab 0.3 mg/kg Q2W in AGAVE-201. The Q4W dosing strategy at the 0.6 mg/kg dose identified no new safety signals. Patients had a prolonged treatment duration (median, 20.9 months [1.7 y]), and 84% of patients continued treatment, suggesting ongoing clinical benefit. These data show the safety and feasibility of 0.6 mg/kg Q4W dosing in alignment with the AGAVE-201 protocol.

ASSESSMENTS OF BONE HEALTH AMONG PATIENTS WITH CHRONIC GRAFT-VERSUS-HOST DISEASE RECEIVING AXATILIMAB IN THE AGAVE-201 TRIAL

Doris M. Ponce[1], *Gabriela B. Thoennissen*[2], *Jordan Fortunato*[3], *Zhenyi Xue*[3], *Amandeep Salhotra*[4]
[1]*Memorial Sloan Kettering Cancer Center, New York, NY, United States of America (the),* [2]*Incyte Biosciences International Sàrl, Morges, Switzerland,* [3]*Incyte Corporation, Wilmington, DE, United States of America (the),* [4]*City of Hope National Medical Center, Duarte, CA, United States of America (the)*

Background: Bone mineral density (BMD) loss is a common complication of allogeneic hematopoietic stem cell transplantation, often related to pretransplantation chemotherapy, radiation exposure, and immunosuppressive therapy for chronic graft-versus-host disease (cGVHD). BMD loss results from gonadal hormonal deficiencies, disturbances in calcium and vitamin D homeostasis, and osteoblast and osteoclast dysfunction. Colony-stimulating factor 1 (CSF-1), a CSF-1 receptor (CSF-1R) ligand, is a key regulator in bone-remodeling pathways, as shown in CSF-1–knockout and CSF-1–deficient mice, which present with severe skeletal phenotypes. Axatilimab is a high-affinity monoclonal antibody that targets CSF-1R signaling to deplete monocytes and macrophages, key drivers of inflammation and fibrosis in patients with cGVHD. Thus, the potential effects of axatilimab on bone health are of clinical interest. The objective of this analysis is to evaluate bone-health associated parameters in patients with refractory cGVHD who received axatilimab in the pivotal, phase 2 AGAVE-201 trial (NCT04710576).

Methods: In AGAVE-201, patients were randomized to intravenous axatilimab 0.3 mg/kg every 2 weeks (Q2W), 1 mg/kg Q2W, or 3 mg/kg every 4 weeks (Q4W). Bone turnover markers, specifically bone-specific alkaline phosphatase (BAP) and C-telopeptide of cross-linked type 1 collagen (CTX), were assessed at baseline, throughout treatment, and at treatment end. Changes in bone biomarkers were summarized using descriptive statistics. The data cutoff was March 30, 2025.

Results: Of the 241 patients enrolled, 239 received axatilimab (0.3 mg/kg Q2W, n=79; 1 mg/kg Q2W, n=81; 3 mg/kg Q4W, n=79). Among all 241 patients, the median (range) baseline age was 53 (7–81) years; 151 patients (62.7%) were male, and median (range) follow-up was 31.2 (0–46.5) months. Prior bone-related medications included vitamin D (50.6%), calcium combinations (14.9%), calcium (13.7%), bisphosphonates (11.6%), and calcium carbonate (1.7%). Concomitant bone-related medications included vitamin D (56.8%), calcium combinations (19.1%), bisphosphonates (18.3%), calcium (17.8%), and calcium carbonate (2.9%). Concomitant corticosteroid use at baseline was reported in 65.3% of patients, with a mean daily dose of 19.4 mg. Bone-related medical conditions in patients' medical histories included osteoporosis (19.5%), osteopenia (16.2%), osteonecrosis (7.9%), osteoarthritis (4.1%), bone pain (1.2%), osteolysis, osteoporotic fracture (both 0.8%), bone fissure, bone surgery, decreased bone density, osteochondrosis, and osteosclerosis (each 0.4%). Changes from baseline in BAP and CTX at Cycle 6 Day 1 and end of treatment were

minimal (Table). Across all doses, bone-related treatment-emergent adverse events (TEAEs) were grade 1 or 2 and included osteopenia (n=6 [2.5%]), osteoarthritis (n=5 [2.1%]), bone pain, osteonecrosis (both n=4 [1.7%]), musculoskeletal pain (n=2 [0.8%]), bone infarction, coccydynia, increased vitamin D, and osteochondroma (each n=1 [0.4%]). Fractures of any grade occurred in 17 patients (7.1%), with ≥2 fractures occurring in 3 patients (1.3%).

Table. Baseline and Changes in Bone Biomarkers Among Patients in AGAVE-201

		Axatilimab 0.3 mg/kg Q2W (n=79)		Axatilimab all doses (N=239)	
Parameter	Visit	n	Mean (SE)	n	Mean (SE)
BAP, U/L	Baseline	77	27.1 (3.08)	233	26.2 (1.47)
	Change from baseline to C6D1	53	0.9 (1.08)	135	−0.2 (1.52)
	Change from baseline to EOT	32	−1.0 (2.07)	110	−0.4 (0.88)
CTX, µg/L	Baseline	77	0.4 (0.04)	233	0.4 (0.02)
	Change from baseline to C6D1	53	−0.0 (0.03)	136	−0.1 (0.02)
	Change from baseline to EOT	33	−0.0 (0.05)	112	−0.1 (0.02)

BAP, bone-specific alkaline phosphatase; C6D1, Cycle 6 Day 1; CTX, C-telopeptide of cross-linked type 1 collagen; EOT, end of treatment; Q2W, every 2 weeks.

Conclusions: In AGAVE-201, axatilimab was associated with minimal changes in bone turnover markers in patients with cGVHD. Bone-related TEAEs were rare, with only a small number of patients having multiple fractures; this is notable given that 65.3% of patients received concomitant corticosteroids. These findings may indicate that axatilimab had minimal effects on bone metabolic markers, although additional analyses, including bone density measurements in this population with refractory cGVHD, are needed.

Background: Acute and chronic graft-versus-host disease (aGvHD, cGvHD) represents a major cause of morbimortality after allogeneic hematopoietic cell transplant (Allo-HCT). After steroid failure, ruxolitinib represents a standard of care in steroid-refractory or dependent-GvHD (SR/SD-GvHD), in acute and chronic. However, the prognosis and clinical management of patients resistant or intolerant to second-line (2L) ruxolitinib is uncertain.

Methods: This retrospective study included patients from EBMT centers within the Spanish Group of Hematopoietic Stem Cell Transplantation and Cellular Therapy. Inclusion criteria: 1) patients undergoing allo-HCT; 2) diagnosed with acute or chronic SR/SD-GvHD, 3) failure (resistance or intolerance) to 2L ruxolitinib. The primary endpoint was the overall response rate (ORR) after third-line (3L) treatment. Secondary endpoints were overall survival (OS) and non-relapse mortality (NRM).

Results: Sixty-six patients treated with ruxolitinib 2L were included. Patients underwent Allo-HCT between 2008-2022. Table 1 summarises patient's characteristics.

Thirty patients were diagnosed with SR/SD-aGVHD and received ruxolitinib as a 2L. The gut was the most affected organ with score 3-4 (18 patients, 60%), followed by the skin (6; 20%), and the liver (4; 13%). Ruxolitinib discontinuation was due to GVHD progression (11 patients; 37%), suboptimal response (7; 23%), infection (2; 7%), toxicity (1; 3%), other reasons (3; 11%) and death (4; 13%). Out of 30 patients, 23 received a 3L, which consisted on extracorporeal photopheresis (ECP) (7 patients; 23%), infliximab (4; 13%), mesenchymal stromal cells (MSC) (3; 10%), vedolizumab (2; 6%), fecal microbiota transplantation (2; 6%) and five patients other therapies. The 28-day ORR after 3L was 33%, including 6 patients (20%) with CR and 4 (13%) with PR. Twenty-six patients (86%) died during the study period. The most common cause of death was GVHD progression (12 patients; 46%). With a median OS of 4 months, the estimated 3-month OS was 58.6% (95%CI 40.8%-76.4%); and the 2 year NRM was 82%.
Regarding SR/SD-cGVHD, 36 patients received ruxolitinib as a 2L. Skin (23 patients; 63%), liver (13; 36%) and ocular (13; 36%) were the most frequently affected organs at cGvHD diagnosis. The most common cause of ruxolitinb discontinuation was no response in 19 patients (53%). Twenty-six patients received a 3L, which consisted on ECP (11; 42%), mTOR inhibitor (6; 19%), calcineurin inhibitors (3; 11%), MSC (1; 4%), alpha 1-antitrypsin (1; 4%), T regulatory cells (1; 4%), belumosudil (1; 4%), and other therapies in 2 patients. Out of 26 patients, 18 (69%) were evaluable for response. The 6-month ORR after 3L was 66%, including 3 patients (16%) with CR and 9 patients (50%) with PR. Thirteen patients died during the study period. The most common cause of death was infection (8; 61%). With a median follow up of 4 years, the estimated 2 year-OS was 79,7% (95% CI 66.2%-93.2%) and the 2-year NRM was 23% (95%CI 9.2%-37.4%).

SR/SD-aGVHD, *n* (%) MAGIC score 3 MAGIC score 4	30 (45%) 14 (47%) 8 (27%)
SR/SD-cGvHD, *n* (%) NIH score moderate NIH score severe	36 (55%) 12 (33%) 18(50%)

N number, *MDS* myelodysplastic syndrome, *MPN* myeloproliferative neoplasm, *MAC* myeloablative conditioning, *RIC* reduced intensity conditioning, *MRD* matched related donor, *MUD* matched unrelated donor, *MMUD mismatched unrelated donor, GVHD* graft-versus-host disease, *CNI-based* calcineurin inhibitor based, *PT-Cy* Post-Transplant Cyclophosphamide, *MAGIC* Mount Sinai Acute GVHD International Consortium, *NIH score* National Institutes of Health Consensus score.

Conclusions: This nationwide cohort shows that, aGvHD patients failing to 2L ruxolitinib associate with low response rates (33%) and dismal survival. Conversely, cGvHD patients failing to 2L ruxolitinib associate with an encouraging ORR >60%. The advent of novel therapies for cGvHD could help to improve these outcomes.

IMPACT OF POST-TRANSPLANT CYCLOPHOSPHAMIDE DOSE REDUCTION ON THE INCIDENCE OF COMPLICATIONS AND RELAPSE AFTER ALLOGENEIC TRANSPLANTATION

María Panizo-Inogés[1], *Belén Villacres*[1], *Almudena Beneto*[1], *Andrea Urtasun*[1], *Sara Villar*[1], *José Rifón*[1]
[1]*Clínica Universidad de Navarra, Pamplona, Spain*

Background: Graft-versus-host disease (GVHD) is one of the main complications of allogeneic hematopoietic stem cell transplantation (allo-HSCT), significantly affecting morbidity, mortality, and quality of life. Post-transplant cyclophosphamide (PTCy) has been established as an effective strategy for GVHD prophylaxis. However, the standard dose (100 mg/Kg) may be associated with delayed engraftment, a higher risk of infections, and other complications such as thrombotic microangiopathy (TMA) or sinusoidal obstruction syndrome (SOS). A reduced cyclophosphamide dose (80 mg/Kg) has been evaluated in terms of efficacy and safety in several studies, both with matched and alternative donors. The objectives were to evaluate the efficacy and safety of reducing the post-transplant cyclophosphamide dose to 80 mg/Kg as a strategy for GVHD prophylaxis in matched and alternative donors.

Methods: A retrospective observational study was conducted in a cohort of 200 patients who underwent allo-HSCT at Clinica Universidad de Navarra between February 2016 and May 2025. Two groups were compared according to the PTCy dose administered: standard dose (100 mg/Kg) and reduced dose (80 mg/Kg). All patients had a minimum follow-up of 6 months, and relevant clinical and laboratory data were collected. Statistical analysis was performed using STATA v12.

Results: Baseline characteristics are shown in Table 1. Of the 200 patients included, 130 (65%) received the standard dose and 70 (35%) received the reduced dose.
Reduced-dose PTCy showed no significant association with engraftment (OR 0.94, p=0.92), nor with MAT (OR 1.52, p=0.55), SOS (0.56 p=0.31) or relapse (OR 0.70, p=0.40).
Similarly, reduced-dose PTCy was not significantly associated with acute GVHD of any grade (OR 0.78; p=0.41) nor clinically relevant acute GVHD (grade ≥2) (OR 0.57; p=0.13). In contrast, reduced-dose PTCy was significantly associated with a lower risk of chronic GVHD (OR 0.22; 95% CI 0.08-0.60; p< 0.01).
Regarding hemorrhagic cystitis, a lower incidence was observed in patients receiving reduced-dose PTCy compared with standard-dose PTCy (18.6% vs. 30.8%), although this association was not statistically significant (OR = 0.51; p=0.06).
Reduced-dose PTCy was associated with a significantly lower likelihood of CMV reactivation compared with the standard dose (OR 0.16; 95% CI 0.08–0.30; p<0.01). Overall, 56% of patients (n=111) received CMV reactivation prophylaxis with letermovir. In the multivariable logistic regression model, both letermovir prophylaxis (OR 0.30; 95% CI 0.14–0.63; p < 0.01) and reduced-dose PTCy (OR 0.34; 95% CI 0.15–0.75; p < 0.01) were independently associated with a lower likelihood of CMV reactivation.

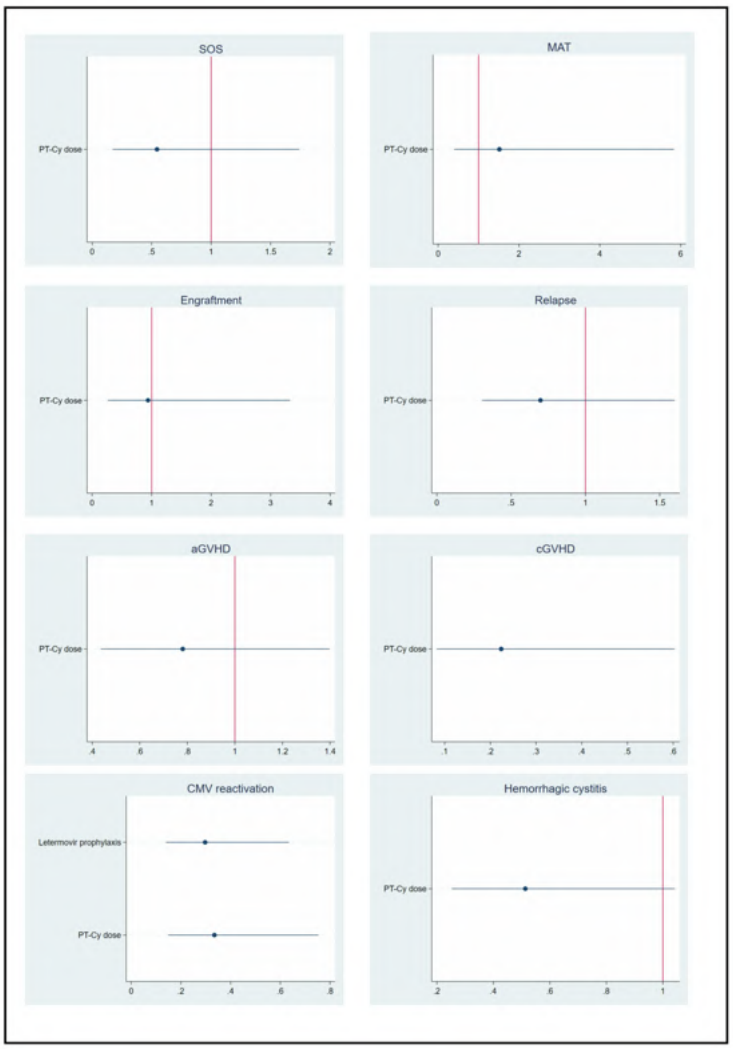
Conditioning regimen AMA AIR	 78 (60) 52 (40)	 53 (76) 17 (24)	 131 (66) 69 (34)	0.03
Preconditioning EASIX score, median (IQR)	0.71 (0.36-2.21)	0.81 (0.44-1.82)	0.74 (0.40-1.96)	0.53



Conclusions: The reduced PTCy dose appears to be an effective and safe strategy, lowering the risk of CMV reactivation and chronic GVHD without increasing relapse or other adverse

events. It also showed a trend toward reduced hemorrhagic cystitis, although this did not reach statistical significance, likely due to limited sample size.

Disclosure: The author declares no conflicts of interest related to this work.

Background: Chronic Graft-versus-Host disease (cGvHD) remains a leading cause of morbidity and mortality after allogeneic Haematopoietic Stem Cell Transplantation (allo-HSCT). Genital location affects both sexes, but in women it is underdiagnosed and causes more sexual dysfunction. The added presence of physiological changes due to Premature Ovarian Failure (POF) further compound sexual morbidity, as several symptoms overlap with those of genital cGvHD.
The study aimed to assess the incidence of genital GvHD and to evaluate potential delays in its diagnosis compared with oral cGvHD.

Methods: This retrospective, single-center observational study included 121 consecutive female recipients of allo-HSCT treated between January 2011 and March 2022. The study was censored at 4.4 years, as this corresponds to the latest time point at which genital cGVHD developed in the series.Consequently, all patients who did not reach this follow-up duration and had not developed genital cGVHD were excluded from the analysis (36 of 121 in total). Statistical analyses were therefore performed on a cohort of 85 patients, whose clinical and demographic characteristics are detailed in Table 1.

Table 1. Baseline characteristics of patients analyzed with and without cGvHD

Survival Lives Dead	12 (92%) 1 (7,7%)	40 (56%) 32 (44%)	0,012

Results: After a median follow-up of 3.1 (range, 0.8–6.9),13 of 85 evaluable patients (15%) developed genital cGvHD, with a median time from HCT to diagnosis of 28 months (IQR, 4.7–55.3), whereas oral cGvHD was diagnosed earlier, at a median of 8.2 months (IQR, 3.4–48.9).
In multivariable analysis, oral cGvHD, premature ovarian failure (POF), and myeloablative conditioning were independently associated with the development of genital (Figure 1A).Genital cGvHD severity was also significantly associated with POF (p = 0.02): 89% of

patients with severe genital cGvHD had POF, compared with 25% of those with mild disease (Figure 1B).

Survival analyses demonstrated that patients who developed cGvHD had a significantly higher overall survival compared with those who did not (p = 0.02; Figure1C). Stratification by disease severity revealed a higher probability of survival among patients with mild cGvHD (p = 0.037; Figure 1D). When analyses were restricted to genital involvement, patients with genital cGvHD also exhibited superior overall survival (p = 0.022; Figure 1E).

A

Genital cGvHD

VARIABLES	*Odds Ratio*	*CI*	*p*
Myeloablative conditioning regimen	6.2394	0.9380-124.8153	0.1062
cGvHD	6.0033	1.5244-28.0619	0.0140
POF	4.3851	1.0304-23.8308	0.0585

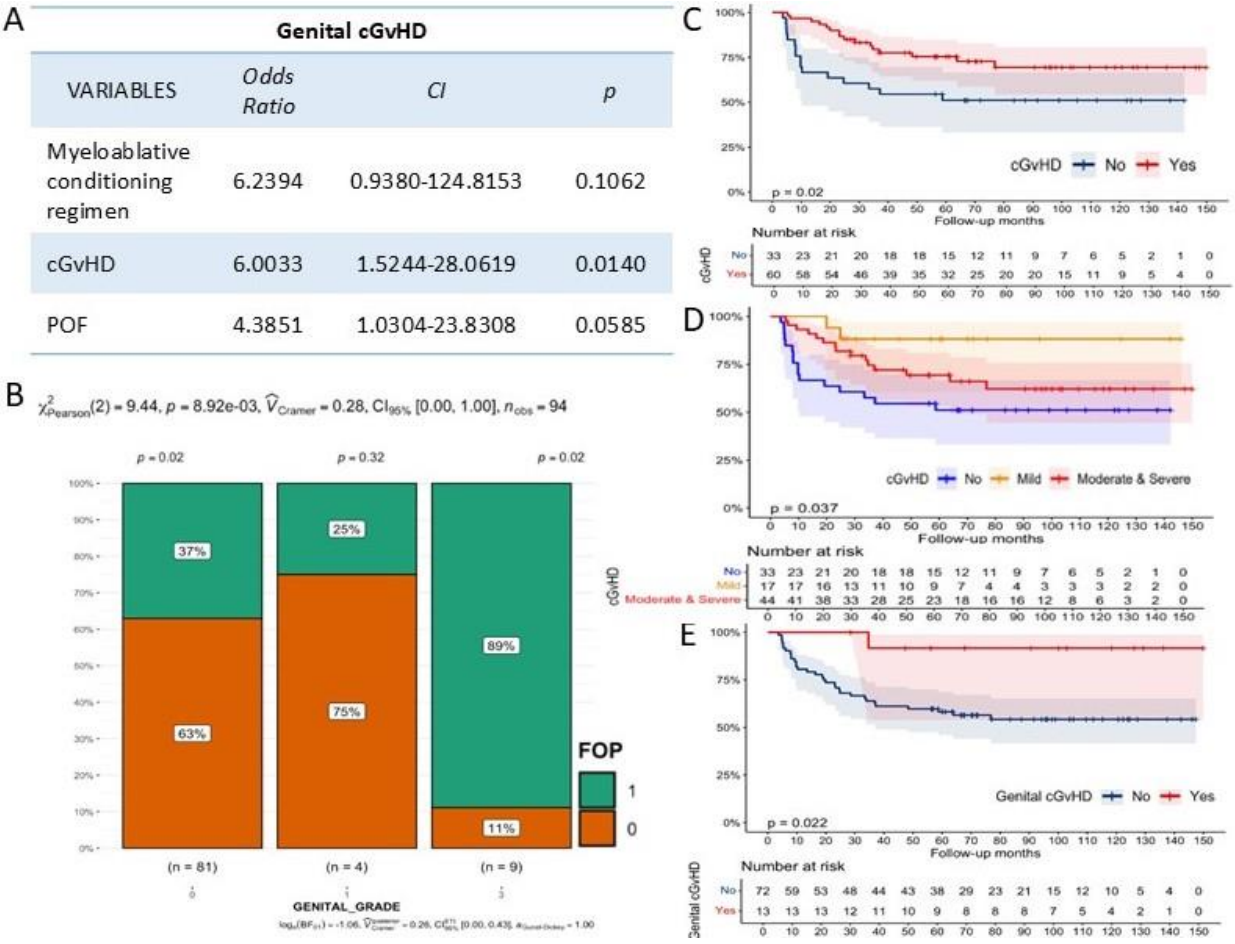

Figure 1A: Multivariate analysis of genital cGvHD.
Figure 1B: between POF and genital cGvHD and its grades 0, 1, and 3. Statistical test: Pearson's chi-square
Figure 1C: Overall survival (OS) according to the presence or absence of global cGVHD. Kaplan-Meier graphs. Log-rank stadistical test.
Figure 1D: Overall survival (OS) in patients with genital cGVHD, stratified by mild versus moderate–severe disease, compared with patients without GVHD.
Figure 1E: Overall survival (OS) according to the presence or absence (yes/no) of genital cGVHD.

Conclusions: In conclusion, genital cGVHD appears to be underdiagnosed and diagnosed later in our cohort compared with previously published studies. The presence of oral cGVHD may serve as an early clinical biomarker for the development of genital cGVHD. Therefore, once oral cGVHD is confirmed, early referral of HSCT recipients to specialised gynaecology units is warranted to enable timely diagnosis of genital cGVHD, as delays in treatment may worsen long-term sequelae and adversely affect quality of life.

REDUCED-DOSE POST TRANSPLANTATION CYCLOPHOSPHAMIDE (PTCY) IN HEMATOPOIETIC STEM CELL TRANSPLANTATION: LEARNINGS FOR THE FUTURE

Rohan Halder[1], *Mansi Bidla*[1], *Reema Singh*[1], *Niharika Bhatia*[1], *Garima Sarpal*[1], *Aakanksha Singh*[1], *Swapnil Tripathi*[1], *Sakshi Bhatnagar*[1], *Mayank Soni*[1], *Vipul Sheth*[1], *Narendra Agrawal*[1], *Dinesh Bhurani*[1]
[1]*Rajiv Gandhi Cancer Institute and Research Centre, New Delhi, India*

Background: Post-Transplant cyclophosphamide (PTCy) has been widely accepted as the graft-versus-host disease (GVHD) prophylaxis following hematopoietic stem cell transplantation (HSCT) in the setting of haploidentical transplants and also matched related or unrelated donor transplants. PTCy has been effective in preventing GVHD without increasing the risk of relapse. However, prolonged cytopenias, cardio-toxicity, viral infections and hemorrhagic cystitis are adverse events that warrant caution. While standard dose PTCy (100mg/kg) has been used historically, recent data suggest a reduced dose might be equally effective with favourable outcomes while reducing the associated toxicities.

Methods: This was a retrospective analysis reviewed from the data of patients who underwent HSCT with PTCy prophylaxis between January 2021 to March 2025 at Rajiv Gandhi Cancer Institute and Research Centre, New Delhi, India.

Results: A total of 173 patients (Standard dose (SD): 113 and Low-dose (LD): 60) who underwent HSCT with PTCy prophylaxis were included. Median follow-up was 11 months. The median age, hematopoietic comorbidity index (HCT-CI) scores were similar across both the cohorts. Acute Myeloid Leukemia/Myelodysplastic Syndrome was the most common disease in most cases (32.7% [SD] vs. 50%[LD]). Peripheral blood was the most common stem cell source (100%). Myeloablative conditioning was employed in most cases (SD: 67.3% vs. LD: 48.3%). Donors were haploidentical (SD: 65.5% vs. LD: 71.7%) in most cases, followed by matched sibling donors (MSD) (SD: 27.4% vs. LD: 20%) and matched unrelated donors (MUD) (SD: 7.1% vs. LD: 8.3%).
Neutrophil (14 days; range-10-31) and platelet engraftment (14 days: range-11-30) were earlier in the low dose PTCy arm when compared to the standard dose (Neutrophil: 16 days (range:11-30) and platelets: 17 days (range:10-44)). The incidence of bloodstream infections was similar in both the cohorts. There was a signal for lower rates of invasive

fungal infections (IFI) in the low-dose PTCy cohort. Acute GVHD grade 1 was significantly higher in the low-dose PTCy cohort but there was no increase in grade 2-4 rates in either cohort. Deaths due to Cardiac toxicity, veno-occlusive disease and primary graft failure were seen in two, three and five patients all in the SD cohort.
One-year PFS was 79.7% with standard-dose PTCy and 82.2% with low-dose PTCy, while 2-year PFS for the standard-dose group was 66.5% (p-value = 0.549). One-year OS was similar between groups (74.0% vs 71.1%, p-value = 0.696), but only the standard-dose cohort maintained a 2-year OS of 69.6%, as the low-dose group reached a median OS of 18 months due to limited follow-up.

Conclusions: Our study suggests that reduced-dose PTCy is feasible in our setting and was associated with earlier engraftment, which is an important landmark during HSCT. Overall, no statistically significant differences in PFS or OS were observed between standard-dose and low-dose PTCy, indicating that both regimens provided comparable long-term disease control and survival within the limitations of follow-up duration, retrospective nature and cohort size. Prospective, randomised controlled trials would be needed to confirm our findings.

A SINGLE TRANSPLANT PROGRAM EXPERIENCE IN TERMS OF GVHD PROPHYLAXIS: IS LESS DOSES OF METHOTREXATE BETTER THAN MORE?

Cristina Luise[1], *Mariangela Pedata*[1], *Maria Celentano*[1], *Stefania Leone*[1], *Annalisa Pitino*[2], *Cira Riccardi*[1], *Ilaria Migliaccio*[1], *Serena Marotta*[1], *Angela Carobene*[1], *Simona Maria Muggianu*[1], *Lidia Altomare*[1], *Mario Toriello*[3], *Daniela Graziano*[1], *Giovanni Luigi Tripepi*[4], *Alessandra Picardi*[1]
[1]*AORN Cardarelli, Naples, Italy,* [2]*IFC-CNR, Rome, Italy,* [3]*AORN Santobono Pausilipon, Naples, Italy,* [4]*IFC-CNR, Reggio Calabria, Italy*

Background: Methotrexate (MTX) represents the standard prophylaxis for GVHD in matched allogeneic stem cell transplantation (HSCT). However, the optimal dosing schedule among the available MTX regimens is still debated. Based on this background, a retrospective study comparing two MTX schedules was performed within the Transplant Program of AORN Cardarelli in Naples to assess their impact on acute and chronic GVHD incidence and grading, infections, gastrointestinal (GI) toxicity and grade, overall survival (OS), time to discharge, engraftment, non-relapse mortality (NRM), and time to relapse (TTR).

Methods: To compare the safety and efficacy of administering 4 (N=59) versus 3 (N=29) MTX doses (15 mg/m² on day +1, and 10 mg/m² on days +3, +6, and +11 only in the four-doses group), we conducted a target trial emulation (TTE) using two real-world cohorts of patients affected by AML/MDS and ALL. Baseline imbalances between groups were evaluated through standardized mean differences (SMD), with SMD ≥|0.10| indicating meaningful imbalance. Variables exceeding this threshold were used to create weights via the propensity

score calculation and generate a weighted pseudo-population (inverse probability of treatment weighting, IPTW) in which the two arms were balanced. Weighted logistic regression models assessed acute and chronic GVHD and their grade, infections, and GI toxicity and grade, and results expressed as odds ratio (OR); weighted Cox models evaluated time to discharge, engraftment, and OS. NRM and TTR were analysed using Fine-Gray competing-risk models, considering death due to relapse or other causes as the competing event for NRM, and NRM as the competing event for TTR. Results from survival models were expressed as hazard ratio (HR).

Results: After IPTW adjustment, baseline characteristics were well-balanced (all SMD<|0.07|) between groups (Table 1).
In the weighted pseudo-population, GI toxicity and its maximum grade were significantly lower in the three-doses group (OR 0.17, 95% CI 0.06-0.47, p<0.01; maximum grade: OR 0.17, 95% CI 0.04-0.77, p=0.01). No significant differences were observed in aGVHD (OR 1.19, 95% CI 0.39-3.65, p=0.79; maximum grade: OR 1.10, 95% CI 0.11-10.48, p=0.93) and cGVHD (OR 2.64, 95% CI 0.93-7.45, p=0.18; maximum grade: OR 1.17, 95% CI 0.32-4.24, p=0.85), time to discharge (HR 1.19, 95% CI 0.75-1.89, p=0.45), or engraftment (HR 1.40, 95% CI 0.91-2.14, p=0.13).
Overall, 28.4% of patients died, with a NRM of 7.9% and the median survivals were not reached. In the pseudo-population, no significant differences emerged between the two regimens for OS, NRM or TTR (HR 0.76, 95% CI 0.25-2.28, p=0.62; SHR 1.38, 95% CI 0.21-8.96, p=0.74; SHR 0.55, 95% CI 0.16-1.91, p=0.35).

Table 1. Baseline characteristics

Conclusions: Data concerning the impact of three versus four doses of MTX, as prophylaxis of GVHD in matched allogeneic HSCT at single adult Transplant Program, showed that the omission of the fourth dose of MTX did not significantly affect the transplant outcomes in terms of engraftment, NRM, TTR, OS, aGVHD and cGVHD occurrence and grading. The reduction of MTX doses may reduce severe mucosal damage and the consequent GI toxicity, incidence and maximum grade.

SYSTEMIC TREATMENT WITH THE ROCK2 INHIBITOR BELUMOSUDIL IN OCULAR CHRONIC GRAFT VERSUS HOST DISEASE

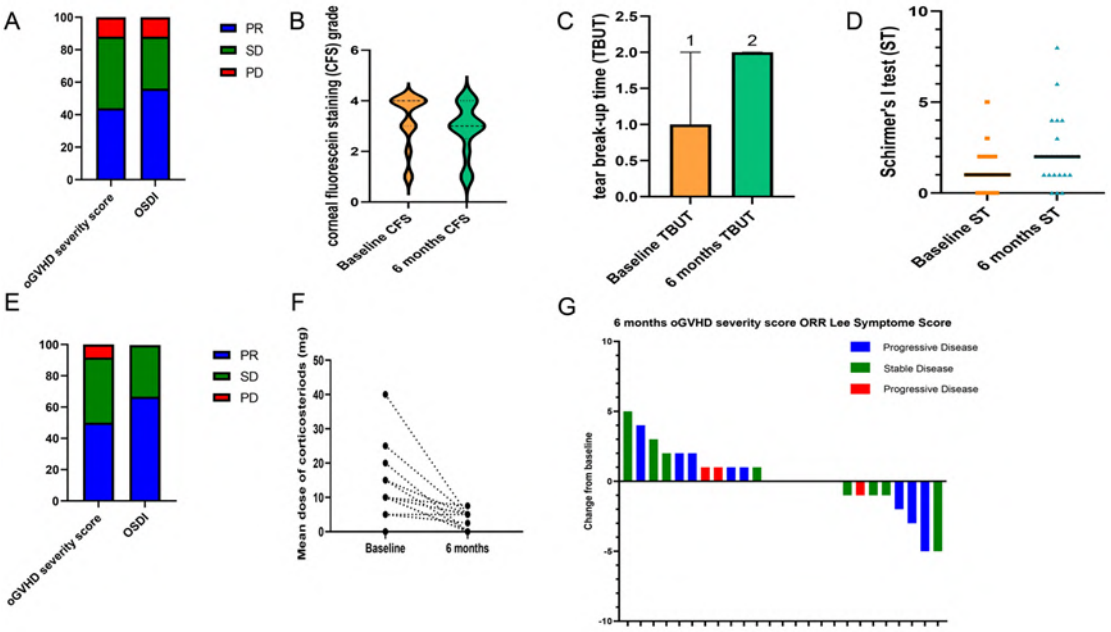
Yibo Wu[1,2,3], *Bei Ye*[4], *Xiaoyu Lai*[1,2,3], *Lizhen Liu*[1,2,3], *Luxin Yang*[1,2,3], *Lin Li*[1,2,3], *Jimin Shi*[1,2,3], *Yanmin Zhao*[1,2,3], *Jian Yu*[1,2,3], *Xiaolin Yuan*[5], *Panpan Zhu*[1,2,3], *Chixin Du*[4], *He Huang*[1,2,3], *Jianyong Wang*[4], *Yi Luo*[1,2,3]
[1]*The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China,* [2]*Liangzhu Laboratory, Hangzhou, China,* [3]*Institute of Hematology, Zhejiang University, Hangzhou, China,* [4]*Department of Ophthalmology, The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China,* [5]*Department of Hematology, Zhejiang Cancer Hospital, Hangzhou Institute of Medicine (HIM), Chinese Academy of Sciences, Hangzhou, China*

Background: To evaluate the efficacy of oral belumosudil on ocular surface disease (OSD) in patients with steroid-refractory chronic graft-versus-host disease (cGVHD).

Methods: We retrospectively analyzed patients with steroid-refractory cGVHD and ocular involvement (oGVHD) who received systemic belumosudil. Ocular assessments were performed at baseline and at the 6-month primary efficacy endpoint, including: the International Chronic Ocular GVHD Consensus Group severity score, NIH eye score (0-3), corneal fluorescein staining (CFS) grade (0-4), tear break-up time (TBUT), Schirmer's I test without anesthesia (ST), and the Ocular Surface Disease Index (OSDI). The 6-month overall

response rate (ORR), organ-specific responses, and adverse events were evaluated per NIH consensus criteria.

Results: Among 67 steroid-refractory cGVHD patients treated with belumosudil (200 mg daily), 38 had oGVHD with NIH eye score 2(1-3) and oGVHD severity score 9(1-10) respectively. Of these, 25 patients completed both baseline and 6-month assessments. The cohort had high-risk features: 48.0% (12/25) had severe NIH-grade systemic disease and 64.0% (16/25) had conjunctival fibrosis.
At 6 months, the oGVHD severity score improved in 44.0% (11/25), was stable (SD) in 44.0% (11/25), and progressed (PD) in 12.0% (3/25). OSDI improved in 56.0% (14/25), was SD in 32.0% (8/25) and PD in 12.0% (3/25) (Fig 1A).
Objective signs showed improved from baseline: CFS decreased from 4 (1-4) to 3 (1-4) (Fig 1B) , TBUT increased from 1.0 s (0.8-4.78) to 2.0 s (0-5) (Fig 1C), and ST improved from 1.0 mm (0-5) to 2.0 mm (0-22) (Fig 1D).
Greater benefit was observed in the 12 patients (48.0%) who achieved systemic ORR at 6 months. In this subgroup, the oGVHD severity score improved in 50.0% (6/12), was stable in 41.7% (5/12) and progressed in 8.3% (1/12). OSDI improved in 66.6% (8/12), was stable in 33.3% (4/12) and none worsened (Fig 1E). Objective signs also improved: CFS decreased from 4 (1-4) to 3 (1-4), TBUT increased from 1.0 s (0.8-2.0) to 2.0 s (0.5-3.0), and ST improved from 1.0 mm (0-2.0) to 2.0 mm (0-6.0).
Visual acuity remained stable across all groups. Corticosteroid dose reduction was achieved in 48.0% (12/25) of patients (Fig 1F). The eye Lee Symptom Scale score remained unchanged (7 [2-12] vs. 7 [1-15]) (Fig 1G). Treatment was well-tolerated with no drug-related discontinuations or severe hematologic toxicities.



Conclusions: Systemic belumosudil treatment demonstrated a high response rate, significant improvements in international oGVHD severity scores and ocular surface

parameters, and favorable tolerability in steroid-refractory oGVHD patients. Notably, the greatest ocular benefit was closely associated with systemic overall response, indicating that systemic response may serve as a predictor for ocular outcomes in cGVHD management.

DONOR- AND DOSE- SPECIFIC ENDOTHELIAL ACTIVATION AND CLINICAL OUTCOMES AFTER ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE

Queralt Salas[1], *Blanca De Moner*[1], *María Suárez-LLedó*[1], *Julia Martinez-Sachez*[1], *Ana Belén Moreno-Castaño*[1], *Laua Guardia*[1], *Cristina Moreno*[1], *Esther Carcelero*[1], *Paola Charry*[1], *Joan Cid*[1], *Miquel Lozano*[1], *Begoña Fernández*[1], *Laura Rosiñol*[1], *Enric Carreras*[2], *Francesc Fernández-Avilés*[1], *Montserrat Rovira*[1], *Carmen Martínez*[1], *Maribel Díaz-Ricart*[1]

Background: Post-transplant cyclophosphamide (PTCy) is widely used for GVHD prophylaxis across donor types. Although experimental data suggest that PTCy induces endothelial stress, clinical characterization of early endothelial activation in allo-HCT remains limited. At our institution, PTCy-based prophylaxis has been progressively implemented since 2013; tacrolimus (TK) is routinely combined, and mycophenolate mofetil (MMF) is added in haploidentical transplants (haplo-HCT). In 2021, PTCy dosing was reduced to 40 mg/kg/day in 10/10 HLA-matched donors to mitigate early toxicity.
Given the central role of endothelial dysfunction in post-transplant complications, this study describes endothelial activation patterns and compares clinical results of allo-HCT performed with PTCy across donor types.

Methods: Ninety-five consecutive adults receiving allo-HCT with PTCy between August 2022 and January 2025 were included. Endothelial activation was monitored using serial EASIX scores from baseline to day +180. Biomarkers of endothelial injury (VWF, thrombomodulin [TM], TNFR1) and inflammatory/GVHD signaling (REG-α, ST2) were quantified from cryopreserved plasma collected at admission, day 0, +7, +14, and +21.

Results: Among 95 patients, 50 (52.6%) received grafts from HLA-matched donors (PTCy40-TK), 25 (26.3%) from 9/10 mismatched unrelated donors (MMUD, PTCy50-TK), and 20 (21.1%) underwent haplo-HCT (PTCy50-TK-MMF). All CMV-positive recipients received letermovir, and all patients received G-CSF from day +7.
As reported in Table 1, baseline characteristics were balanced. Engraftment was slightly faster in HLA-matched allo-HCT. TA-TMA was only documented in MMUD recipients (20%; p=0.016), whereas VOD was infrequent. Haplo-HCT showed the highest burden of early toxicity, including graft failure (10.0%), cardiac events (20% vs. 0–2%; p=0.001) and infectious complications such as bloodstream infections (45%), BK hemorrhagic cystitis

(10%), and invasive fungal infections (20%).
Acute GVHD rates were comparable across HLA-matched, MMUD, and haplo-HCT cohorts: grade II–IV (24%, 24%, 20%; p=0.915) and grade III–IV (10%, 12%, 15%; p=0.829). Two-year moderate–severe cGVHD incidence was similarly low (12.6%, 13.2%, 10.9%; p=0.678). Overall survival did not differ significantly (2-year: 73.2%, 84.0%, 70.0%; p=0.953), with low rates of non-relapse mortality (2-year: 0%, 8%, 5%). However, relapse incidence at two years remained substantial (38.8%, 16.7%, 29.9%; p=0.094), reflecting the high-risk features of the population transplanted during this period.
Endothelial activation increased during the early post-transplant period in all transplant settins (Figure 1). However, Haplo-HCT displayed the highest EASIX values across all time points, with a sharp post-PTCy increase from 1.24 (day 0) to 4.67 (day +7), peaking at 7.38 (day +14), and remaining elevated at 7.61 (day +21). TNFR1 and TM trajectories mirrored EASIX profiles, reinforcing the greater endothelial stress in haplo-HCT. ST2 and REG-α medians were also higher in haplo-HCT, with ST2 presenting pronounced peaks between days +7 and +14, and REG-α remaining persistently elevated. Moreover, espite receiving reduced PTCy dosing, HLA-matched transplants consistently showed the lowest endothelial activation.

2-Year Overall Survival 2-year Cumulative Incidence of Disease Relapse 2-year Non-Relapse Mortality	73.2 (58.3-83.5) 38.8 (25.0-54.3) 0	84.0 (62.8-93.7) 8.0 (1.3-22.9) 0	70.0 (55.1-92.1) 29.9 (6.0-39.9) 0	0.953 0.093 0.073

Conclusions: Endothelial activation after allo-HCT with PTCy appears influenced by donor type and PTCy dosing. Haplo-HCT showed the highest endothelial stress and the greatest burden of early infectious and cardiovascular complications, despite similar GVHD rates and survival outcomes across groups. Results support the conduction of studies evaluating whether early biomarker dynamics can predict post-transplant complicationss.

Clinical Trial Registry: No applicable.

EFFICACY OF CNI-FREE GVHD PROPHYLAXIS IN PEDIATRIC PATIENTS UNDERGOING HAPLOIDENTICAL HEMATOPOIETIC STEM CELL TRANSPLANTATION AFTER PRIOR MONOCLONAL ANTIBODY THERAPY

*Nikita Levkovsky[1], Polina Kozhokar[1], Lubov Tsvetkova[1], Zhemal Rakhmanova[1], Anna Osipova[1], **Tatyana Bykova**[1], Elena Semenova[1], Alexander Kulagin[1], Ivan Moiseev[1], Ludmila Zubarovskaya[1]*
[1]Pavlov First Saint Petersburg State Medical University, Saint Petersburg, Russian Federation (the)

Background: Allogeneic hematopoietic stem cell transplantation (allo-HCT) is an effective therapy for children with high-risk acute lymphoblastic leukemia (ALL) in remission. Furthermore, it represents a key therapeutic strategy for patients with relapsed or refractory ALL who achieve remission following treatment with monoclonal antibodies (e.g., blinatumomab or inotuzumab ozogamicin). However, in this setting, allo-HCT carries a substantial risk of endothelial damage, leading to complications such as sinusoidal obstruction syndrome (SOS) and transplant-associated thrombotic microangiopathy (TA-TMA). This risk is further compounded by graft-versus-host disease (GVHD) prophylaxis regimens based on calcineurin inhibitors (CNIs), particularly in patients with a history of intensive prior therapy, including a second allo-HCT. These challenges underscore the need for developing CNI-free GVHD prophylaxis protocols for this vulnerable group of patients.

Methods: This single-center retrospective cohort study enrolled 63 pediatric patients (<18 years) with ALL who received haploidentical HCT following prior treatment with inotuzumab ozogamicin and/or blinatumomab. Patients were stratified into two cohorts according to the GVHD prophylaxis regimen: with or without calcineurin inhibitors (Table 1). The GVHD prophylaxis backbone for all patients consisted of post-transplant cyclophosphamide (PTCy) administered on days +3 and +4. In the CNI-based group (n=24), all patients received a combination of tacrolimus and an mTOR inhibitor. In the CNI-free group (n=39), prophylaxis comprised mTOR inhibitor only.

Patients and HCT characteristics	CNI N=24	CNI-free N=39	p value

Age, years, median	7.9 (3.92)	8.7 (4.25)	0.457
Gender Female Male	 7 (29.2%) 17 (70.8%)	 12 (30.8%) 27 (69.2%)	1.000
HCT number First Second	 20 (83.3%) 4 (16.7%)	 34 (87.2%) 5 (12.8%)	0.721
Graft source Bone marrow PBSC	 19 (79.2%) 5 (20.8%)	 33 (84.6%) 6 (15.4%)	0.735
Conditioning regimens Myeloablative Reduced intensity	 15 (62.5%) 9 (37.5%)	 7 (17.9%) 32 (82.1%)	**0.001**
Remission status before HCT No remission Remission	 7 (29.2%) 17 (70.8%)	 13 (33.3%) 26 (66.7%)	0.947
MRD Negative Positive	 12 (50.0%) 12 (50.0%)	 20 (51.3%) 19 (48.7%)	1.000
Therapy used prior HCT Blinatumomab Blinatumomab and inotuzumab ozogamicin Inotuzumab ozogamicin	 15 (62.5%) 3 (12.5%) 6 (25.0%)	 15 (38.5%) 6 (15.3%) 18 (46.2%)	0.226

Results: With a median follow-up of 374 days (range, 15–2092), the incidence of acute GVHD did not differ significantly between the CNI-based and CNI-free groups (60% vs. 67%, p=0.86). Similarly, comparable rates were observed for grade 2-4 aGVHD (40% [95% CI 19 – 61%] vs. 53% [95% CI 34 – 70%], p=0.3) and grade 3-4 aGVHD (25% [95% CI 9 – 46%] vs. 27% [95% CI 12 – 43%], p=0.84) (Fig.2). There were no significant differences in the frequency and severity of organ involvement, including skin (p=0.79), gastrointestinal tract (p=0.74), or liver (p=1.0). Engraftment rates were comparable (83% vs. 77%, p=0.71), with a uniform median time to engraftment of 21 days. Notably, the incidence of SOS/TA-TMA showed a non-significant trend towards being higher in the CNI-based group (33% vs. 15%, p=0.097). One-year overall survival (57% vs. 59%, p=0.5), cumulative

incidence of relapse (45% vs. 53%, p=0.4), and non-relapse mortality (12% in both groups, p=0.95) were not significantly different. In multivariate analysis, ALL remission (HR 0.35; 95%CI 0.14-0.89; p=0.028) and use of a reduced-intensity conditioning (HR 0.24; 95%CI 0.06-0.92; p=0.037) were associated with better overall survival outcomes, while the use of intotuzumab ozogamicin before HCT significantly reduced OS (HR 5.6; 95%CI 1.8-17.9; p=0.004). Only positive MRD status before HCT was associated with significant increase of relapse probability (90% [95% CI 25 – 99%] vs. 30% [95% CI 13 – 50%]). We observed a trend towards a higher incidence of chronic GVHD in the CNI-free group (33% vs. 15%, p=0.13).

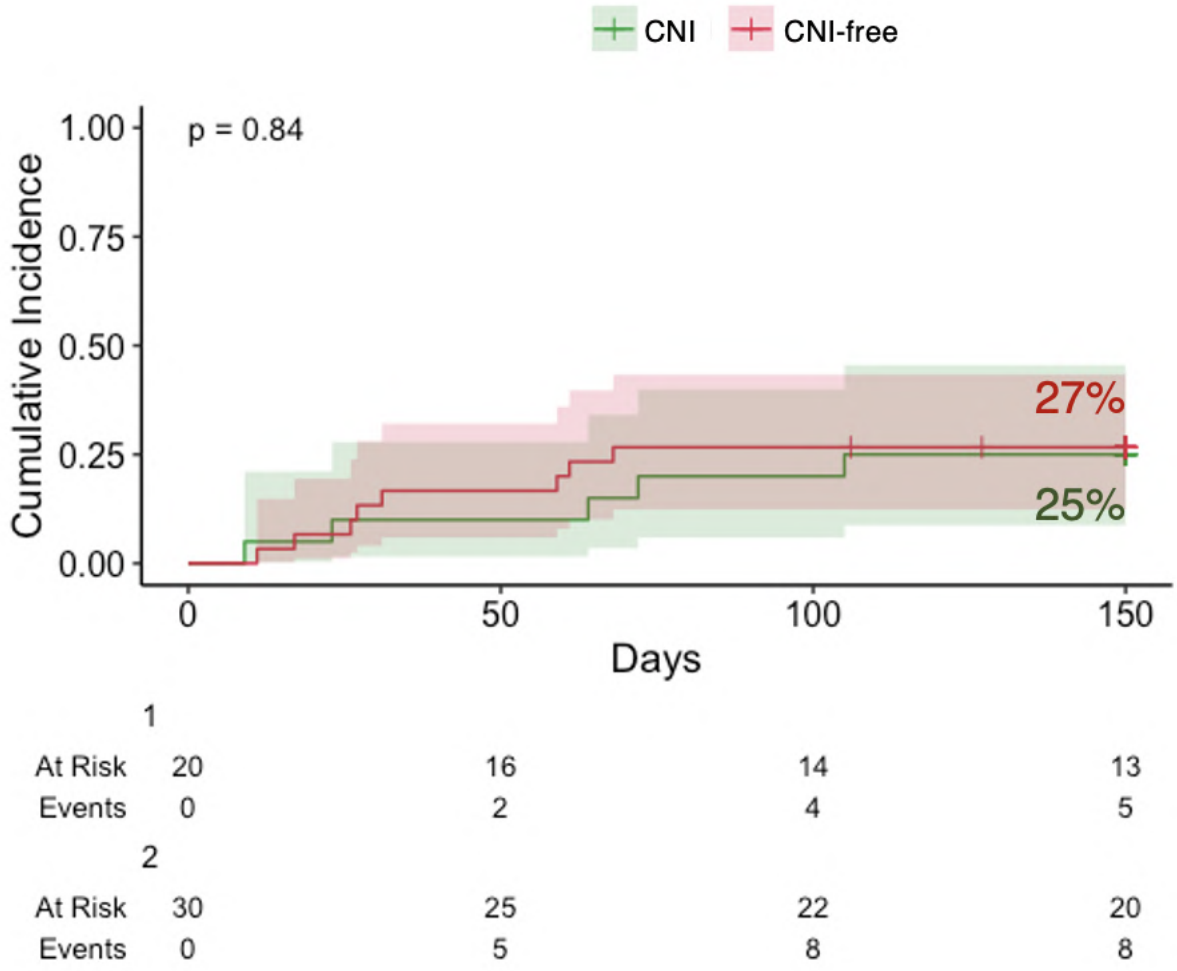

Fig. 1 Cumulative incidence of grades 3–4 acute GVHD, by GVHD prophylaxis regimen

Conclusions: Our findings suggest that CNI-free prophylactic regimens yield comparable survival outcomes and provide similar control over acute GVHD relative to standard CNI-based protocols. Future research should focus on elucidating the risk factors for chronic GVHD in this setting and developing targeted strategies to reduce its incidence.

Disclosure: Nothing to declare.

B046

VIRAL INFECTION WITHIN STEROID REFRACTORY/DEPENDENT GVHD PATIENTS TREATED WITH RUXOLITINIB: A SINGLE CENTER ANALYSIS

[1]*Unit of Blood Diseases and Bone Marrow Transplantation, Department of Clinical and Experimental Science, University of Brescia, ASST Spedali Civili di Brescia, Brescia, Italy*

Background: Graft-versus-host disease (GVHD) is a major complication of allogeneic hematopoietic stem cell transplantation (allo-HSCT) and a leading cause of non-relapse mortality. While corticosteroids remain first-line therapy, up to 50% of patients develop steroid-refractory or steroid-dependent (SR/D) GVHD. Ruxolitinib, a selective JAK1/2 inhibitor, has demonstrated superior responses in both acute and chronic SR/D GVHD (REACH2/REACH3 trials). Its immunosuppressive effect increases the risk of bacterial, viral, and fungal infections. Herein we analyzed viral reactivation incidence and its impact on overall survival (OS) in patients who developed GVHD requiring treatment in our centre.

Methods: All allo-HSCT patients transplanted between 2018 and 2024 that developed GVHD were considered eligible for this study. Among 308 transplanted patients, 160 (52%) experienced GVHD. Acute myeloid leukemia (AML) was the most frequent indication for allo-HSCT. Conditioning intensity was evenly distributed between myeloablative (MAC) and reduced-intensity regimens (RIC). Nearly half of the patients (48.1%) received grafts from matched unrelated donors, followed by HLA-identical siblings and haploidentical donors. Peripheral blood stem cells were the predominant graft source. GVHD prophylaxis was primarily based on ATG. GVHD cases were subsequently stratified into two groups: steroid-sensitive (SS) GVHD and SR/D GVHD, the latter treated with ruxolitinib as second-line therapy. Finally, we evaluated the incidence of viral reactivations in both groups, with specific attention to CMV, EBV, HHV-6, and adenovirus. Overall survival (OS) was estimated using Kaplan–Meier analysis.

Results: Baseline demographic and transplant-related characteristics are summarized in Table 1. The 8-year OS was 53% in patients with SS-GVHD and 61% in those with SR/D-GVHD, with no significant difference ($p = 0.1229$). In the SR/D-GVHD cohort, 8-year overall survival (OS) was 56% in patients who experienced at least one viral infection versus 70% in those without viral infections ($p = 0.7624$). Similar findings were observed when restricting

the analysis to CMV reactivation: 8-year OS was 49% in SR/D-GVHD patients with CMV reactivation and 74% in those without (p = 0.2588; Figure 1A). Among patients with CMV reactivation, 8-year OS did not differ significantly between SS-GVHD and SR/D-GVHD patients treated with ruxolitinib (52% vs 49%, respectively; p = 0.7192; Figure 1B). Relapse incidence was comparable between the SS-GVHD and SR/D-GVHD groups (Table 1) and was 33% among SR/D-GVHD patients with CMV reactivation. In this subgroup, the main causes of death were relapse (50%), infections (30%), and acute GVHD (20%), with no significant differences compared with the SS-GVHD and SR/D-GVHD groups.

Conclusions: Viral infections remain a relevant complication after allo-HSCT, particularly in patients with GVHD requiring intensified immunosuppression. In our cohort, viral reactivations, including CMV, were frequent among SR/D-GVHD patients treated with ruxolitinib but were not associated with a significant impairment in long-term overall survival. Notably, CMV reactivation did not translate into increased infection-related mortality, with relapse remaining the leading cause of death across all groups. Overall, these findings suggest that ruxolitinib can be used as second-line therapy for SR/D-GVHD without an apparent detrimental impact on survival, even in the context of common viral reactivations, when appropriate monitoring and pre-emptive strategies are applied.

	Total patients with acute or chronic GvHD (160)	SS GvHD (97)	SR/D GvHD treated with Ruxolitinib (63)	P valu

BENEFITS OF A MULTIDISCIPLINARY COMMITTEE FOR THE TREATMENT OF CHRONIC GVHD: CASE REPORTS AS A PARADIGM FOR COLLABORATIVE CARE

David Gomez Rocha[1], *Alejandro Luna de Abia*[1], *Anabelle Chinea*[1], *Adrián Sánchez-Tornero*[1], *Diego Buendia-Castaño*[1], *David Mingo*[1], *Juan Rigual Bobillo*[1], *Ana Jaureguizar*[1], *Blanca Mur Molina*[1], *Laura Carral Fernandez*[1], *Laura Barbero del Olmo*[1], *David Pozo*[1], *Paula Guijarro Martínez*[1], *Begoña Hinojo*[1], *Pilar Herrera Puente*[1], *Javier López-Jiménez*[1]
[1]*Instituto Ramón y Cajal de Investigación Sanitaria - IRYCIS, Madrid, Spain*

Background: Chronic graft-versus-host disease (cGVHD) affects more than one third of patients undergoing allogeneic hematopoietic stem cell transplantation and can involve multiple organs.
This multisystem involvement may benefit from collaboration among different specialists who can provide tailored solutions for each of the potential complications of the disease. In this context, the Ramón y Cajal Hospital in Madrid, Spain, has a dedicated multidisciplinary committee for the management of this condition. This committee is composed of specialists in Hematology, Pulmonology, Ophthalmology, Dermatology, Rehabilitation, and Pharmacy, and is open to the inclusion of other departments in the future.

Methods: Based on our center`experience, we present four illustrative cases of patients with cGVHD who have particularly benefited from management by our committee.

Results: Table 1 summarizes the main information regarding medical history, cGVHD characteristics, and the committee's approach for each patient.
Below, we describe how the committee's intervention contributed to clinical improvement in each case.

	Medical history					cGVHD		
	Age	**Gender**	**Underlying disease**	**Relevant comorbidities**	**Years since HCT**	**Month of onset**	**Lee Score at the time of assessment**	**Treatment at th**
Patient 1	47	Male	MDS	-COPD -Smoker	6	+14	14 points: - 5 skin - 6 eyes - 2 mouth - 1 breath	- Ruxolitinib 5mg - Belumosudil 20 - Lungs: fluticaso bromide, and vila azithromycin - Eyes: Insulin ey times a day, auto retinol palmitate lubricants and m
Patient 2	32	Male	MonoMAC syndrome	- CKD3b - Lymphedema left lower limb -Previous pulmonary cGVHD	4	+17	5 points: - 4 skin - 1 eyes	- Cyclosporine A - Ursodeoxycholi - Lungs: montelu and vilanterol - Clobetasol nail - Eyes: cyclospor serum, acetylcyst

Patient 3	31	Male	AML	- Mild iron overload	3	+17	27 points: - 15 skin - 5 eyes/mouth - 1 digestion - 1 muscle - 2 energy - 2 mental	- Belumosudil 20 - Famotidine - Atarax - Beclomethason
Patient 4	51	Female	AML	- Severe combined immunodeficiency - Recurrent lung infections	3	+13	7 points - 1skin - 3 eyes - 3 breath	-Cyclosporine A 5 -Belumosudil 200 -Ruxolitinib 10mg -Prednisone 10m -Lungs: montelu budesonide, iprat tiotropium and ol -Infectious proph cotrimoxazole, is -Eyes: cyclospori eye serum, lubric - Ursodeoxycholi

Patient 1. Ocular worsening: Despite all treatments administered, the patient showed no improvement. He was referred to the ophthalmologist on the committee, who realized that the autologous serum was only increasing inflammation; therefore, it was replaced with plasma, since this provides additional regenerative and anti-inflammatory factors that are not present in serum, which improved the patient's clinical condition.
Patient 2. Ankle sclerosis with impaired dorsiflexion; asthma: Rehabilitation proposed several options that are not commonly considered by hematologists, such as performing an ankle MRI to better determine the cause, using botulinum toxin, and prescribing specific exercises. Additionally, this patient's previous diagnosis of pulmonary cGVHD was re-evaluated, reconsidered as bronchial asthma, and the pulmonary treatment was adjusted accordingly.
Patient 3. Sclerodermiform cutaneous cGVHD: With the treatment administered up to that point, the patient had multiorgan cGVHD with good evolution in all areas except the skin, presenting the lesions shown in Figure 1b. Together with the Dermatology Department, tocilizumab was initiated—monthly at first and later every three months—with clinical improvement beginning after the second dose. A 12-point decrease in the "skin" domain of the Lee score was achieved, along with recovery of sweating and body hair. Grade III neutropenia developed as an adverse effect but resolved with a single dose of G-CSF.

Patient 4. Severe pulmonary cGVHD: The patient had difficulty achieving respiratory improvement, due to recurrent infections, and lung transplantation had been proposed as primary option. She was re-evaluated, and recovery was optimized through respiratory physiotherapy, FAM therapy, optimization of bronchodilator therapy with closed triple therapy (LABA/LAMA/ICS), and temporarily increasing azithromycin to 600 mg for six days, followed by a return to the previous dose of 250 mg three days per week. Prednisone was gradually discontinued, and immunoglobulins were administered every three weeks. The patient achieved pulmonary improvement, avoiding need for transplantation.

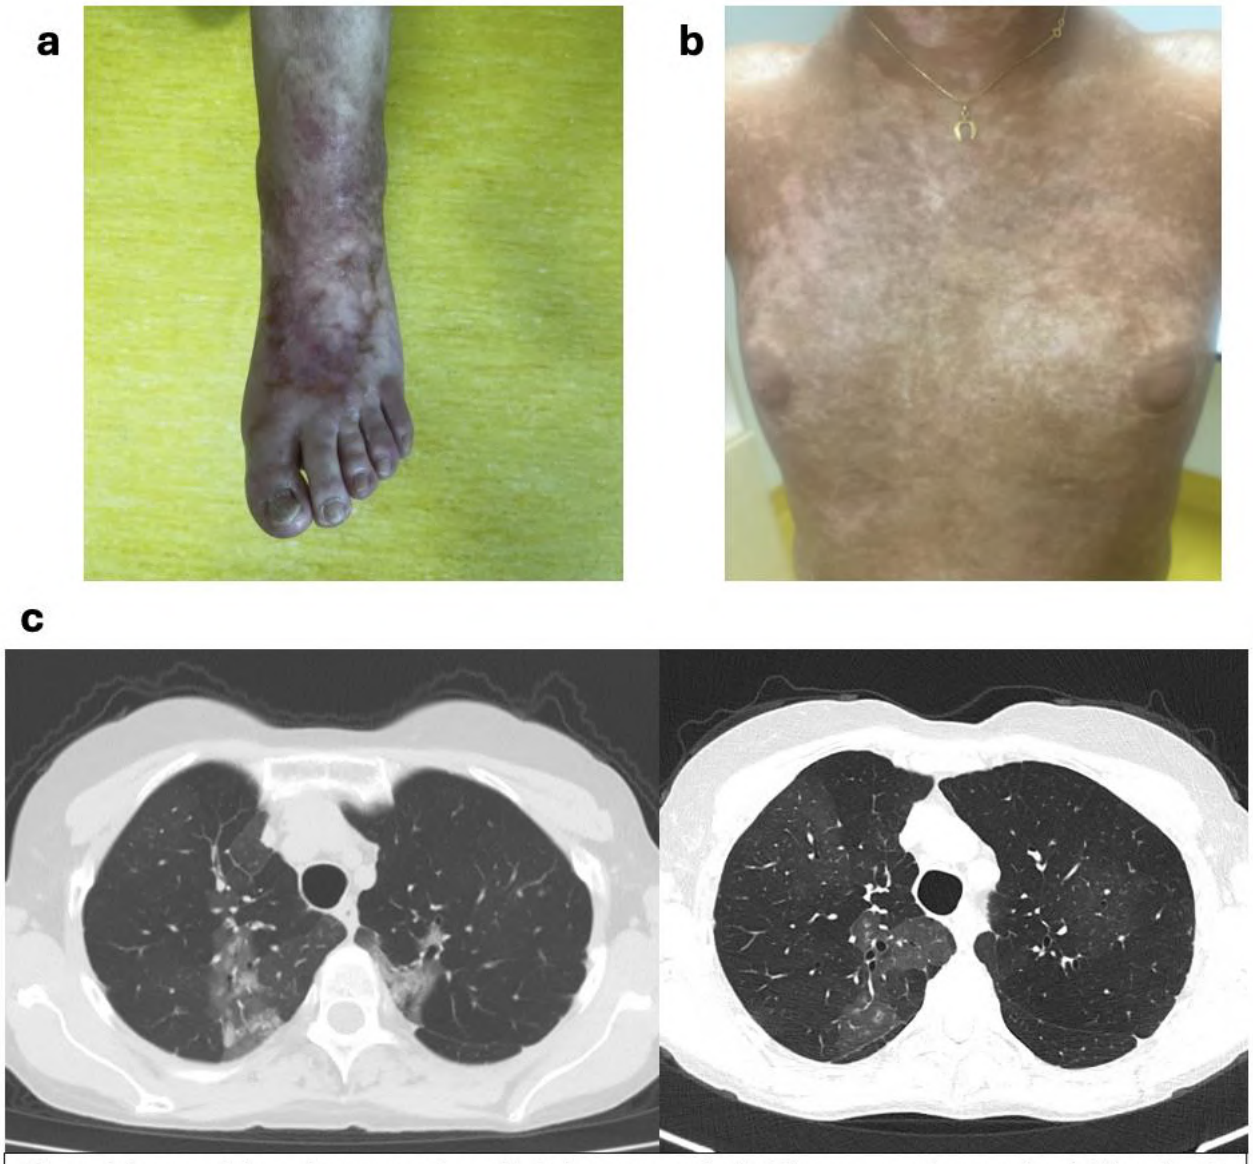

Figure 1: Images of the patients were taken with their consent and with full assurance of anonymity. **a)** Skin sclerosis on the dorsum of the left foot of patient 2. **b)** Skin of patient 3 with poikiloderma, hair loss, and lichen planus-like, sclerodermiform lesions, associating onychodystrophy. **c)** Chest CT scan of patient 4 before (left) and after (right) the committee's intervention, showing improvement of the pulmonary complications derived from cGVHD (bronchiolitis obliterans with radiological improvement of the micronodular involvement and consolidation areas).

Conclusions: The GVHD committee at our hospital reflects a collaborative effort among various specialists focused on the management of patients with this condition. We believe that this kind of multidisciplinary approach provides clear clinical benefit among patients with GVHD, particularly in cases with several organs involved.

EFFICACY AND SAFETY OF BELUMOSUDIL-ECP (EXTRACORPOREAL PHOTOPHERESIS) COMBINATION THERAPY IN REFRACTORY CHRONIC GRAFT-VERSUS-HOST DISEASE (CGVHD) AND CORRELATION WITH CYTOKIN KINETIC: A SINGLE-CENTER RETROSPECTIVE STUDY

Roberto Maggi[1], Luca Di Marino[1], Sabrina Giammarco[1], Elisabetta Metafuni[1], Maria Assunta Limongiello[1], Giuseppina Massini[1], Caterina Giovanna Valentini[1], Piccirillo Nicola[1], Simona Sica[1], ***Chiusolo Patrizia***[1]
[1]*Policlinico Universitario Agostino Gemelli, Rome, Italy*

Background: Chronic GVHD, a key complication of allogeneic transplantation affecting quality of life even at mild stages, remains inadequately controlled by corticosteroids, while novel approaches such as the ROCK2 inhibitor belumosudil and ECP, especially in combination, show encouraging therapeutic potential.

Methods: At our institution, Fondazione Policlinico Gemelli, between February 2024 and November 2025, we enrolled nine patients (2 females and 7 males) with moderate to severe chronic GVHD (according to the NIH grading system) refractory to at least two prior lines of therapy (median 4 lines). All patients received belumosudil (400 mg daily for those on proton pump inhibitors, 200 mg for others) in combination with extracorporeal photopheresis (ECP; two procedures per month, intensified to twice every two weeks in case of flare). Cytokine parameters (IL-2, IL-6, and sST2) were measured at therapy initiation and on the day of the first ECP each month. **Patient characteristics' are summarized in Table 1.**

Table 1. Patient characteristics

Patient	Age (years)	Underlying disease	Donor type	GVHD prophylaxis	Prior therapy lines	cGVHD grade at belumosudil start	Organs involved
1	25	HL	URD 8/8	CSA-MMF + PT-Cy	>5	Severe	Skin, intestine
2	55	HL	APLO	CSA-MMF + PT-Cy	>5	Severe	Skin, intestine
3	21	AML	Sibling	CSA-MTX	1	Severe	Lung
4	27	B-ALL	Sibling	CSA-MMF + PT-Cy	3	Moderate	Joint/fascia, mouth, skin

5	57	MPN	URD 8/8	CSA-MMF + PT-Cy	2	Moderate	Liver, eye, skin
6	64	AML	APLO	CSA-MMF + PT-Cy	3	Severe	Lung, skin
7	41	NHL	Sibling	CSA-MMF + PT-Cy	3	Severe	Skin
8	33	HL	APLO	CSA-MMF + PT-Cy	4	Moderate	Skin, oral cavity
9	53	MPN	MUD 8/8	CSA-MMF + PT-Cy	3	Severe	Skin

Results: At belumosudil initiation, six patients remained on corticosteroids, one on ruxolitinib, four on cyclosporine, and two on mycophenolate mofetil. Median treatment duration was 14 months (range, 4–22).

One patient discontinued therapy after 4 months due to disease progression and subsequently underwent lung transplantation; the remaining eight continued treatment.

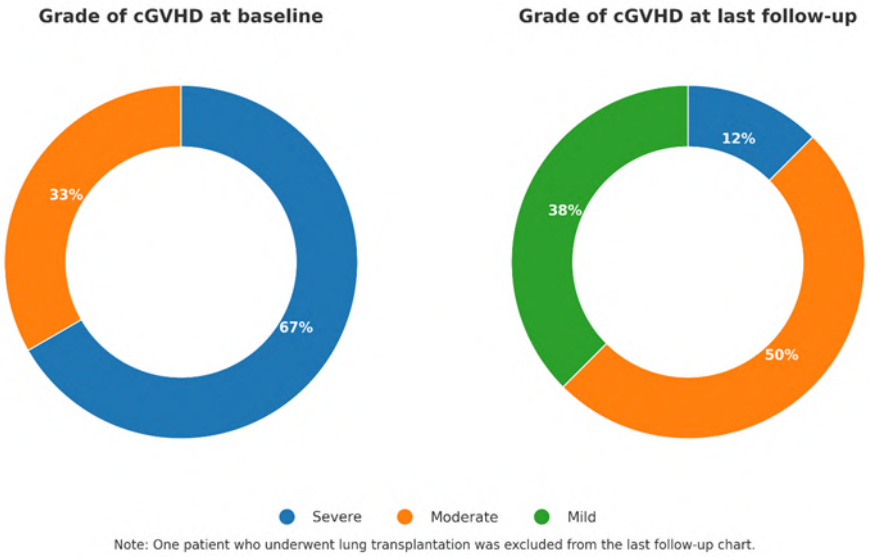
Among these eight patients, **six** reached the 12-month treatment evaluation: **five** achieved a **partial response** (three improved from severe to mild cGVHD; two maintained moderate cGVHD but were able to discontinue or significantly reduce concomitant immunosuppressive therapy), and **one** achieved **stable disease** (this patient had isolated pulmonary involvement, with no improvement but also no further deterioration, unlike prior treatment lines).

The remaining **two patients** were evaluated at 6 months of treatment (as they had not yet reached one year) and both achieved **partial responses**—one improving from severe to moderate cGVHD, and the other maintaining moderate disease with reduction of concomitant immunosuppression.

Among patients treated for more than one year, **two experienced a cGVHD flare** requiring reintroduction of low-dose corticosteroids, which are still ongoing; both presented with pulmonary reactivation.

cGVHD outcomes in our patient cohort at last follow-up are summarized in **Figure 1**.

During combination therapy, **three infectious episodes** occurred, **two** of which were severe and required hospitalization. According to cytokine analyses, median sST2 and IL-6 values appeared to decrease during the first months of treatment in patients who experienced clinical improvement.



Conclusions: The combination of belumosudil and ECP was well tolerated, with no patients discontinuing treatment due to intolerance. In our small cohort, this regimen resulted in favorable clinical responses among heavily pretreated patients. Notably, patients with predominant pulmonary cGVHD appeared to be less responsive to therapy. Larger studies with extended follow-up are warranted to confirm the efficacy and safety of this approach and to further investigate potential correlations between cytokine dynamics and cGVHD progression.

B049

BELUMOSUDIL TREATMENT FOR CHRONIC GRAFT-VERSUS-HOST DISEASE: REAL-WORLD CLINICAL DATA FROM FRANCE

*David Michonneau[1], **Florent Malard**[2], Michael Loschi[3], Anne Huynh[4], Leonardo Magro[5], Maud D'Aveni[6], Nicolas Vallet[7], Darko Kiprijanovski[8], Chaimae Ighidi[8]*
[1]Université Paris Cité, INSERM UMR1342, Institut de Recherche Saint-Louis, Hôpital Saint-Louis, AP-HP, Paris, France, [2]Sorbonne Université, Centre de Recherche Saint-Antoine, INSERM UMRs938, Hôpital Saint-Antoine, AP-HP, Paris, France, [3]Centre Hospitalier Universitaire de Nice, Nice, France, [4]Centre Hospitalier Universitaire de Toulouse, Institut Universitaire du Cancer de Toulouse – Oncopole, Toulouse, France, [5]Centre Hospitalier Universitaire de Lille, Lille, France, [6]Centre Hospitalier Régional Universitaire de Nancy, Vandœuvre-lès-Nancy, France, [7]Centre Hospitalier Régional Universitaire de Tours, Hôpital Bretonneau, Tours, France, [8]Sanofi, Gentilly, France

Background: Corticosteroids are the first-line treatment for post-transplant chronic graft-versus-host disease (cGvHD); however, adverse effects and steroid refractoriness in ~50% of patients have driven the development of novel agents. Belumosudil, an oral, selective Rho-associated coiled-coil containing protein kinase 2 (ROCK2) inhibitor, is approved as a third-line cGvHD treatment. In France, belumosudil became accessible to patients on 13 March 2022 via a compassionate use programme, providing an opportunity to evaluate its use in clinical practice.

Methods: On 26 September 2023, a compassionate access programme with a protocol for therapeutic use and patient follow-up for belumosudil was implemented. Thereafter, 143 patients with cGvHD who received belumosudil were enrolled under this programme until 25 March 2025. The inclusion criteria were age ≥12 years, weight ≥40 kg, Karnofsky score (≥16 years) or Lansky score (<16 years) ≥60, moderate-to-severe cGvHD diagnosis per National Institutes of Health (NIH) criteria, and prior treatment with 2–5 systemic lines of therapy (LOTs). Patients received belumosudil at a dose of 200 mg daily, which was increased to 200 mg twice daily if administered concurrently with a potent CYP3A inducer or proton-pump inhibitor. Organ-specific responses were assessed to evaluate efficacy.

Results: The median age of the 143 patients was 59.0 (IQR, 44.0–66.0) years, with 136 (95.1%) adults (aged ≥18 years) and 7 (4.9%) children (aged 12–18 years). Forty-nine (34.3%) patients were female and 94 (65.7%) were male. Of 143 patients, 34 (23.8%) had moderate cGvHD and 109 (76.2%) had severe cGvHD. The median number of prior LOTs was 3.0 (IQR, 2.0–4.0). Nine (6.3%) patients had not received ruxolitinib or systemic corticosteroids in prior LOTs. Sixteen (11.2%) patients received treatment concomitantly with a potent CYP3A inducer, and 83 (58%) received treatment concurrently with a proton-pump inhibitor. Fifty-one (35.7%) patients had confirmed belumosudil administration, evidenced by at least one follow-up or treatment discontinuation form.
Organ-specific response data were available for 38 of these 51 patients at 3 months. Responses were observed in patients with inflammatory and fibrotic cGvHD manifestations, including prototypic fibrotic changes in the lungs. At 3 months, among 34.3% of patients showing lung manifestations, 5.3% experienced symptom disappearance and 7.9% showed improvement; among 21% showing gastrointestinal symptoms, 7.9% experienced symptom disappearance and 7.9% showed improvement; among 15.8% showing musculoskeletal involvement, 7.9% showed improvement; among 76.4% showing skin manifestations, 7.9% experienced symptom disappearance and 39.5% showed improvement; and among 39.5% showing oral cavity manifestations, 5.3% experienced symptom disappearance and 18.4% showed improvement. These results were sustained at 9 and 12 months. However, considering the low number of sheets collected and discontinuation sheets received at these timepoints, interpretation of efficacy results and quality of life could not be performed. No new adverse event was reported beyond those previously published for belumosudil.

Conclusions: Organ-specific responses were observed across organs in all dose groups, including organs with the most fibrotic changes. This analysis confirmed the safety profile of belumosudil, agreeing with previously published data. As of July 2025, 281 patients have been recruited, and the overall analysis might reveal better efficacy outcomes with belumosudil.

B050

MORTALITY BY ORGAN-SPECIFIC FIBROTIC MANIFESTATIONS IN PATIENTS WITH CHRONIC GRAFT-VERSUS-HOST DISEASE IN THE UNITED STATES

Kevin Hall[1], Lauren Rota[2], Shaum Kabadi[2], Kathy Marshall[2], Robert Schwenk[3], Nataly Bleibdrey[2], Mithun Manoharan[4], Allison Smither[5], ***Alyshah Abdul Sultan***[2]
[1]Department of Pharmaceutical Services, Winship Cancer Institute of Emory University, Atlanta, United States of America (the), [2]Sanofi, Morristown, United States of America (the), [3]Sanofi, Berlin, Germany, [4]nference inc, Bengaluru, India, [5]nference inc, Cambridge, United States of America (the)

Background: Fibrotic manifestations of cGVHD can affect multiple organs including lung, skin, gastrointestinal tract, and joint/fascia, leading to significant morbidity and mortality; however, the real-world impact of organ-specific fibrotic manifestations on mortality has not been well characterized. This study evaluated the impact of organ-specific fibrosis on all-cause mortality.

Methods: Patient electronic medical records de-identified in a HIPAA-compliant manner from a multisite academic medical center in the US were analyzed to identify adults (aged ≥18 years) with first allogenic hematopoietic stem cell transplantation (aHSCT) and cGVHD diagnosis between 1 January 2015 and 31 May 2024. A large language model (LLM) with tailored prompts was leveraged to identify lung, skin, gastrointestinal (GI), and joint/fascia fibrosis from unstructured patient notes using predefined fibrosis-suggestive and -specific terms developed with clinical expert input. Fibrosis presence was assessed from 90 days before through the day of their first identified cGVHD diagnosis in the health care system (baseline) and post-cGVHD diagnosis (follow-up). Landmark analyses at 1-year post-cGVHD diagnosis evaluated the impact of fibrosis on all-cause mortality. Differences in overall survival were assessed by Cox hazard regression and the log-rank test.

Results: Of 925 patients meeting inclusion criteria, median age at diagnosis was 60 years, 91% were White, 57% male, with acute myeloid leukemia (34%) and myelodysplastic syndrome (23%) being most common pre transplant diagnoses. Mean follow-up was 33.1 months. 1/2 Internal Overall, 49% of patients had evidence of selected fibrosis at some point in their medical record with fibrosis of skin being the most common (31%) followed by fibrosis of lung (17%), joint and fascia (16%) and GI (5%). Of 674 patients alive and contributing data at 1-year landmark timepoint, 259 patients had evidence of fibrosis. Patients with fibrosis at one-year landmark had more severe cGVHD at baseline (30% vs 19%) and were prescribed more systematic treatments compared to patients with no fibrosis including ruxolitinb and ECP. Whilst median survival was not reached for landmark cohort, survival at 36 month was lower for those with lung fibrosis compared to those without fibrosis at landmark (77.6% vs 89.7%, p-value 0.039) corresponding to a hazard ratio of 1.72 (95% CI 1.02-2.90).

Conclusions: This real-world evidence study demonstrates that fibrotic manifestations in cGVHD are prevalent. Those developing lung fibrosis had lower overall survival compared to patients without. These findings support the need for early identification and intervention.

B051

SAFETY AND TOLERABILITY OF A CANNABIS-BASED OIL EXTRACT IN MULTIPLE MYELOMA PATIENTS UNDERGOING AUTOLOGOUS STEM CELL TRANSPLANTATION – A PHASE I STUDY

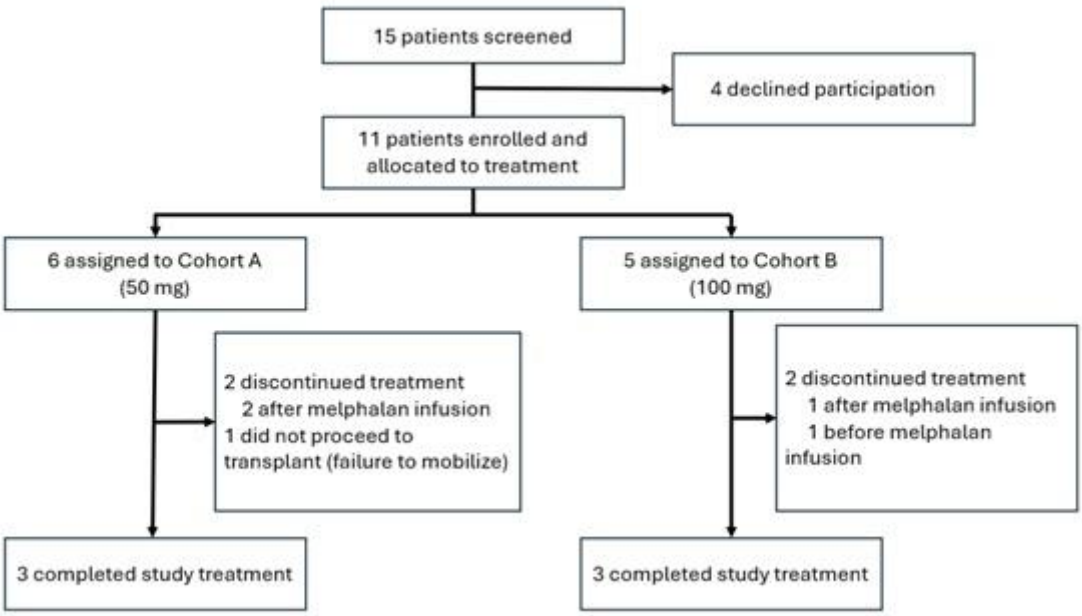
*André Dias Americo[1], **Juliana Matos Pessoal**[1], Isabella Pimentel Pittol[1], Camila Cordeiro Farias[2], Flávia Cortez Colosimo[1], Phillip Scheinberg[1], Alana C. Costa[3], Helena P. G. Joaquim[3], Breno M. de Gusmão[1]*
[1]Beneficiencia Portuguesa de Sao Paulo, São Paulo, Brazil, [2]BP Beneficência Portuguesa de São Paulo, São Paulo, Brazil, [3]GreenCare Pharma, São Paulo, Brazil

Background: Patients submitted to autologous stem cell transplantation face a heavy burden of symptoms such as nausea, mucositis and pain. Cannabidiol-based (CBD) products may alleviate such symptoms. However, CBD safety in the setting of high-dose chemotherapy is not well established. Objective: to assess the safety of a cannabis-based oil in patients undergoing aHSCT with high-dose melphalan (HDM) for multiple myeloma and plasma cell dyscrasias.

Methods: We planned a classical 3+3 dose-finding study with escalating doses of a CBD-rich extract (160 mg/mL; CBD 96 mg/mL; THC 2.4 mg/mL; GreenCare Pharma®), followed by an expansion cohort of 15 patients at the maximum tolerated dose (MTD). Patients received

50 mg, 100 mg, 200 mg or 300 mg in cohorts A, B, C and D, respectively. Patients with prior severe psychiatric disorders or using clobazam or valproate were considered ineligible. The extract was administered from 7 days prior to graft infusion to 15 days after hospital discharge. Predefined dose-limiting toxicities (DLTs) included elevation of hepatic enzymes and severe psychiatric toxicities (unwanted psychotropic effects, hallucinations, delusions, psychosis, major depressive episodes or mania/hypomania).

Results: From June 2024 to May 2025, fifteen patients were screened, 11 were recruited and 10 patients undergoing aHSCT received at least one dose of CBD and were included in the analysis. Participants median age was 63 years [range 42-67], 3/10 were female and 9/10 received 200 mg/m² of melphalan, while one participant received 140 mg/m². Median exposure to the study drug was 35 days [range 7–43]. No DLTs were observed among the 11 participants. Engraftment occurred after a median of 11 days [range 11–14] from graft infusion in all transplanted patients. Severe nausea attributed to extract occurred in 1 patient prior to HDM, leading to withdrawal from the protocol. After HDM, 8 of 9 evaluable patients reported severe nausea attributed to extract, and 3 of them discontinu
ed therapy. Therefore, severe nausea was 8.89 times more likely after HDM (95% CI 1.36–57.8). Among transplanted patients, 6 experienced a documented infection during aHSCT, and all had grade 3 febrile neutropenia. No patient required ICU admission, and all participants were alive after 224 days of follow-up [range 173-224].



Conclusions: Most patients either complained of nausea or discontinued therapy shortly after HDM. This transplant period is characterized by a high incidence of dysgeusia, chemotherapy-induced nausea and vomiting and oral mucositis, which may have contributed to poor tolerability of the oil-based CBD formulation. Difficulties in maintaining patients on-protocol, together with budgetary constraints, led investigators to terminate the study early. Considering aHSCT outcomes, there were no concerns regarding safety, rates of engraftment

and infection/febrile neutropenia were within the expected range.
In the present study, CBD-rich oil was not associated with DLTs but was poorly tolerated, particularly in the post-HDM period, due to nausea and taste intolerance. Future research in this setting should consider alternative CBD formulations, such as capsules or transdermal patches.

Clinical Trial Registry: NA

PROPHYLACTIC TOCILIZUMAB FOR THE PREVENTION OF ACUTE GRAFT-VERSUS-HOST DISEASE IN MATERNAL HAPLOIDENTICAL HEMATOPOIETIC STEM CELL TRANSPLANTATION: A PROSPECTIVE SINGLE-ARM STUDY

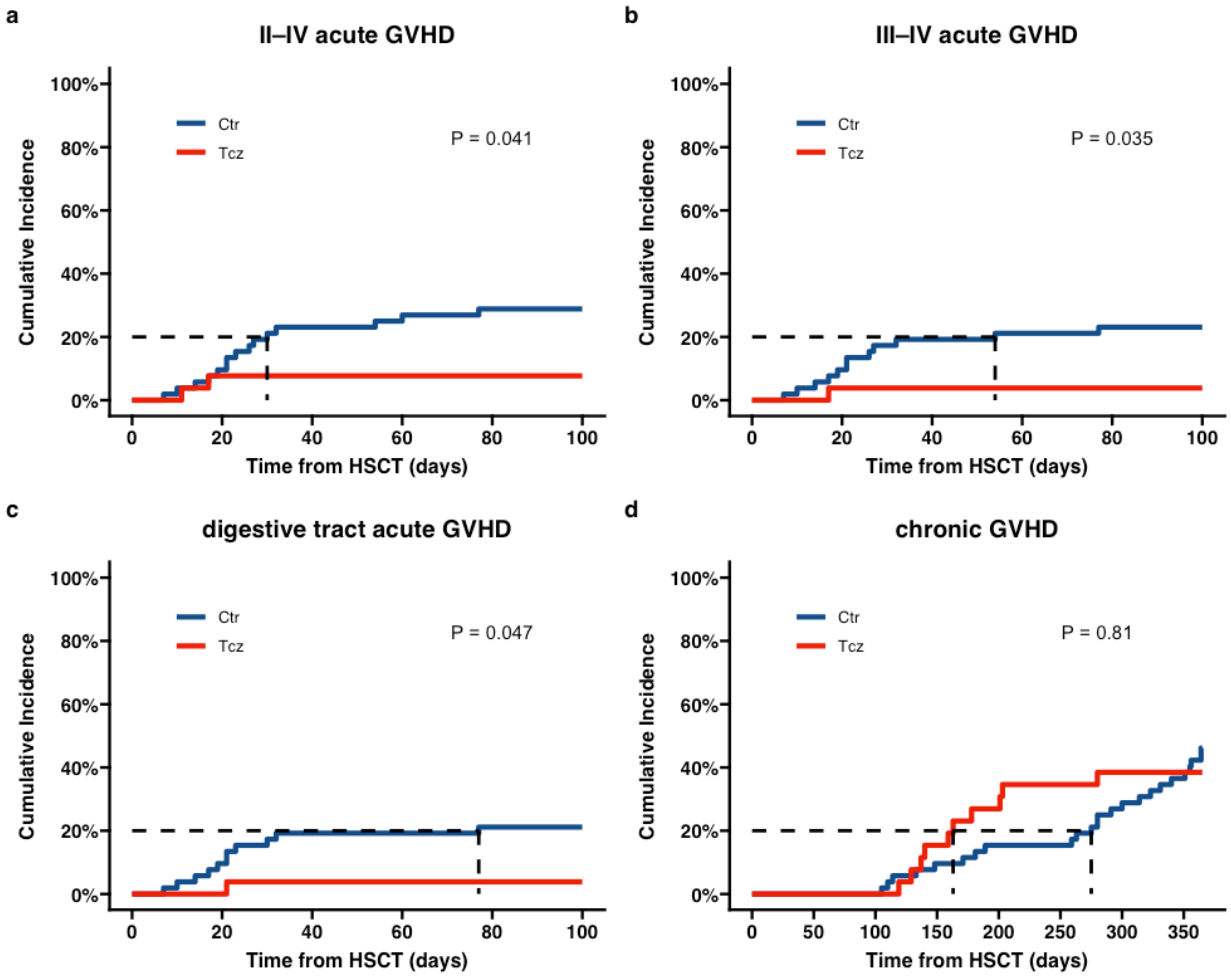
*Shipei Xiang[1], Xiaoyu Lai[1], Luxin Yang[1], **Yibo Wu**[1], Jimin Shi[1], Yanmin Zhao[1], Jian Yu[1], Huarui Fu[1], Yishan Ye[1], Huang He[1], Lizhen Liu[1], Yi Luo[1]*
[1]The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China

Background: Haploidentical hematopoietic stem cell transplantation (haplo-HSCT) is increasingly performed worldwide, and maternal donors represent an important alternative donor source, particularly in regions with limited availability of HLA-matched donors. However, maternal donors are associated with a higher risk of acute graft-versus-host disease (aGVHD), potentially related to heightened alloimmune priming and early inflammatory activation. Tocilizumab (TCZ), an IL-6 receptor antagonist, has shown efficacy in steroid-refractory aGVHD and in prophylaxis after HLA-matched transplantation. However, its role as upfront prophylaxis in maternal haploidentical transplantation remains unclear. We therefore conducted a prospective study to assess the safety, efficacy, and immunologic impact of prophylactic TCZ in maternal haplo-HSCT.

Methods: From March 2021 to April 2024, 26 patients who received haplo-SCT from maternal donors in the Bone Marrow Transplantation Center of the First Affiliated Hospital of Zhejiang University School of Medicine were enrolled in tocilizumab prevention trial. All patients received a myeloablative BUCY-based conditioning regimen. Anti-thymocyte globulin Fresenius (ATG-F 10mg/kg) or anti-thymocyte globulin-Genzyme (ATG-G 6mg/kg) was applied. One intravenous dose of TCZ (8 mg/kg) was given the day before stem cell transfusion along with standard GVHD prophylaxis (cyclosporin plus short-term methotrexate and mycophenolate mofetil). Outcomes were compared with a matched historical control cohort receiving identical conditioning and prophylactic regimens except for TCZ. The trial was registered at Clinicaltrials.gov (NCT04688021).

Results: Twenty-six patients received prophylactic TCZ and were compared with 54 matched historical controls with balanced baseline characteristics. The median onset of aGVHD was 17 days (range, 12–30) in the TCZ group and 21 days (range, 14–38) in controls. By day 100

post-transplant, the cumulative incidence of grade II–IV and grade III–IV aGVHD was significantly reduced in the TCZ group compared with controls (7.7% vs 28.8% and 3.9% vs 23.1%, respectively; P = 0.041 and P = 0.035; Figure 1). Organ-specific analysis further demonstrated a marked reduction in GI aGVHD (3.8% vs 21.2%; P = 0.047), whereas no significant differences were observed in skin or liver involvement.After a median follow-up of 27 months, 1-year overall survival and relapse-free survival were 88.5% and 73.1%, respectively, while transplant-related mortality and relapse incidence were 11.5% and 15.4%. Transplant-related deaths were attributable to cGVHD (n = 1) and sepsis (n = 2), with no excess mortality observed in the TCZ group.Median neutrophil recovery occurred at 16 days in the TCZ group versus 14 days in controls, whereas platelet recovery was comparable. The cumulative incidence of cGVHD did not differ between groups. Rates of severe infections were consistent with historical experience, and no infusion-related adverse events attributable to TCZ were observed.Early cytokine profiling showed a transient elevation of serum IL-6 after transplantation, consistent with pharmacodynamic receptor blockade. Immune monitoring demonstrated early $CD8^+$ T-cell expansion with delayed $CD4^+$ T-cell recovery, resulting in a temporary reduction in the $CD4^+/CD8^+$ ratio that normalized by day 180.



Conclusions: In conclusion, prophylactic tocilizumab is safe, biologically rational, and clinically promising for reducing aGVHD after maternal haploidentical HSCT. Larger multicenter randomized trials are warranted to validate these findings.

ABATACEPT FOR GVHD PROPHYLAXIS IN PEDIATRIC STEM CELL TRANSPLANTATION: A SINGLE-CENTER EXPERIENCE FROM SAUDI ARABIA

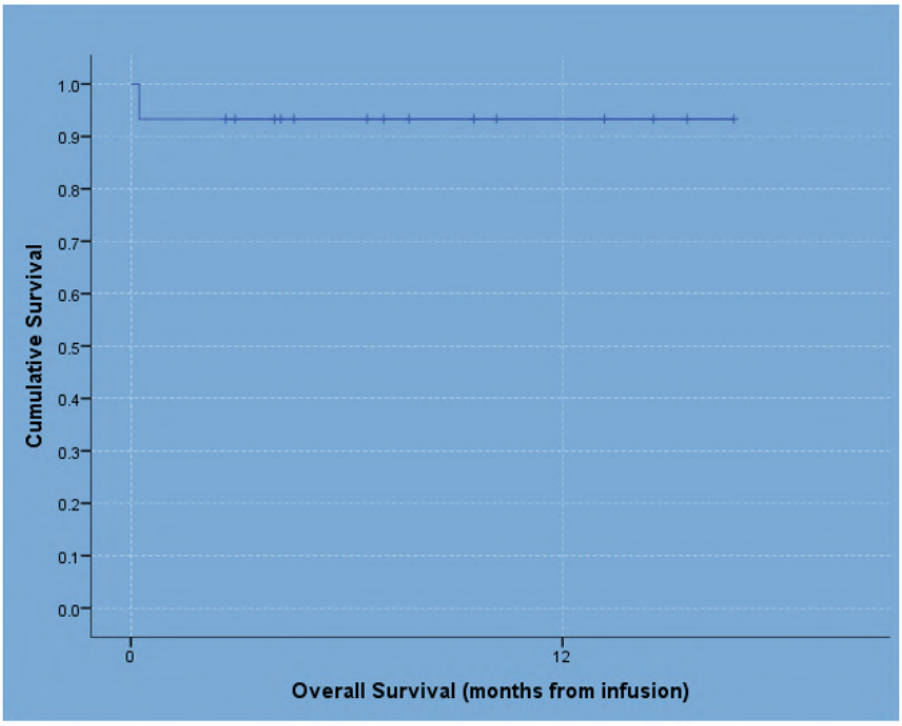
*Samer Markiz[1], **Hawazen Alsaedi**[1], Khawar Siddiqui[1], Muhammad Zulfiqar[1], Saadiya Khan[1], Abdullah Aljefri[1], Awatif AlAnazi[1], Mouhab Ayas[1], Ibrahim Ghemlas[1], Ali Al-Ahmari[1]*
[1]King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

Background: Graft-versus-host disease (GVHD) remains a major complication of allogeneic hematopoietic stem cell transplantation (HCT), particularly in the setting of HLA disparity. It continues to pose a significant clinical challenge and contributes to transplant related mortality despite over five decades of advancements in GVHD prophylaxis. In 2021, the FDA approved abatacept (Orencia) in combination with calcineurin inhibitors (CNIs) and methotrexate (MTX) for acute GVHD prophylaxis in adults and children ≥2 years undergoing matched or 1 allele-mismatched unrelated donor HCT. While its efficacy and safety have been demonstrated in multicenter trials, data in pediatric populations, especially from the Middle East, remain limited.

Methods: We retrospectively analysed 15 consecutive pediatric patient (less than 14 years) who underwent allogeneic HCT between 2024–2025 and received abatacept-based GVHD prophylaxis. Median age at infusion was 2.8 years (range 0.3–12.3); 12 (80%) were males. Fourteen patients (93.3%) had non-malignant disorders. Stem cell sources included bone marrow in 13 (86.7%) and peripheral blood in 2 (13.3%). Donors were matched related in 8 (53.3%), mismatched related in 5 (33.3%), and haploidentical in 2 (13.3%). Myeloablative conditioning was used in 14 (93.3%) patients. Median CD34+ cell dose was 7.1 × 10^8/kg of body weight.

Results: Fourteen patients (93.3%) achieved complete hematopoietic recovery, with median time neutrophil and platelet engraftment of 14 days (range 12–19) and 22 days (range 14–42) respectively. Among 12 evaluable patients at day +120, acute GVHD (only skin) occurred in 2 (16.7%; Grade II and III), while chronic GVHD (moderate-sk in) was observed in 2 (16.7%) and was not preceded by acute GVHD. Transplant-related toxicities included hypertension (50%) and isolated cases (8.3% each) of seizure, SOS/VOD, interstitial pneumonia, hemorrhagic cystitis, encephalopathy, and mucositis. Infectious complications occurred in 10 (83.3%) patients: 8 (66.7%) bacterial, 5 (41.7%) viral and 4 (33.3%) fungal. CMV reactivation was documented in 4 (33.3%). At a median follow-up of 7.0 months (95% CI: 4.9–9.2), overall survival was 93.3% ± 6.4%. One patient (6.7%) died early post-transplant (day+10); this child had severe combined immunodeficiency with a history of recurrent bacteremia and PICU admissions prior to HCT. All surviving patients maintained

engraftment and demonstrated stable immune reconstitution at last follow up.



Conclusions: In this single-center pediatric cohort, abatacept-based prophylaxis was associated with low rates of acute and chronic GVHD compared to historical cohorts using ATG based -regimen. It showed favorable survival outcomes, despite frequent infectious complications. These findings support the safety and efficacy of abatacept in pediatric HCT, though larger studies with longer follow-up are warranted to confirm its role in diverse transplant settings.

PET-CT AND CHRONIC GVHD: A DIAGNOSTIC TOOL AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION ? A PROSPECTIVE INTERVENTIONAL STUDY WITHIN CHU CAEN NORMANDY, FRANCE

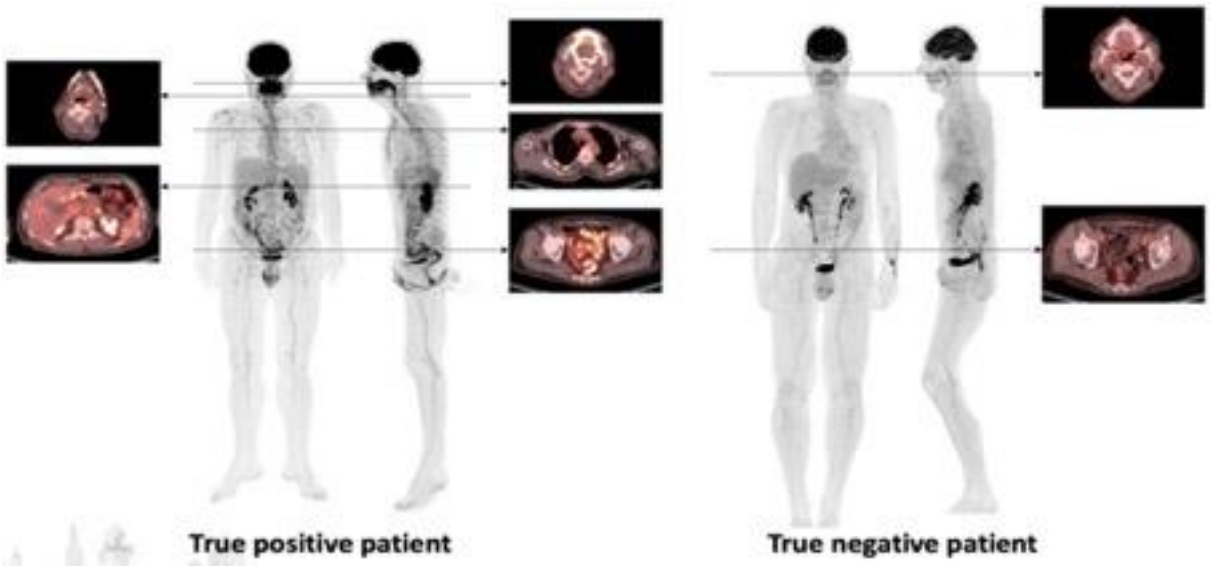
Quentin Levesque[1], *Charline Lasnon*[1], *Hyacinthe Johnson-Ansah*[1], *Hélène Fouques*[1], *Anne Claire Gac*[2], *Oumedaly Reman*[1], *Gandhi Laurent Damaj*[1], *Nicolas Aide*[2], *Sylvain Chantepie*[1]
[1]*CHU Caen Normandie, Caen, France,* [2]*Polyclinique du Parc, Caen, France*

Background: Allogeneic hematopoietic stem cell transplantation (allo-HSCT) remains a curative treatment for numerous malignant and benign hematologic diseases, but its benefit is often offset by graft-versus-host disease (GVHD), the leading cause of non-relapse morbidity and mortality. Chronic GVHD (cGVHD) develops in 30–70% of patients. Diagnosis is primarily clinical and must be confirmed by histology, which remains the gold standard despite its invasiveness. FDG PET-CT has shown potential value in acute GVHD due to its non-invasive nature, but its role in chronic GVHD remains unclear. This study aimed to assess the diagnostic accuracy of FDG PET-CT for cGVHD after immunosuppressive withdrawal.

Methods: In this prospective study conducted at the Institut d'Hématologie de Basse-Normandie, 42 patients transplanted between 2015 and 2019 were screened. Thirty-five patients ultimately underwent FDG PET-CT for diagnostic evaluation; seven were excluded due to consent withdrawal, disease progression, loss to follow-up, death, refusal, or non-interpretable imaging. FDG PET-CT was completed approximately one month after discontinuation of immunosuppressive therapy. PET results were blinded to clinicians and used for research purposes only. Patients were monitored monthly for 6 months, and cGVHD was assessed using the 2014 NIH criteria. PET findings were compared with clinical diagnosis and histological confirmation when available.

Results: The median age was 56 years. Conditioning regimens were myeloablative (14.3%), reduced-intensity (71,4%), and sequential (14,3%). Graft sources included peripheral blood stem cells (88,6%), bone marrow (8.6%), and cord blood (2.8%). GVHD prophylaxis varied according to conditioning regimen. FDG PET/CT was performed at a median of 161 days post-transplant. Among the 35 patients, 27 (77%) developed cGVHD. FDG PET/CT was positive in 15 patients (43%). Diagnostic performance showed a sensitivity of 44,4% ($CI_{95\%}$[0,28 ; 0,62]), specificity of 62,5%($CI_{95\%}$[0,31 ; 0,86]), positive predictive value of 80%, and negative predictive value of 25%. From this data, the likehood ratios (LR) calculated are 1,19 ($CI_{95\%}$[0,44 ; 3,19]) for the positive one (LR+) and 0,89 ($CI_{95\%}$[0,47 ; 1,68]) for the negative one (LR-).

Conclusions: FDG PET-CT demonstrated limited diagnostic accuracy for chronic GVHD after immunosuppressive withdrawal. Given its low sensitivity and limited predictive value, FDG PET-CT does not appear suitable for routine evaluation of suspected chronic GVHD in this setting. Alternative non-invasive biomarkers or imaging strategies should be explored.



Disclosure: Nothing to declare.

REAL-WORLD EFFICACY AND TOXICITY PROFILE OF RUXOLITINIB IN PEDIATRIC ACUTE AND CHRONIC GRAFT-VERSUS-HOST DISEASE: A MULTICENTER RETROSPECTIVE STUDY

Andrea Buonsante[1], *Marco Sindoni*[1], *Maria Gabelli*[2], *Maria Sambuco*[3], *Manuela Tumino*[2], *Sonia Bonanomi*[4], *Sara Napolitano*[4], *Pietro Casartelli*[4], *Marta Adavastro*[4], *Francesca Vendemini*[4], *Giulia Prunotto*[4], *Marta Verna*[4], *Giovanna Lucchini*[4], *Linda Rossini*[2], *Chiara Mainardi*[2], *Giulia Reggiani*[2], *Antonio Marzollo*[2], *Marta Pillon*[2], *Alessandra Biffi*[2,5], *Adriana Balduzzi*[4,1], *Giorgio Ottaviano*[4]
[1]*University of Milano-Bicocca, Monza, Italy,* [2]*University Hospital of Padova, Padova, Italy,* [3]*IRCCS Ospedale San Raffaele, Milano, Italy,* [4]*Fondazione IRCCS San Gerardo dei Tintori, Monza, Italy,* [5]*University of Padova, Padova, Italy*

Background: Ruxolitinib has been the first drug approved for acute and chronic GvHD in patients≥12 years with inadequate response to corticosteroids or other systemic therapies. The pediatric population affected by GvHD is highly heterogeneous, thus real-world studies are essential to identify potential predictors of response and toxicity in this setting.

Methods: We retrospectively analyzed 51 pediatric patients (0-18 years) treated with ruxolitinib for GvHD between 2016 and 2024 in 3 Italian centres (acute n=29; chronic n=17; overlap n=1; acute and chronic n=3; overlap and chronic n=1). GvHD was steroid-resistant in 51%, steroid-dependent in 38%, and steroid-naïve in 11% of cases. Kaplan–Meier and cumulative incidence analyses were used to evaluate time to treatment failure.

Results:

In acute GvHD the overall response (OR) and complete response (CR) rates were 78% and 50%, respectively. Multi-organ involvement was associated with a significantly lower response to ruxolitinib compared to isolated skin aGvHD (OR 59% vs 100%, p=0.007).

In chronic/overlap GvHD the OR and CR rates were 78% and 26%, respectively. OR was significantly associated with the number of prior immunosuppressive lines, being higher in patients who had received two or fewer lines before ruxolitinib (p = 0.03). Ruxolitinib enabled steroid tapering in 75% of patients with both acute and chronic/overlap GVHD, with complete steroid discontinuation—without the need for additional immunosuppressive therapy—achieved in 38% and 58% of cases, respectively.

Patients with aGvHD grade III–IV had the highest and earliest failure incidence (p 0.005), in particular they experienced a 60 days- and 90 days-CIF of 46.9% and 74.7% respectively, concerning ruxolitinib discontinuation for non-response or initiation of additional immunosuppression. When including ruxolitinib discontinuation due to toxicity as a failure event, failure-free survival was significantly lower in aGvHD grade III–IV (9% at 6 months, p < 0.005), with children aged 6–12 years being the most affected (p = 0.019).

No significant differences in overall response rates were observed across age groups; however, patients aged 6–12 years showed a lower complete response rate compared to those aged ≥12 years with aGvHD (p 0.02).

Response rates were comparable between patients starting ruxolitinib at reduced age-adjusted doses and those receiving standard doses, while toxicity was slightly higher in the latter group (43% vs 33%). All steroid-naive patients (n=6) responded to Ruxolitinib.

Ruxolitinib was discontinued due to toxicity in 20/51 patients (39%). The most common toxicity was hematologic. 30/51 patients (59%) had infections requiring specific therapy during Ruxolitinib treatment, while 16/51 patients (31%) had viral reactivations.

Conclusions: Our study supports the efficacy of ruxolitinib in pediatric patients with both acute and overlap/chronic GvHD, including children <12 years. Lower complete response rates observed in children aged 6–12 years with aGvHD warrant further investigation. The comparable response observed even in patients receiving lower-than-age-recommended starting doses suggests that a dose-escalation strategy may help mitigate toxicity without compromising efficacy. The higher failure-free survival in patients with lower grade aGvHD suggests an early-stage ruxolitinib initiation.

Disclosure: Nothing to declare.

B056

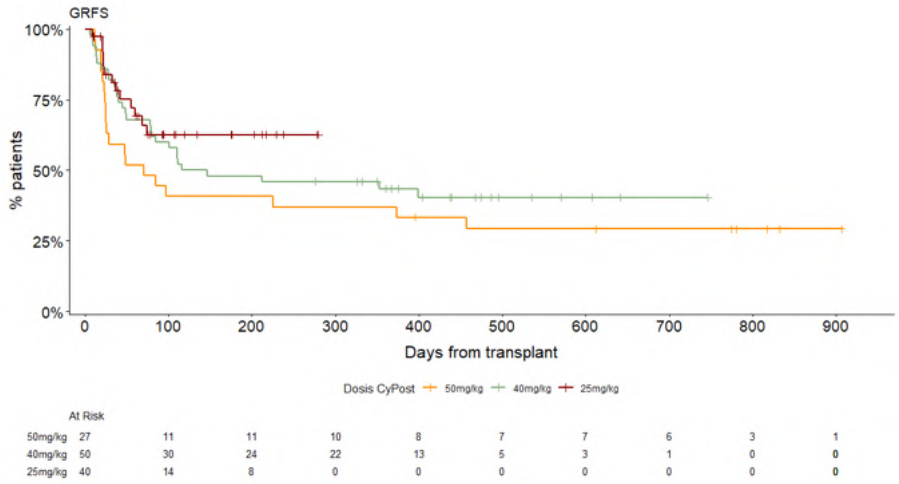
"EFFECT OF REDUCING THE DOSES OF CYCLOPHOSPHAMIDE ON OUTCOMES AND ON IMMUNE RECOVERY"

Francisco Manuel Martín Domínguez[1], *Guillermo Oliva Ariza*[1], *Patricia Alcalde Mellado*[1], *Alicia Jordano Jiménez*[1], *Cristina Blázquez Goñi*[1], *Belén León Dominguez*[1], *Nancy Rodríguez Torres*[1], *Ana Hernández Martín*[1], *Laura Pérez Ortega*[1], *Ildefonso Espigado Tocino*[1], *Marta Reinoso Segura*[1], *Maria Reyes Jiménez León*[1], *Estefanía Menéndez Pedregal*[1], *Teresa Caballero Velázquez*[1], *José Antonio Pérez Simón*[1]
[1]*Virgen del Rocío University Hospital, Seville Biomedicine Institute (IBiS/CSIC), Seville, Spain*

Background: Post-transplant cyclophosphamide (PTCy) 50 mg/kg on days +3 and +4 has become one of the standard graft-versus-host disease (GvHD) prophylaxis after allogeneic stem cell transplantation. Although effective, it may cause early toxicity. Reduced-dose PTCy regimens aim to preserve efficacy while minimizing adverse effects.

Methods: Single-center retrospective study of adult patients, consecutively undergoing allogeneic hematopoietic stem cell transplantation (HSCT) between May2023 and Sept2025. Patients received PTCy according to one of three regimens: a) 50 mg/kg on days +3 and +4 combined with tacrolimus or sirolimus and mycophenolate mofetil (MMF); b) 40 mg/kg on days +3 and +4 combined with tacrolimus and MMF; or c) 25 mg/kg on days +3 and +4 combined with sirolimus and MMF. The primary endpoints included overall survival (OS), GvHD-free-survival, GVHD-free/relapse-free survival (GRFS), cumulative incidence of relapse (CIR), non-relapse mortality (NRM), cumulative incidence and severity of acute (aGvHD) and chronic graft-versus-host disease (cGvHD). Quantification of major leukocyte subsets in blood was assessed by flow cytometry at days +100 and +180 after HSCT. Analyses were performed in *R* (R Core Team, 2021) using Kaplan–Meier and Cox models.

Results: A total of 117 patients were included (a=27, b=50 and c=40). No significant differences were observed among the groups regarding HCT-CI, underlying disease, stem cell source or infusion-related parameters. A statistically significant reduction in the incidence of haemorrhagic cystitis (33% vs 22% vs 10%; p=0.01) and sinusoidal obstruction syndrome/veno-occlusive disease (22% vs 0% vs 10%; p=0.005) was observed in patients receiving reduced-dose PTCy.
In contrast, no significant differences were found in terms of OS at day 200 [55% vs 68% vs 72% (p=0.3)], GvHD-free-survival at day 200 [55% vs 62% vs 73% (p=0.3)], GRFS at day 200 [41% vs 48% vs 63% (p=0.2)], CIR at day 200 [8% vs 15% vs 0% (p=0.16)], NRM at 100 days [41% vs 25% vs 27% (p=0.16)], aGvHD grades 2-4 at day 100 [40% vs 30% vs 47% (p=0.17)], aGvHD grades 3-4 at day 100 [39% vs 20% vs 25% (p=0.16)], overall cGvHD at day 275 [8% vs 10% vs 11% (p=0.97)] and moderate to severe cGvHD at day 275 [6% vs 8% vs 10% (p=0.95)].
Regarding immune cell reconstitution, patients who received a reduced dose of PTCy showed higher T-cell counts (129 [55–353] vs. 298 [135–489] vs. 460 [244–1099], p=0.02) at day +100 after HSCT, across all major T-cell subsets. However, by day +180 after the transplant, these differences remained significant only for CD4+ T cells (195 [100–217] vs. 263 [166–339] vs. 311 [247–459], p=0.03). These findings suggest a dose-dependent effect of PTCy on post-transplant immune reconstitution of the T-cell compartment.



Conclusions: Cyclophosphamide dose reduction appears to be safe and effective, showing no inferiority to the standard-dose regimen in terms of efficacy and safety. Moreover, lower PTCy doses were associated with reduced early post-transplant toxicity and a more favourable pattern of immune reconstitution. These results suggest that optimized, reduced-dose PTCy regimens may improve post-transplant outcomes without compromising disease control or GvHD prevention.

Disclosure: Nothing to declare.

RUXOLITINIB UTILIZATION IN STEROID-REFRACTORY GVHD DURING THE PTCY ERA: A COMPARATIVE ANALYSIS WITH AN HISTORICAL ATG COHORT

Riccardo Marnoni[1], *Simone Maifredi*[1], *Rachele De Domenico*[1], *Marco Galli*[1], *Silvia Zanon*[1], *Mirko Farina*[1], *Gabriele Magliano*[1], *Enrico Morello*[1], *Vera Radici*[1], *Paolo Clementi*[1], *Francesca Bonati*[1], *Laura Donatoni*[1], *Simona Bernardi*[1], *Federica Re*[1], *Alessia Cavalleri*[1], *Alessandro Leoni*[1], *Domenico Russo*[1], *Michele Malagola*[1], *Daniele Avenoso*[1]
[1]*Unit of Blood Diseases and Bone Marrow Transplantation, Department of Clinical and Experimental Science, University of Brescia, ASST Spedali Civili di Brescia, Brescia, Italy*

Background: Acute and chronic Graft-Versus-Host Disease (GVHD) remain major contributors to morbidity and mortality following allogeneic hematopoietic stem cell transplantation (allo-HSCT). Despite the adoption of post-transplant cyclophosphamide (PTCy)–based prophylaxis, which is standard in haploidentical transplantation and more recently also in matched unrelated donor transplantation, acute GVHD (aGVHD) still occurs in approximately 30–50% of patients (pts) and chronic GVHD (cGVHD) in 30–70%.

Corticosteroids represent the standard first-line therapy; however, up to 50% of pts develop steroid-refractory (SR) disease. Since 2018, ruxolitinib has been validated as an effective second-line agent in the REACH2 and REACH3 trials. Here, we describe real-world clinical use patterns of ruxolitinib for SR-GVHD during the PTCy era in comparison with ATG-based GVHD prophylaxis.

Methods: A single-center retrospective study was performed including patients who underwent allo-HSCT between 2018 and 2024 and subsequently developed steroid-refractory acute or chronic GVHD treated with ruxolitinib. Major transplant-related outcomes were compared between patients receiving PTCy-based versus ATG-based GVHD prophylaxis.

Results: A total of 250 patients were included. Five-year overall survival (OS) from transplantation was 54.2%, with no significant difference between ATG- and PTCy-based GVHD prophylaxis (51.2% vs 55.4%, respectively; p=0.228). Five-year non-relapse mortality (NRM) was 23.7% overall and was higher in the PTCy group compared with the ATG group (36.2% vs 18.1%; p=0.02).
Acute GVHD occurred in 44.4% of patients (111/250), with 22.5% presenting with grade III–IV disease. Among patients with acute GVHD, 52.3% developed steroid-refractory disease. Ruxolitinib was administered in 69.0% of SR-aGVHD cases. Among ruxolitinib-treated patients, 55.0% had received ATG-based prophylaxis, 32.5% PTCy-based prophylaxis, and 12.5% cyclosporine plus MTX/MMF. The median duration of ruxolitinib treatment was 101 days (range 13–382). Median overall survival for ruxolitinib-treated SR-aGVHD patients was 50 months, and 100-day failure-free survival (FFS) was 86.7%.
Chronic GVHD developed in 22.8% of patients (57/250), with 80.7% classified as moderate to severe. Steroid-refractory disease occurred in 59.6% of cGVHD cases, and ruxolitinib was used in 67.6% of these patients. Among ruxolitinib-treated SR-cGVHD cases, 73.9% had received ATG-based prophylaxis, 17.4% PTCy-based prophylaxis, and 8.7% cyclosporine plus MTX. The median duration of ruxolitinib treatment was 237 days (range 16–1044). Median overall survival was not reached, and 1000-day FFS from transplantation was 85.0%.

SR	58	23,2	52,3	**% on SR GVHD**
SR treated with Ruxo	40	16,0	36,0	69,0
Chronic GVHD				
Any grade	57	22,8	100,0	
Moderate-Severe	46	18,4	80,7	
SR	34	13,6	59,6	
SR treated with Ruxo	23	9,2	40,4	67,6

Conclusions: In this real-world cohort, ruxolitinib demonstrated sustained efficacy in the treatment of steroid-refractory acute and chronic GVHD across different GVHD prophylaxis strategies. Although PTCy-based prophylaxis is associated with lower rates of chronic GVHD in the contemporary transplant setting, clinically relevant SR-cGVHD remains a significant unmet need. Our findings indicate that ruxolitinib retains clinical activity and durability of response in this context, supporting its role as an effective second-line therapy for SR-GVHD irrespective of the upfront prophylaxis strategy.

Disclosure: None.

B058

CLINICAL FEATURES AND OUTCOME OF CHRONIC GVHD IN PEDIATRIC PATIENTS: A MULTICENTER STUDY ON BEHALF OF THE SPANISH GROUP FOR HEMATOPOIETIC TRANSPLANTATION AND CELL THERAPY(GETH-TC)

Laura Alonso Garcia[1], *Ivan Lopez Torrija*[2], *Maria Isabel Benitez Carabante*[1], *Monica Lopez Duarte*[3], *Blanca Molina Angulo*[4], *Luz Uria Oficialdegui*[1], *Sara Vinagre*[4], *Paula Mazorra*[5], *Marta Gonzalez-Vicent*[4], *Mercedes Plaza Fornieles*[6], *Cristina Diaz de Heredia*[1]
[1]*Hospital Infantil Universitari Vall d'Hebron, Barcelona, Spain,* [2]*Hospital Sant Pau, Barcelona, Spain,* [3]*Hospital Universitario Marqués de Valdecilla, Santander, Spain,* [4]*Hospital Infantil Niño Jesús, Madrid, Spain,* [5]*Hospital Sant Joan de Déu, Barcelona, Spain,* [6]*Hospital Virgen de la Arrixaca, Murcia, Spain*

Background: Chronic graft-versus-host disease (cGVHD) is a major cause of morbidity and the leading cause of non-relapse mortality among long-term survivors after pediatric allogeneic hematopoietic stem cell transplantation (HSCT). However, the incidence and outcomes in children remain poorly characterized. The impact of cGVHD in pediatric patients may be greater due to longer life expectancy. This study aims to describe clinical features and outcome of pediatric patients diagnosed with cGVHD following HSCT.

Methods: Retrospective analysis of pediatric patients who underwent allogeneic HSCT between January 2018 and December 2023 in transplant units of the GETH-TC and were diagnosed with cGVHD.

Results: A total of 63 patients were included from 5 hospitals. Median age at HSCT was 9.6 years (IQR 5.2–13.1), with a median follow-up of 3.63 years (IQR 2.3–5.4). The median time from HSCT to cGVHD diagnosis was 0.54 years (IQR 0.36–0.94).Underlying disease was malignant in 74% (ALL 46%, AML 14%) and non-malignant in 26% (including inborn errors of immunity 12.7% and metabolic disorders 3.2%).
Most patients received myeloablative conditioning (87%), based on TBI for 12.8 % and chemotherapy for the rest. Serotherapy was administered to 47.6%. Peripheral blood was the predominant stem cell source (65%), followed by bone marrow (32%). Donor types included haploidentical (43%), MSD(16%), MUD(22%), and MMUD (16%). Graft manipulation (mainly αβ T-cell depletion) was performed in 24%. Prior acute GVHD occurred

in 86%.
At cGVHD onset, severity was mild in 27%, moderate in 51%, and severe in 22%, with maximum severity reaching severe in 45%. The most frequently involved organs were skin (74.6%), mucosa (39.7%), lung (36.5%), liver (34.9%), eye (33.3%), gut (23,8%), fascia (4.8%). Autoimmunity was described in 4.8% and pleural or pericardial effusion in 1.6%
Complications were reported in 35 patients (56.5%), including viral infections (37.1%) and bone-related problems (48.6%).
Treatment response:72.6% of patients required more than one line, with 8 receiving up to five lines of treatment.
Thirteen patients died. Two due to leukemia relapse and for the rest, the causes of death were: infectious complications in 5, including influenza and pneumococcal septic shock; thrombotic microangiopathy and infection; pulmonary haemorrhage; respiratory failure due to progressive pulmonary cGVHD; complications after lung transplantation; surgical complications. One patient died of causes not related to HCT.
Overall survival at 12 months post-cGVHD diagnosis was 88.7% (95%CI: 77.7–94.4), and at 24 months, 85.2% (95%CI: 73.5–92.0).
Of the 50 patients that are alive, with median follow-up of 4.64 years, 16 present active cGVHD and 22 still receive immunosuppression.

Conclusions: This series provides a valuable clinical picture of pediatric cGVHD in recently transplanted patients. Despite the high overall survival, the probability of achieving freedom from cGVHD and immunosuppression remains low and the burden of treatment and associated complications is high.
The most frequent cause of death remains infectious complications, which reminds us of the importance of optimal infectious prophylaxis for these patients, including flu and pneumococcal vaccination.
This results highlight the importance of developing transplant strategies that avoid chronic GVHD, and we believe also provide valuable information to inform families.

Disclosure: None.

B059

CHARACTERISTICS OF CLINICAL TRIALS IN GRAFT-VERSUS-HOST DISEASE: LANDSCAPE OF STUDY DRUGS AND ASSESSMENT OF OUTCOME MEASURES

*Philipp Melhorn[1], Nina Dominik[1], Lina Zoe Rüsing[1], Julia Cserna[1], **Hanna A. Knaus**[1], Axel Schulenburg[1], Margit Mitterbauer[1], Hildegard T. Greinix[1], Werner Rabitsch[1]*
[1]Medical University of Vienna, Vienna, Austria

Background: Graft-versus-host disease (GvHD) has a significant impact on survival and quality of life of patients after allogeneic hematopoietic stem cell transplantation (HCST), and patients frequently do not respond to currently available treatments, calling for further advances through clinical trials.

Methods: Based on study registration records from ClinicalTrials.gov (from database inception to 2025-10-31), completed and ongoing GvHD treatment studies were evaluated with respect to general trial characteristics, eligibility criteria, treatments, and endpoints.

Results: Of the 1,063 interventional treatment studies identified by an initial database search, 382 clinical trials investigated treatments for manifest GvHD (3.4% early phase 1, 16.0% phase 1, 19.1% phase 1/2, 39.0% phase 2, 2.4% phase 2-3, 11.3% phase 3, and 2.9% phase 4 trials; 6.0% missing). The median enrollment count was 25 patients and 31.4% of trials were randomized, with significant differences ($p<0.001$) based on study phase (median number of 17, 30, and 105 patients included and randomization in 14.8%, 31.5%, and 74.4% for phases 1, 2, and 3, respectively). Overall, 43.2% of trials investigated acute GvHD and 48.2% chronic GvHD (3.1% either and 5.5% not specified), with significantly ($p=0.039$) more phase 2 trials (48.4% vs 32.7%) and significantly ($p<0.001$) longer study durations for chronic GvHD (median duration for primary outcome of 3.2 vs 2.0 years and for the overall study of 4.0 vs 2.9 years). Concerning the period of study initiation, 31.2% were started in 2006-2015 and 59.9% in 2016-2025. Studies from the later period were significantly more likely to have parallel study groups (34.5% vs 26.1%, $p=0.002$), to be shorter in overall duration (3.0 vs 4.0 years, $p<0.001$), and to recruit in multiple ($n>5$) centers (33.2% vs 16.8%, $p<0.001$). Registered studies were predominantly conducted only in the United States (48.7%) and to a lesser extent only in Europe (12.4%). Over time, there was a rise in registered trials per year (>30 trials per year in 2024 and 2025). The most frequent treatments studied were corticosteroids (n=64), followed by mesenchymal stem cells (n=52), ruxolitinib (n=31), extracorporeal photopheresis (n=26), fecal microbiota transplantation (n=17), rituximab (n=15), belumosudil and cyclosporin (n=13 each), itacitinib (n=11), axatilimab and donor regulatory T-cells (n=10 each), and ibrutinib (n=9). In terms of primary endpoints, response was most frequently assessed (56.4%), followed by safety (27.5%), dosing (12.3%), patient-reported outcomes (6.4%), a composite of either efficacy or treatment failure (5.1%), pharmacokinetics and survival (2.7% each), feasibility (1.9%), and other measures (12.6%). The relevant point in time for overall response rate assessment was earlier for acute (median: 4 weeks, Q1–Q3: 4–7.5 weeks) than for chronic GvHD (median 26 weeks, Q1–Q3: 24–52 weeks). Of all completed trials (n=228), 38.6% had been withdrawn or terminated prematurely (n=37/81 or 45.7% due to slow accrual).

Conclusions: Acute and chronic GvHD remain major areas of clinical research, with their distinct clinical courses reflected in differences in trial design and outcome measures. Recent shifts toward multicenter designs, shorter study durations, and more frequent evaluation of targeted therapies suggest evolving priorities and growing methodological maturity in GvHD trial planning.

Disclosure: Nina Dominik received travel support from Gilead. Lina Zoe Rüsing received honoraria for lectures or advisory board participation from Johnson & Johnson, GSK, and Pfizer; and travel support from Johnson & Johnson and Sanofi. Julia Cserna received honoraria for presentations from Sobi; and travel support from Neovii and Sanofi. Hildegard T Greinix received honoraria for presentations at scientific meetings from Therakos, Sanofi, Neovii, and Novartis. Werner Rabitsch received speakers' honoraria from Therakos, Kite Gilead, and MSD; honoraria for advisory board participation from Kite Gilead, BMS, Johnson&Johnson, Novartis, and MSD; and travel support from Neovii. Philipp Melhorn,

Hanna Knaus, Axel Schulenburg, and Margit Mitterbauer have no conflicts of interest to disclose.

B060

IMPACT OF ANTI-T-LYMPHOCYTE GLOBULIN DOSING ON GRAFT VERSUS HOST DISEASE IN MATCHED SIBLING PERIPHERAL BLOOD STEM CELL TRANSPLANTATION

Radwan Massoud[1], *Evgeny Klyuchnikov*[1], *Silke Heidenreich*[1], *Maroly Bohorquez Manjarres*[1], *Ina Rudolph*[1], *Rolf Krause*[1], *Claudia Langebrake*[1], *Adrin Dadkhah*[1], *Rusudan Sabauri*[1], *Christian Niederwieser*[1], *Mathias Schäfersküpper*[1], *Franziska E. Marquard*[1], *Maraike Harfmann*[1], *Max Wichmann*[1], *Sofia Oechsler*[1], *Gunnar Weise*[1], *Catherina Lueck*[1], *Nico Gagelmann*[1], *Kristin Rathje*[1], *Normann Steiner*[2], *Christine Wolschke*[1], *Francis Ayuk*[1], *Nicolaus Kröger*[1]
[1]*Department of Stem Cell Transplantation, University Medical Center Hamburg-Eppendorf, Hamburg, Germany,* [2]*Department of Internal Medicine V Hematology and Oncology, Innsbruck Medical University, Innsbruck, Austria*

Background: Anti-T-lymphocyte globulin (ATLG) is routinely used for graft-versus-host disease (GVHD) prophylaxis in allogeneic stem cell transplantation; however, the optimal ATLG dose in matched sibling donor peripheral blood stem cell transplantation (MSD-PBSCT) remains undefined. Lower doses may result in insufficient GVHD prevention, whereas higher doses may increase immunosuppression and compromise graft-versus-leukaemia effects. We evaluated the impact of two ATLG dosing strategies on transplant outcomes, with a primary focus on GVHD-free, relapse-free survival (GRFS) and moderate-to-severe chronic GVHD (cGVHD).

Methods: We conducted a single-centre retrospective cohort study including 165 consecutive adult patients with haematological malignancies who underwent MSD-PBSCT between 2011 and 2022. Patients received either ATLG 15 mg/kg (ATLG-15, n=71) or 30 mg/kg (ATLG-30, n=94; Grafalon®). Primary endpoints were moderate-to-severe cGVHD and GRFS. Secondary endpoints included overall survival (OS), progression-free survival (PFS), non-relapse mortality (NRM), relapse incidence, acute GVHD, and engraftment. Propensity score matching (PSM) was performed to reduce baseline imbalances, and a predefined subgroup analysis was conducted in AML/MDS patients not receiving total body irradiation (TBI).

Results: At 2 years, the cumulative incidence of moderate-to-severe cGVHD was significantly lower in the ATLG-30 group compared with ATLG-15 (28% vs. 43%, p=0.045). In multivariable analysis, ATLG-30 was independently associated with improved GRFS (HR 0.47, 95% CI 0.25–0.88; p=0.02). Two-year GRFS was 36% in the ATLG-30 group versus 24% in the ATLG-15 group (p=0.10). No significant differences were observed between groups in 2-year OS (77% vs. 72%, p=0.2), PFS (65% vs. 60%, p=0.4), NRM (6% vs. 13%, p=0.11), or cumulative incidence of relapse (28% vs. 25%, p=0.64). Neutrophil (median 11 vs. 12 days, p=0.004) and platelet engraftment (median 12 vs. 15 days, p=0.0002)

occurred earlier with ATLG-15, without a survival advantage.
In the PSM cohort, ATLG-30 remained associated with superior GRFS (p=0.047) and showed a consistent trend toward reduced moderate-to-severe cGVHD (p=0.067). Among AML/MDS patients without TBI (n=108), ATLG-30 was associated with a significantly lower incidence of moderate-to-severe cGVHD (19% vs. 38%, p=0.039).

Conclusions: In MSD-PBSCT, ATLG 30 mg/kg was associated with a clinically meaningful reduction in moderate-to-severe chronic GVHD and improved GRFS, without adversely affecting relapse or non-relapse mortality. These findings support a quality-of-survival benefit of higher ATLG dosing in this setting and warrant prospective validation in multicentre studies.

B061

SAFETY AND EFFICACY OF ABATACEPT IN THE MANAGEMENT OF STEROID-REFRACTORY CHRONIC GRAFT-VERSUS-HOST DISEASE. A SINGLE CENTER EXPERIENCE

Panagiotis Dolgyras[1], *Ioannis Papadopoulos*[1], *Raphail Tzanninis*[1], *Christos Demosthenous*[1], *Zoi Bousiou*[1], *Anna Vardi*[1], *George Karavalakis*[1], *Nikolaos Spyridis*[1], *Eleni Gavriilaki*[2,1], *Katherine Kosmidou*[1], *Alkistis-Kira Panteliadou*[1], *Ioannis Batsis*[1], *Ioanna Sakellari*[1]
[1]*George Papanikolaou Hospital, Thessaloniki, Greece,* [2]*Aristotle University of Thessaloniki, Thessaloniki, Greece*

Background: Despite therapeutic advances, steroid-refractory chronic graft-versus-host disease (cGVHD) remains a major clinical challenge, particularly in patients with significant cytopenias who have limited treatment options. Abatacept, a CTLA-4–Ig fusion protein that binds CD80/CD86 on antigen-presenting cells and inhibits T-cell activation, is currently FDA-approved only for the prophylaxis of acute GVHD. Its role as salvage therapy in steroid-refractory cGVHD requires further evaluation. This study assessed the efficacy and safety of abatacept in this setting.

Methods: We conducted a retrospective analysis of consecutive patients with NIH-defined moderate or severe steroid-refractory cGVHD who received abatacept at our center between 2024–2025. Abatacept was administered at 10 mg/kg weekly for the first three doses and every four weeks thereafter. Patient characteristics, organ involvement, previous therapies, cytopenias, treatment response, steroid tapering, and adverse events were recorded.

Results: Nine patients were included (median age 44.8 years, range 20–58). Underlying diagnoses were B-ALL (n=4), AML (n=3), and NHL (n=2). Stem-cell donors were matched sibling (n=5), matched unrelated (n=3), and haploidentical (n=1). The median interval from transplant to abatacept initiation was 18.6 months (3.4–61). Prior to treatment, 3 patients had moderate and 6 had severe cGVHD. Organ involvement included skin (9/9), oral mucosa

(5/9), gastrointestinal tract (4/9), eyes (4/9), liver (1/9), and lungs (2/9). One patient had steroid- and rituximab-refractory autoimmune hemolytic anemia. Patients had received a median of 3 prior systemic lines (1–5) and all were on corticosteroids (mean dose 0.66 mg/kg). Only three had previously received ruxolitinib, discontinued due to toxicity and five were undergoing ECP.
cGVHD Responses at 1, 3, and 6 months and cytopenias evolution are summarized in Table 1.

Table 1. Response to Treatment**.**

Timepoint	Anemia ≥GIII	Neutropenia ≥GIII	Thrombocytopenia ≥GIII	≥1 Cytopenia ≥GIII	cGVHD Response	Mean PDN Dose (mg /kg)
Baseline	1/9	3/9	6/9	7/9	-	0.66
1 month (n=9)	1/9	1/9	6/9	7/9	5/9 PR 4/9 SD	0.38
3 months (n=6)	1/6	1/6	2/6	2/6	2/6 CR 2/6 PR 2/6 SD	0.22
6 months (n=6)	0/6	0/6	0/6	0/6	2/6 CR 2/6 PD after PR 2/6 PR after SD	0.12

PDN: Prednisolone, CR: Complete Response, PR: Partial Response, SD: Stable Disease, PD: Progressive Disease

During six-month follow-up, six lower respiratory tract infections occurred, alongside other infectious episodes (Clostridium difficile colitis, febrile neutropenia, bacteremia). Mean hospitalization duration was 9 days (0–20). Abatacept was discontinued in one patient due to recurrent grade 3 infections. Two patients died within two months: one because of relapsed B-ALL (MRD-positive pre-transplant) and one because of septic shock in the context of poor performance status and recurrent infections prior to abatacept inanition.
Among the five patients with longer follow-up (median 10 months, range 9–16), none remains on abatacept: four switched to ruxolitinib (three due to progression, one as treatment continuation), while one patient in sustained CR is off any therapy. One patient with Richter's transformation relapsed.

Conclusions: Abatacept appears to be a safe and effective therapeutic option for steroid-refractory cGVHD. Moreover, abatacept seems to enable meaningful steroid sparing. In patients with severe cytopenias who cannot tolerate other established therapies, abatacept may serve as a viable alternative or bridging therapy until hematologic recovery.

Disclosure: Nothing to declare.

OUTCOMES AFTER ALLOGENEIC STEM CELL TRANSPLANTATION FOR MYELOFIBROSIS WITH PERI-TRANSPLANT-RUXOLITINIB PROPHYLAXIS

Miriam Mozaffari Jovein[1], *Thomas Meyer*[1,2], *Miguel Waterhouse*[1], *Dietmar Pfeifer*[1], *Jesús Duque-Afonso*[1], *Kristina Maas-Bauer*[1], *Ralph Wäsch*[1], *Jürgen Finke*[1], *Robert Zeiser*[1,3,4], *Claudia Wehr*[1]
[1]*Medical Center - University of Freiburg, Freiburg im Breisgau, Germany,* [2]*Collaborative Research Institute Intelligent Oncology (CRIION), Freiburg, Germany,* [3]*German Cancer Consortium (DKTK) and German Cancer Research Center (DKFZ), Freiburg/Heidelberg, Germany,* [4]*Signalling Research Centres BIOSS and CIBSS - University of Freiburg, Freiburg, Germany*

Background: While the innovation of the JAK-inhibitor ruxolitinib has expanded the treatment possibilities for myelofibrosis (MF), allogeneic stem cell transplantation (alloHCT) still represents the only curative treatment. Relapse after alloHCT is frequent and complications like graft-versus-host disease (GvHD), transplant-related toxicity and infections remain serious concerns.

Methods: We retrospectively analyzed data from 68 adults with MF (Table 1) after first alloHCT between 04/2008 and 04/2025. Peri-transplant-ruxolitinib prophylaxis was added 08/2023 and administered 2x5mg/d from d-7 to d-2 and from d+4 to d+21 before dose reduction to 1x5mg/d and discontinuation on d+28. Statistical analyses were performed with R (Version 4.3.2). Primary endpoint was GvHD-relapse-free survival (GRFS). Secondary endpoints were overall survival (OS) and disease-free survival (DFS).

Results: Peri-transplant-ruxolitinib prophylaxis was added in 20.6%. Median follow-up time after alloHCT was 23.3 months (range 0.2-182.6). Patients receiving peri-transplant-ruxolitinib displayed a tendency towards longer GRFS (2-year GRFS with ruxolitinib: 51.0%, 2-year GRFS without ruxolitinib: 18.5% (n.s.)), OS (2-year OS 92.9% vs. 63.0% (n.s.)) and DFS (2-year DFS 79.6% vs. 57.4% (n.s.)) (Figure 1). In multivariate cox regression analysis including patient-, disease- and treatment-specific characteristics, peri-transplant-ruxolitinib and a higher transplant conditioning intensity (TCI) positively and significantly impacted GRFS (addition of peri-transplant-ruxolitinib: HR 0.276, p=0.017, TCI intermediate vs. low: HR 0.375, p=0.0155), while year of alloHCT, age at alloHCT and hematopoietic cell transplantation-specific comorbidity index (HCT-CI) showed no significant impact.
Driver mutations at primary diagnosis were present in: *CALR* n=11 (16.2%), *JAK2* n=30 (44.1%) and *MPL* n=7 (10.3%). Pre-alloHCT treatments included ruxolitinib (73.5%), hydroxyurea (42.6%) and supportive therapies (17.6%, e.g erythropoietin, anagrelide and phlebotomy). All patients received peripheral blood stem cell grafts, mostly from 10/10 matched unrelated donors (MUD, 67.7%) (Table 1) after conditioning with fludarabine, thiotepa and melphalan (FTM, 44.1%), fludarabine, carmustin and melphalan (FBM, 30.9%) or thiotepa, fludarabine and treosulfan (TFTreo, 25.0%). GvHD prophylaxis consisted of a backbone of cyclosporine A (CsA) + mycophenolate (MPA) in 85.3% or everolimus + MPA in 14.7% of patients and was combined with serotherapy (anti-T-lymphocyte globulin (ATLG) or alemtuzumab) in 80.9% of cases.
Prevalence of GvHD requiring systemic treatment (acute GvHD (aGvHD) or chronic GvHD

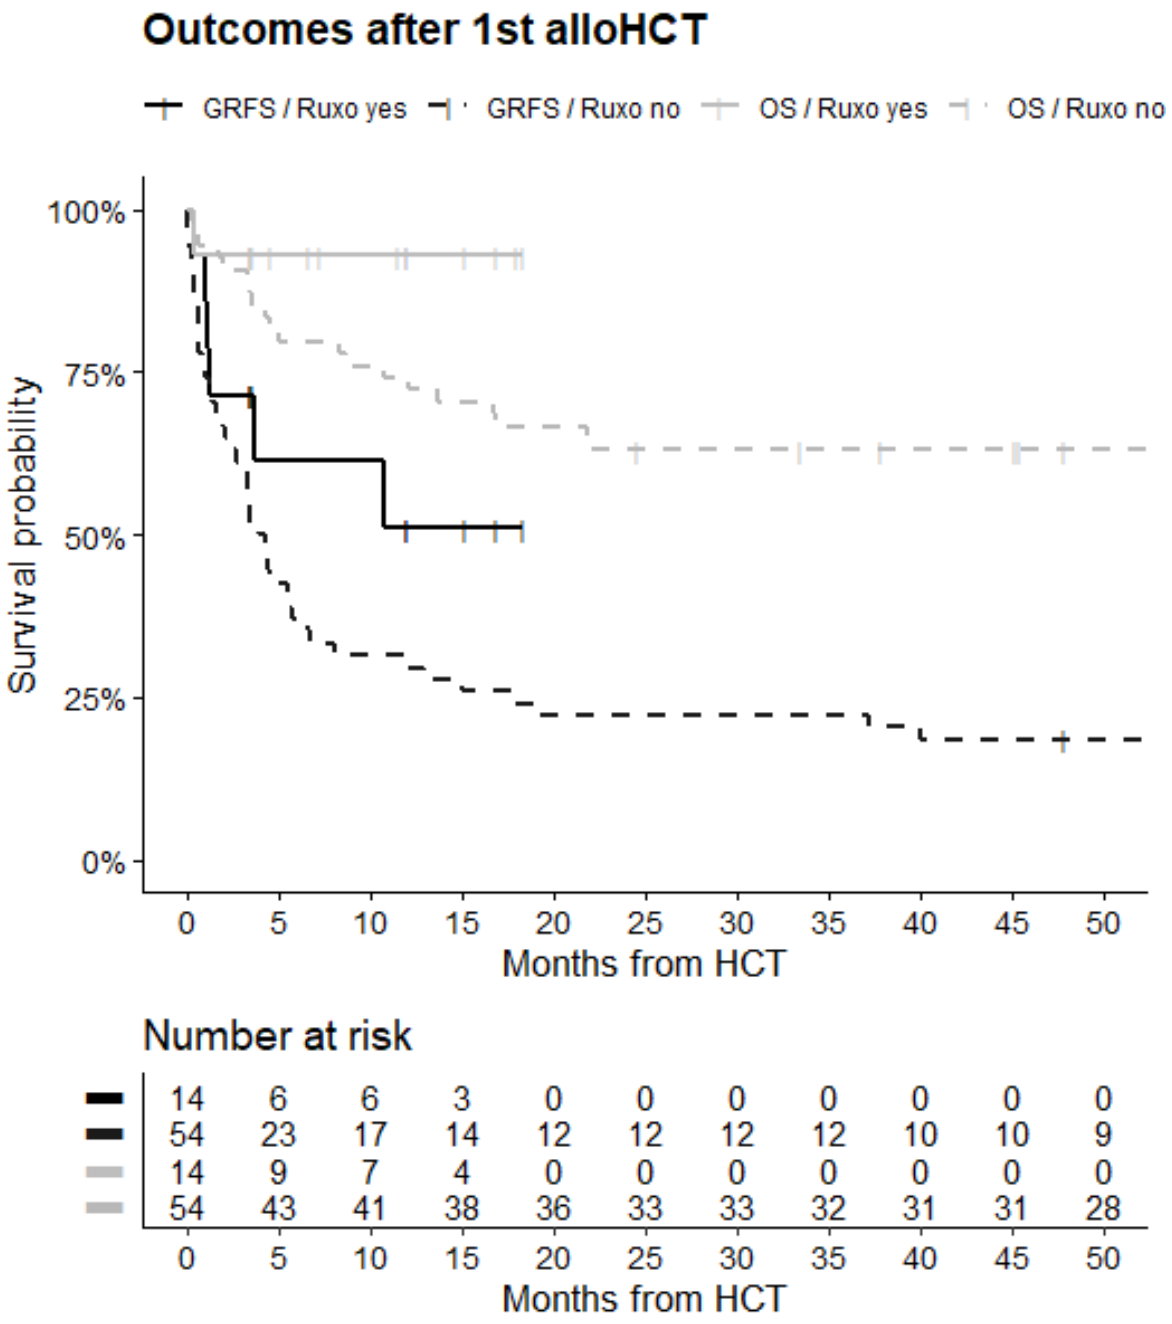
(cGvHD)) was 50.0% in the entire cohort (with ruxolitinib: 28.6%, without ruxolitinib: 55.6%) and distributed equally between aGvHD (overall: 36.8%, with ruxolitinib: 28.6%, without ruxolitinib: 35.2%) and cGvHD (overall: 32.4%, with ruxolitinib: 7.1%, without ruxolitinib: 38.9%). Ruxolitinib as treatment for steroid refractory GvHD was administered in 50% of those cases.
After alloHCT 77.9% of patients achieved complete remission (CR). At last follow-up 26 (38.2%) patients were deceased. Death prior to d+30 post alloHCT occurred in 7 (10.3%) patients (with ruxolitinib: n=1 (7.1%), without ruxolitinib: n=6 (11.1%)) and 15 (22.1%) patients died within the first year (with ruxolitinib: n=1 (7.1%), without ruxolitinib: n=14 (25.9%)). Leading causes of death were primary disease (30.8%), GvHD (30.8%) and infections (23.1%), followed by graft failure (7.7%), and toxicity (7.6%).

Table 1: Patient, alloHCT and treatment characteristics of 68 patients.

Age at HCT in years (median, range)	62 (18-76)
Sex	
female, n (%)	25 (36.8%)
male, n (%)	43 (63.2 %)
Time from diagnosis to alloHCT (months), median (range)	31.5 (0.3-383.5)
HCT-CI at alloHCT, median (range)	3 (0-7)
Disease	
Primary Myelofibrosis, n (%)	37 (54.4%)
Secondary Myelofibrosis, n (%)	31 (45.6%)
Donor match	
MRD, n (%)	12 (17.6%)
MUD, n (%)	46 (67.6%)
MMRD, n (%)	2 (2.9%)
MMUD, n (%)	8 (11.8%)
TCI Score	
low, n (%)	21 (30.9%)
intermediate, n (%)	47 (69.1%)

Table 1: Patient, alloHCT and treatment characteristics of 68 patients.

Abbreviations: HCT, hematopoietic stem cell transplantation; HCT-CI, Hematopoietic Cell Transplantation-specific Comorbidity Index; PV, polycythemia vera; ET, essential thrombocytosis; MRD, matched related donor; MUD, matched unrelated donor; MMRD, mismatched related donor; MMUD, mismatched unrelated donor; TCI, transplant conditioning intensity.



Conclusions: While MF patients are at risk for early death due to GvHD, relapse and infections after alloHCT, the addition of peri-transplant-ruxolitinib prophylaxis represents a promising strategy to optimize outcomes in this group.

Clinical Trial Registry: Not applicable.

Disclosure: The authors declare no conflicts of interest.

B065

IMPACT OF PULMONARY FUNCTION TESTING ON BRONCHIOLITIS OBLITERANS SYNDOME AND OUTCOME AFTER HEMATOPOIETIC STEM CELL TRANSPLANT

*Antonia Ricchiuto[1], Eleonora Prete[1], Francesco Aji[1], **Rosa De Francesco**[1], Loredana Panico[1], Vincenzo Pavone[1], Pasquale Barone[1], Anna Mele[1]*
[1]Cardinale G. Panico, Tricase, Italy

Background: Bronchiolitis obliterans syndrome (BOS) is a progressive small airway disease that can develop after hematopoietic stem cell transplantation (HSCT), often with poor therapeutic response and progression to respiratory failure. Diagnosis relies on pulmonary function test (PFT). We investigated the role of PFT as a prognostic marker in BOS and graft-versus-host disease (GvHD) after HSCT.

Methods: We performed a retrospective study of patients undergoing allogeneic HSCT from January 2018 to May 2025 at the Cardinale G. Panico Hospital (Tricase, Italy). Inclusion required baseline pre-transplant spirometry and informed consent. We used modified criteria from the 2005 NIH consensus definitions for BOS. Mid-expiratory flow at 75% of forced vital capacity (MEF75), 50% (MEF50), 25% (MEF25), and the mid-expiratory flow range between 75% and 25% (MEF75–25) ≤60% predicted were evaluated as additional markers of small airway obstruction and as potential predictors of BOS. Statistical analyses were conducted using Statistical Package for the Social Sciences, version 20.0 (SPSS 20.0). Associations with BOS, acute GvHD and chronic GvHD were examined through univariate testing, with significant variables entered into multivariate logistic regression. Odds ratios were calculated and significance was set at $\alpha = 0.05$. Time-to-event outcomes were analyzed using Kaplan–Meier estimates.

Results: The baseline characteristics of patients are shown in Table 1. Among 105 included patients (median age 56 years), 60% had a past or current smoking history, and 6% had pre-transplant chronic obstructive pulmonary disease (COPD). Acute leukemia was the most common indication for HSCT. Overall, 69% of patients received a matched unrelated donor transplant. BOS was diagnosed in 7 (7%) patients, at a median of 297 days (243-344) after HSCT, during a median follow-up of 492 days (391-1937) from the time of HSCT. All patients with BOS had evidence of chronic GVHD at another site. Univariate analysis showed that patients' clinical features, hematologic disease, smoking history, and pre-transplant COPD diagnosis were not significantly associated with BOS. Transplant-related variables likewise showed no significant impact on BOS onset (Table 1). The median Forced Expiratory Volume in 1 second (FEV1) was 98% of the predicted value (75–112) in patients with BOS and 103% (49–153) in those without BOS, with no statistically significant difference. Pre–alloHSCT PFTs showed no significant differences in median FEV_1, Tiffeneau index, MEF75, MEF50, or MEF75–25 between patients who developed BOS and those who did not (Table 1). MEF25 ≤ 60% was present in 86% of BOS cases compared to 47% of non-BOS patients, indicating a

significant association (p = 0,05, table 1). We analyzed the role of pre-transplant PFTs in the development of acute and chronic GvHD. MEF75 ≤ 60% was observed in 19% and 3% of patients with and without acute GvHD, respectively (p = 0.004). None of the examined pre-transplant PFT values showed a statistically significant correlation with the onset of chronic GvHD.

LOW-DOSE WEEKLY CIDOFOVIR AS AN EFFECTIVE PROPHYLACTIC ALTERNATIVE TO LETERMOVIR FOR PRE-ENGRAFTMENT CMV IN ALLOGENEIC HSCT

Santanu Sen[1], *Nirali Sanghvi*[1], *Manam Mehra*[1], *Juhi Mehrotra*[2], *Shyla Sen*[3]
[1]*Kokillaben Dhirubhai Ambani Hospital, Mumbai, India,* [2]*The Hospital for Sick Children, Toronto, Canada,* [3]*Colchester Hospital, Colchester, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Letermovir has redefined cytomegalovirus (CMV) prophylaxis in hematopoietic stem cell transplantation (HSCT) but remains inaccessible in many resource-limited regions. For high-risk patients in the pre-engraftment phase, the myelosuppressive toxicity of

ganciclovir limits its prophylactic use, creating an urgent need for effective, available alternatives. This study performs a head-to-head comparative analysis of low-dose weekly cidofovir as a prophylactic strategy against the benchmark efficacy and safety profile of letermovir.

Methods: In a setting where letermovir is unavailable, we prospectively evaluated weekly low-dose cidofovir (2.5 mg/kg, initiated Day +3, or Day +6 with PTCy) as pre-engraftment CMV prophylaxis in high-risk allogeneic HSCT recipients (R+/D-, haploidentical with PTCy, prior CMV infection). Monitoring included twice-weekly CMV PCR. Outcomes were compared to published letermovir data, focusing on breakthrough reactivation rates, need for secondary therapy, engraftment kinetics, nephrotoxicity, and survival.

Results: Among 32 high-risk patients receiving cidofovir prophylaxis, the breakthrough CMV reactivation rate was 31% (10/32), comparable to the 35-40% range reported with letermovir. Of these 10, 70% (7/10) were controlled by escalating cidofovir to a treatment dose (5 mg/kg/week), avoiding alternative antivirals. One patient (3.1%) required escalation to ganciclovir for disease. Notably, no significant nephrotoxicity or adverse impact on median time to neutrophil (Day +14) or platelet engraftment was observed, mirroring letermovir's favorable myelosuppression profile. There was no attributable mortality.

Conclusions: In a direct efficacy comparison, low-dose weekly cidofovir demonstrates breakthrough rates and a safety profile akin to letermovir for pre-engraftment CMV prophylaxis. For geographical regions where letermovir is unavailable or cost-prohibitive, this protocol provides a highly effective, practical, and cost-conscious prophylactic alternative, potentially mitigating early CMV-related graft compromise without the myelosuppressive risks of ganciclovir. It warrants consideration as a strategic option in global transplant practice.

Disclosure: Nothing to declare.

Hospital of Rouen, Rouen, France, [11]University Hospital of Angers, Angers, France, [12]University Hospital of Tours, Tours, France, [13]Anti Cancer Center Gustave Roussy, Paris, France

Background: Chronic Graft Versus Host Disease (cGVHD) is the most frequent and serious complication after allogenic hematopoietic stem-cell transplantation (allo-HSCT). In Europe, there is no agreed-upon standard of care or preferred therapeutic agents for patients who failed second line of systemic therapy (LOT). Therapeutic management beyond the first LOT remains poorly described. Conventional real-world data collection through manual chart review is time-consuming and costly, while some treatments are not captured in claims data. Thus, we used another approach.
We developed an innovative artificial intelligence natural language processing (AI-NLP) approach to identify and analyze cGVHD cases directly from electronic medical records (EMRs).

Methods: The AI-NLP scanned all EMRs of patients who received an allo-HSCT in 8 French centers, identifying those with cGVHD and at least 1 year of follow-up after cGVHD onset. Relevant information was extracted to structure, derive and infer the variables.
To ensure NLP derived data completeness and accuracy, a 3-step quality control process was performed: review by clinical research associate, comparison with the French Branch of the European Bone Marrow Transplant (EBMT) registry, validation by investigator experts.

Results: Among 513 screened allo-HSCT patients' EMRs, 235 patients developed a cGVHD, and 41 had at least 3 LOTs.
Of these 41 patients, 63.4% were men, mean age at allo-HSCT was 48.3 years, main reason for allo-HSCT was acute myeloid leukaemia (29.3%), myelodysplastic syndrome (19.5%). Median delay from allo-HSCT to cGVHD was 346.6 days. Seventeen patients (77.3%) had severe cGVHD.
The most frequently affected organs were skin (92.7%), gastrointestinal tract (43.9%), lungs (43.9%), liver (43.9%), mouth (39%), eyes (36.6%).
Treatments in LOT 1 were corticosteroids alone for 17 patients (41.5%). Other treatments alone or in association were ciclosporin for 15 patients (36.6%), ruxolitinib for 10 patients (24.4%), and other drugs for 4 patients (9.8%).
Treatments in LOT 2 (alone or in association) were ruxolitinib for 18 patients (43.9%), tacrolimus for 14 patients (34.1%), ciclosporin for 13 patients (31.7%), and other drugs for 5 patients (12.2%).
Treatments in LOT 3 (alone or in association) were ruxolitinib for 28 patients (68.3%), tacrolimus for 14 patients (34.1%), ciclosporin for 14 patients (34.1%), belumosudil for 8 patients (19.5%), and other drugs for 5 patients (12.2%).
At LOT 3:

- Overall response was available for 15 patients; 5 (33.3%) achieved complete response, 7 (46.7%) partial response.
- Mean time to response (time from the LOT initiation to the first documented cGVHD overall partial or complete response) was 191.7 days (11 patients).
- Mean failure free survival (time from the LOT initiation to the date of initiation of a new cGVHD treatment, recurrence/relapse of the underlying disease or death, whichever comes first) was 319.9 days (14 patients).

Conclusions: This is a first insight into the real-world management of cGVHD in France, using AI-NLP to generate a comprehensive, robust and accurate structured dataset, issued from information in electronic medical records of transplanted patients, with minimal burden on the medical teams in the participating centers. These initial analyses describe the therapeutic management and response of patients with cGVHD beyond second-line treatment.

B068

EFFECTIVENESS AND SAFETY OF BELUMOSUDIL FOR CUTANEOUS CHRONIC GRAFT-VERSUS-HOST DISEASE: A RETROSPECTIVE STUDY FROM CHINA

Fengjie Kang[1], Gang Chen[1], Jianli Xu[1], Kaile Zhang[1], Ruixue Yang[1], Chunxia Han[1], Jia Hou[1], Ming Jiang[1], ***Hailong Yuan***[1]
[1]*The First Affiliated Hospital of Xinjiang Medical University, Xinjiang, China*

Background: cGVHD (chronic graft-versus-host disease) is a major cause of morbidity and mortality after allo-HCT. Cutaneous cGVHD is present in upto 80% of patients with cGVHD and clinical presentations vary widely. Belumosudil (BEL), an oral selective Rho-associated coiled-coil–containing protein kinase 2 (ROCK2) inhibitor, was approved as a second-line treatment for steroid-refractory in August 2023 in China. It has been reported with 37% skin-specific ORR in the ROCKstar trial and 40% in Chinese phase II study. The current study aims to assess the efficacy and safety of BEL in cutaneous cGVHD patients at our center.

Methods: In this study, we retrospectively analyzed the clinical data of 21 cutaneous cGVHD adult patients in our center from March 1, 2024 to December 1, 2025. The overall response rate (ORR) and organ-specific responses, especially skin-specific ORR, were assessed using the NIH consensus response criteria. In addition, duration of treatment, OS, recurrence, and safety were also reviewed.

Results: A total of 21 patients were included in this retrospective study, with a median age of 35 years (range, 14-63). Ethnicities included Han (12, 57.1%), Uyghur (8, 38.1%), and Kazakh (1, 4.8%). The cutaneous manifestations of cGVHD were non-sclerotic in 19 patients and sclerotic in 2. Skin presentations with an incidence rate greater than 10% included maculopapular/lichen-planus like eruptions in 14 patients (67%), pruritus in 11 (52%), erythema in 10 (48%), and hyperpigmentation in 5 (24%). At baseline, 2 (9.5%), 14 (66.7%), and 5 (23.8%) patients had mild, moderate, and severe cGVHD, respectively. Treatments comprised second-line (12, 57.1%) and third-line or later (9, 42.9%) therapies. The median duration of treatment was 6.1 months (range, 0.4-21.3), with 12 patients treated for over 6 months. The skin-specific ORR for BEL was 81.0% (17/21) with CR 42.9% (9/21) and PR 38.1% (8/21), with ORR of 83.3% (5/6) for patients with skin-only organ involvement and 73.3% (11/15) for patients with multi-organ involvement. The ORR was 76.2% (16/21) for whole group, the ORRs for second-line and third-line or later therapy subgroups were 83.3% (10/12), and 66.7% (6/9), respectively. According to the NIH Grading, ORR was 100%(2/2), 78.6%(11/14) and 60% (3/5) for mild, moderate, or severe cGVHD. The other organ-specific ORRs are mouth 66.7% (4/6), ocular 87.5% (7/8), hepatic 75%(3/4),Joint 100% (1/1), and lung 0% (1patient PD and 3 patients with stable symptoms). Dose reduction of glucocorticoids and CNIs were common, mainly after 2 weeks of BEL administration. All patients survived without relapse. No new treatment-related adverse events (AEs) or serious AEs occurred.

Characteristic	All patients (n=21)	Characteristic
Age, years, median (range)	35 (14-63)	Non-sclerotic/Sclerotic
Race(Han/Uyghur/Kazakh)	12/8/1	Lines of belumosudil therapy
Sex (Male)	14 (66.7%)	2
Indication for transplant		≥3
AML	10 (47.6%)	Previous treatments
MDS	7 (33.3%)	Systemic corticosteroids
Others	4 (19.1%)	CNI
Donor type (MSD/HID)	2/19	Ruxolitinib
Previous acute GVHD	13 (61.9%)	MTX

Chronic GVHD severity (Mild/Moderate/Severe)	2/14/5	Others(MMF/Basiliximab/MSC/Rituxim
Organs involved at enrollment		Concomitant medications
1/2/3/4	6/9/4/2	MMF
Skin	21 (100%)	Ruxolitinib
Eyes	8 (38.1%)	cGVHD-to-belumosudil interval, mont
Mouth	7 (33.3%)	Follow-up time, months, median
Liver	5 (23.8%)	Duration of belumosudil treatment, m
Lungs	3 (14.3%)	≥6months
Joints	1 (4.8%)	<6months

Conclusions: Belumosudil demonstrated clinical efficacy in patients with cutaneous cGVHD, particularly in those with skin-only involvement and lower baseline NIH severity scores. The superior response observed with second-line use compared to later-line therapies suggests a benefit of earlier intervention.

Disclosure: Nothing to declare.

EARLY RUXOLITINIB USE IN MODERATE-TO-SEVERE PULMONARY CHRONIC GRAFT-VERSUS-HOST DISEASE: A CASE SERIES

Andrés Yesid Bonilla-Salcedo[1], *Rosa Adriana Alvidrez-González*[1], *Mistral Castellanos-Mares*[1], *Victor Iván Salinas-Herrera*[1], *Vicky Margarita Moncada-Gadea*[1], *Grecia Pamela Martínez-Vázquez*[1], *Irma Karen Pellon-Tellez*[1], *Luis Manuel Valero-Saldaña*[1]
[1]*Instituto Nacional de Cancerología, Mexico City, Mexico*

Background: Pulmonary involvement is a severe manifestation of chronic graft-versus-host disease (cGVHD) and is associated with significant morbidity and reduced quality of life after hematopoietic stem cell transplantation (HSCT). The introduction of targeted therapies, including Janus kinase inhibitors, has improved outcomes in steroid-refractory cGVHD. We

report three cases of moderate-to-severe pulmonary cGVHD successfully treated with early ruxolitinib.

Methods: Patient medical records and diagnostic images were reviewed for case descriptions.

Results:

Case 1: A 62-year-old man underwent haploidentical HSCT for acute myeloid leukemia with NPM1 and FLT3-ITD mutations. Comorbidities included type 2 diabetes mellitus and chronic kidney disease stage G2. Conditioning consisted of FluBuCy RIC with post-transplant cyclophosphamide (PTCy). A total of 7.4 × 10^6 $CD34^+$ cells/kg from peripheral blood were infused. Neutrophil and platelet engraftment occurred on days +14 and +16, respectively.

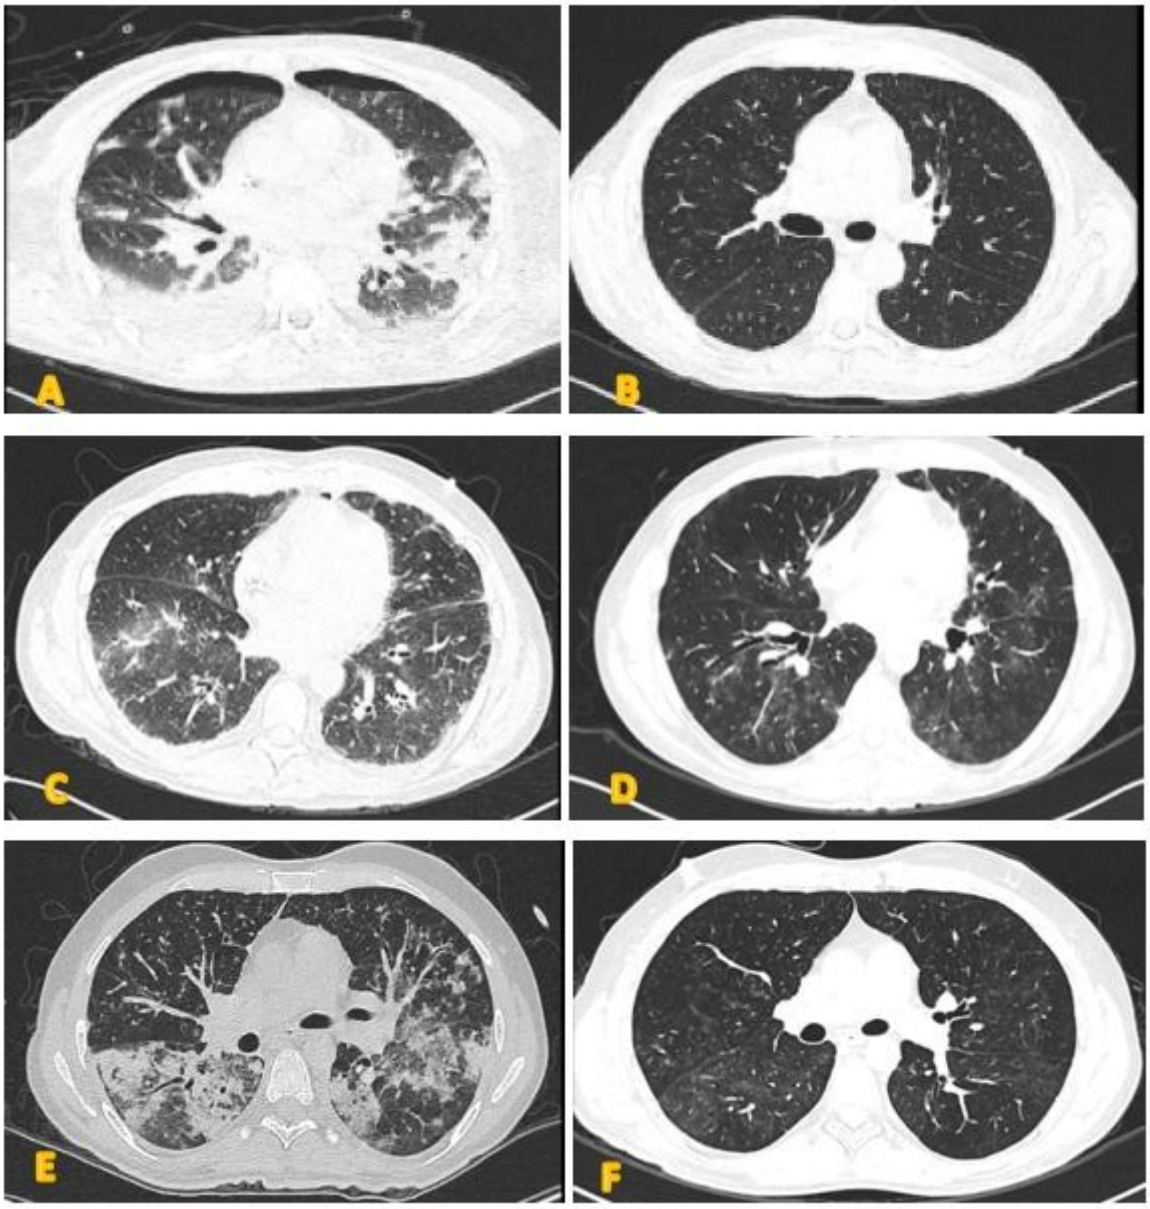
Moderate cGVHD involving skin and eyes developed on day +164 and was treated with systemic corticosteroids, without successful tapering. On day +310, the patient presented with progressive dyspnea and fatigue, evolving to respiratory failure. Chest CT revealed multilobar pneumonia. Despite broad-spectrum antibiotics, mechanical ventilation, and intravenous corticosteroids, clinical response was limited. Ruxolitinib was initiated at 5 mg twice daily, leading to rapid improvement, ventilator withdrawal within 72 hours, and hospital discharge. Follow-up CT showed radiologic resolution with spirometric improvement.

Case 2: A 59-year-old man underwent haploidentical HSCT for high-risk acute lymphoblastic leukemia with CNS involvement and persistent MRD. Comorbidities included treated latent tuberculosis and catheter-related thrombosis. Conditioning consisted of FluBuCy MAC with PTCy, followed by infusion of 7.84 × 10^6 $CD34^+$ cells/kg. Engraftment occurred on days +14 and +18.

He developed grade II cytokine release syndrome and febrile neutropenia. Acute GVHD (MAGIC II, skin stage 3) occurred on day +26, with steroid dependence. On day +137, he presented with cough and hypoxemia. CT angiography showed bilateral ground-glass opacities and interstitial thickening, without pulmonary embolism. Despite systemic steroids, FAM therapy, and antibiotics, respiratory failure progressed, requiring high-flow oxygen. Ruxolitinib 5 mg twice daily was started, resulting in marked clinical improvement within 10 days and subsequent discharge. Follow-up imaging demonstrated pulmonary recovery.

Case 3: A 32-year-old man underwent haploidentical HSCT for acute myeloid leukemia with KMT2A rearrangement. Conditioning consisted of FluBuCy MAC with PTCy, followed by infusion of 7.84 × 10^6 $CD34^+$ cells/kg. Engraftment occurred on days +13 and +15. Acute GVHD (MAGIC I, skin stage 1) developed on day +66.

On day +135, the patient presented with exertional dyspnea and nonproductive cough. Chest CT revealed an organizing pneumonia pattern. Bronchoscopy was negative for infection. Antibiotics, FAM therapy, and ruxolitinib 5 mg once daily were initiated, leading to symptomatic improvement within two weeks and radiologic response on follow-up imaging.



Patient	Time Point	FEV1/FVC (%)	FEV1 (% predicted)	FVC (% predicted)
1	Pre-HSCT	104	34	121
1	Post-HSCT	95	94	99
2	Pre-HSCT	96.9	121	120

2	Post-HSCT	100	95	93
3	Pre-HSCT	110	92.9	83.4
3	Post-HSCT	85	89	90

Conclusions: These cases illustrate the high effectiveness of early ruxolitinib initiation in pulmonary chronic GVHD, including severe presentations requiring respiratory support. Early JAK inhibition may represent a valuable therapeutic strategy in this setting.

Disclosure: The authors declare no conflicts of interest.

P123

FAECAL MICROBIAL TRANSPLANTATION FOR GRAFT-VERSUS-HOST DISEASE

Andrea Henden[1], *Emma Wright*[1], *Michelle Allan*[1], *Nicholas Cullen*[2], *Jing Jie*[3], *Cheryl Hutchins*[1], *Stewart Hunt*[1], *Ashleigh Scott*[1], *Elango Subramoniapillai*[1], *Jason Butler*[1], *Siok Tey*[1], *Cameron Curley*[1], *Glen Kennedy*[1]
[1]*Royal Brisbane and Women's Hospital, Brisbane, Australia,* [2]*QIMR Berghofer, Herston, Australia,* [3]*Queensland University of Technology, Brisbane, Australia*

Background: Graft-versus-Host disease (GVHD) is a potentially fatal complication of bone marrow transplantation (BMT), and its frequency and severity are linked to a poorly diverse gut microbiome. Faecal Microbial transplantation (FMT) transfers diverse microbial populations from a healthy donor into recipients and therefore offers promise as a novel therapy for GVHD. We have completed a pilot clinical trial of FMT after BMT, using the Australian Red Cross Lifeblood Microbiome product in patients with GVHD at the Royal Brisbane and Women's Hospital, Australia.

Methods: 9 patients with steroid refractory (SR) or steroid dependent (SD) gastrointestinal GVHD were treated with a one-time instillation of Lifeblood faecal microbiota transplant via naso-duodenal tube. This product is manufactured from healthy donors and subject to screening for drug resistant organisms. Participants were able to receive all other standard of care treatments including Ruxolitinib. Correlative scientific analysis includes shotgun metagenomic sequencing of donor and recipient faecal microbiome, to determine the impact of donor microbial diversity on recipient outcomes, as well as unbiased metabolomic and proteomic analysis as biomarkers for response.

Results: At 7 days post FMT 2 (22.2%) patients achieved a complete response (CR) and 3 (33.3%) patients a partial response, giving an overall response rate (ORR) of 55.5%. CR rates subsequently increased to 3 (33.3%) at day 14 and 4 (44.4%) at day 28.
No aspiration events occurred. 1 patient experienced a blood stream infection after instillation of FMT with a coliform organism potentially related to the FMT product, however this patient had cultured this organism from prior episodes of sepsis.
All participants had poorer diversity of gut microbial species, reflected by Shannon Index, at

baseline when compared to donors. Achievement of CR was associated with return of gut microbial diversity to near donor levels.
Instillation of FMT was associated with upregulation of serum IL-15 and downregulation of programmed cell death protein 1 and CD-40 ligand.

Conclusions: Use of FMT in highly immunosuppressed patients with SR and SD GVHD is safe and feasible using a single donor FMT product. FMT for SR and SD gut GVHD produced sustained CR in 44.4% of patients and was associated with increases in gut microbial diversity.

GRADE YOUR GVHD YOURSELF - DEVELOPMENT OF AN APP TO DOCUMENT CHRONIC GRAFT -VERSUS-HOST DISEASE BY PATIENTS AND CAREGIVERS

Alexander Denk[1], Raphael Loisl[1], Gerhard Rumpold[2,3], Bernhard Holzner[2,3], Tabea Globuschuetz[1], Matthias Edinger[1,4], Anita Lawitschka[5,6], ***Daniel Wolff***[1]
[1]University Hospital Regensburg, Dept. of Internal Medicine III, Regensburg, Germany, [2]ESD - Evaluation Software Development GmbH, Innsbruck, Austria, [3]Medical University Innsbruck, Dept. of Psychiatry, Psychotherapy, Psychosomatics and Medical Psychology, Innsbruck, Austria, [4]Leibniz Institute for Immunotherapy, Regensburg, Germany, [5]St. Anna Children's Cancer Research Institute, Vienna, Austria, [6]St. Anna Children`s Hospital, Medical University Vienna, Vienna, Austria

Background: The NIH consensus on chronic graft-versus-host disease (cGVHD) recommends complementary use of patient-reported outcome measures (PROMs). However, physician-based severity scoring is limited to outpatient visits, potentially delaying detection of disease onset or worsening. In contrast, patient-reported documentation allows continuous symptom monitoring, enabling earlier identification of flares and deterioration while more accurately reflecting the true symptom burden.

Methods: We developed an APP incorporating existing PROMs to capture symptoms of cGVHD to enable longitudinal monitoring of the symptom burden of patients. The APP allows symptom-documentation 24/7. Data are automatically transferred into the data base of the German-Austrian-Swiss GVHD registry. During pilot testing, patient-reported symptom burden was compared with physician-documentated cGVHD assessments and paper-based PROMs collected during outpatient visits.

Results: The pilot test (PT) of the cGVHD APP was recently completed including ten patients during routine follow-up after allogeneic stem cell transplantation (alloSCT), demonstrating general feasibility. Recruitment in the extension phase is ongoing, with 11 additional patients currently under follow-up. The APP showed sufficient content validity compared to paper-

based PROMs with no relevant symptoms being missed. Patients highlighted the need for a weekly reminder function as well as the availability of the APP results for their outpatient-clinic appointments to discuss the symptom load with their physician.
Moreover, a short cut function to report the absence of symptoms was requested. During PT, APP and paper-based PROM results from the same timeframe were compared across seven domains (skin, eyes, mouth, lung, nutrition, energy, psychological stress) using four severity grades (none-mild, mild-moderate, moderate-quite severe, quite severe-extreme). Overall, a high level of agreement was observed, with concordance in 28 of 42 assessments (67%) and a difference of only one severity grade only in the remaining 14 assessments.

Conclusions: PROM-based remote documentation of cGVHD symptom burden via the APP is feasible in routine clinical practice and has the potential to enhance patient follow-up. Initial results demonstrate a high level of agreement between APP-based PROMs and physician-based assessment, suggesting that, following appropriate validation, the APP could complement physician evaluation; however, confirmation in a larger patient cohort is still required.

Disclosure: Bernhard Holzner & Gerhard Rumpold hold IPRs on the data collection software used in the study.

P125

TREATMENT PATTERN AND EFFECTIVENESS OF BELUMOSUDIL FOR CHRONIC GVHD: A SINGLE-CENTRE, RETROSPECTIVE STUDY IN CHINA

Dong Zhou[1], Yan Yang[1], Zhijie Kang[1], Yuan Huo[1], ***Jinsong Yan***[1]
[1]*The Second Hospital of Dalian Medical University, Dalian, China*

Background: Belumosudil, a novel selectively ROCK2 inhibitor, targets to both the inflammatory and fibrotic processes in chronic graft-versus-host disease (cGVHD). Study KD025-213 demonstrated favorable efficacy and safety of belumosudil for steroid refractory cGVHD. However, real-world evidence of belumosudil, especially in early-line treatment settings, remains limited in China.

Methods: This retrospective study enrolled adult patients treated with belumosudil between April 2023 and November 2025, all of whom had cGVHD after receiving allogeneic stem cell transplantation (allo-HSCT). Patients were stratified by the line of belumosudil therapy (first-line, second-line, and third-or-later-line). Treatment outcomes were assessed using the NIH consensus response criteria for overall response rate (ORR), including complete remission (CR) and partial remission (PR). Changes in cGVHD symptom burden were measured using Lee Symptom Scale (LSS). Failure-free survival (FFS), and overall survival (OS) were also evaluated. Adverse events were recorded throughout the study. The data cutoff date was November 14, 2025.

Results: A total of 36 patients were included and 17 (47 %) were female. Other baseline characteristics were shown in Table 1. Nine (25%), 6 (17%) and 21 (58%) patients received belumosudil as first-line, second-line and third-or-later-line therapy, respectively. The most common indication for transplant was acute myeloid leukemia (AML) (50%) regardless of the line of therapy. Senventy-eight percent of patients had severe cGVHD at baseline. Fifty-three percent of patients had lung involvement, 42% had skin involvement and 39% had eye involvement. All the 27 pretreated patients had prior corticosteroid and 89% of them had prior ruxolitinib. Belumosudil (200mg/d) was initiated at a median of 2 months (range, 0.03-108) after cGVHD diagnosis with a treatment duration of 8±5 months and a median follow-up of 9 months (range, 1-19). Thirty-five patients received combination regimens: 69% combined with corticosteroids, 71% with ruxolitinib, and 3% with calcineurin inhibitor. The ORR for belumosudil was 72% (95%CI, 55-86), comprising a 31% CR, and a 42% PR. The ORRs for the first-line, second-line, third-or-later-line therapy subgroups were 78% (95% CI, 40 -97), 100% (95% CI, 54-100) and 62% (95% CI, 38-82). Twenty (57%) patients archived clinically meaningful symptom improvement (defined as ≥ 7 LSS score reduction from baseline). The 1-year FFS rate was 92% (95% CI, 83-100) and 1-year OS rate was 94% (95% CI, 87-100). Specifically, within the first-line and second-line therapy subgroups, both of these survival metrics were 100% (95% CI, 100-100). Treatment-emergent adverse events (TEAEs) occurred in 12 patients (33%), and the most common TEAE was pneumonia (14%). Two patients (6%) experienced grade ≥3 TEAEs: one had elevated transaminases (>5×ULN) and the other developed grade 3 pneumonia. Two patients, who received combination regimens, died from relapse of leukemia and severe bacterial infection, respectively. No drug-related deaths were reported.

Conclusions: In this retrospective study of Chinese cGVHD patients, belumosudil demonstrated favorable effectiveness and safety profile, with particularly promising clinical outcomes observed in patients receiving it as first-line and second-line therapy.

Table 1. Baseline characteristics

Variables	Total (n=36)	First-line (n=9)	Second-line (n=6)	Third-or-later-line (n=21)

ANTI-T-LYMPHOCYTE GLOBULIN (ATLG) VS. ANTI-THYMOCYTE GLOBULIN (ATG) IN ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION: A PRELIMINARY COMPETING-RISK ANALYSIS

Patricia Flüchter[1,2], *Arthur Zysk*[1], *Sarah Flossdorf*[3], *Anna Ruckdeschel*[1], *Matthias Fante*[1], *Stephan Mielke*[1,4], *Gernot Stuhler*[1], *Torsten Steinbrunn*[1], *Hermann Einsele*[1], *Daniel Teschner*[1], *Jochen Frietsch*[1]
[1]*University Hospital Würzburg, Würzburg, Germany,* [2]*Klinik Favoriten, Vienna, Austria,* [3]*Institute for Medical Informatics, Biometry and Epidemiology, University Hospital Essen, Essen, Germany,* [4]*Karolinska Institutet, Stockholm, Sweden*

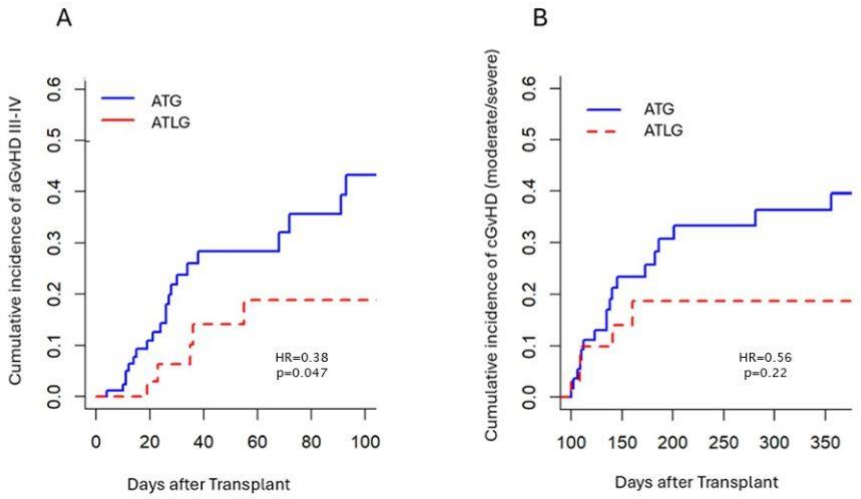
Background: Anti-T-lymphocyte globulin (ATLG, Grafalon®, formerly ATG-Fresenius S) and anti-thymocyte globulin (ATG, Thymoglobulin®, formerly ATG-Genzyme) are widely used as part of GvHD prophylaxis prior to allogeneic hematopoietic stem cell transplantation (AHSCT). However, comparative data on their impact on graft-versus-host disease (GvHD) and post-transplant outcomes remain limited. Therefore, we conducted a retrospective, real-world, single-centre analysis comparing ATLG and ATG in an AHSCT cohort.

Methods: All adult patients undergoing first allogeneic AHSCT at our centre between 2010 and 2014 who received either ATG or ATLG as part of the GvHD prophylaxis were included, regardless of indication. Group assignment was based on availability of the respective preparation. The study was approved by the institutional ethics committee and patient consent for analysis of clinical data was obtained upon registration in the EBMT database. Primary endpoints were grade III-IV acute GvHD (aGvHD; according to Glucksberg

classification) and moderate to severe chronic GvHD (cGvHD; according to NIH criteria). Secondary endpoints included overall survival (OS), GvHD-free, relapse-free survival (GFRS) and non-relapse mortality (NRM). Time-to-event analysis for GvHD and NRM were performed using a competing risk approach, with death (for GvHD) or relapse (for NRM) considered as respective competing events. For competing risk endpoints, cumulative incidences were estimated, and group comparisons were performed using Gray's test. Hazard ratios (HR) were calculated using Fine-Gray regression. For OS and GRFS, survival probabilities were estimated using Kaplan-Meier method and group comparisons were performed using the log-rank test. A p-value of < 0.05 was considered statistically significant. The statistical analysis was conducted using R, Version 4.5.2.

Results: This analysis represents preliminary data from the first evaluation period (2010-2012). A total of 190 patients was included (ATLG: n=131, ATG: n=59), with a median follow-up of 12.6 month. Patients treated with ATLG showed a significantly lower cumulative incidence of aGvHD within 100 days after AHSCT compared with those receiving ATG (HR 0.38, 95% CI [0.15; 0.99], p=0.047). In contrast, no significant difference in the cumulative incidences of cGvHD between day 100 and day 365 was observed (HR 0.56, 95% CI0.23-1.41, p=0.22). Regarding survival outcomes, OS did not differ significantly between ATLG and ATG (p=0.17). Median OS was numerically longer in the ATLG group (1002 days) compared with the ATG group (222 days). GRFS also showed a numerically longer (341 days vs. 159 days) but not statistically significant median duration with ATLG (p=0.093). NRM did not differ significantly between groups (p=0.30), with rates of 31.2% in the ATLG group and 44.2% in the ATG group.

Figure 1: Cumulative incidence of grade III-IV acute GvHD (A) and moderate to severe chronic GVHD (B) after AHSCT
GvHD prophylaxis using ATG is represented by blue solid lines and using ATLG by red dashed lines.



Conclusions: Preliminary 3-year data from this real-world cohort suggest that ATLG is associated with a significant reduction in severe acute GvHD within the first 100 days after

AHSCT compared with ATG. The final results from the entire 5-year cohort will provide a more reliable assessment not only of the GvHD incidence, but also of long-term survival.

REAL-WORLD IMPACT OF RUXOLITINIB IN GRAFT-VERSUS-HOST DISEASE: EXPERIENCE FROM A NATIONAL REFERRAL CANCER CENTER IN MEXICO

Mistral Castellanos Mares[1], *Juan Alberto Rios-Rodriguez*[2], *Rosa Adriana Alvidrez-González*[1], *Andres Yesid Bonilla-Salcedo*[1], *Victor Iván Salinas-Herrera*[1], *Vicky Margarita Moncada-Gadea*[1], *Grecia Pamela Martínez-Vázquez*[1], *Irma Karen Pellón-Téllez*[1], *Luis Manuel Valero-Saldaña*[1]
[1]*Instituto Nacional de Cancerología, Ciudad de Mexico, Mexico,* [2]*Tecnologico de Monterrey, School of Medicine and Health Sciences, Monterrey, Mexico*

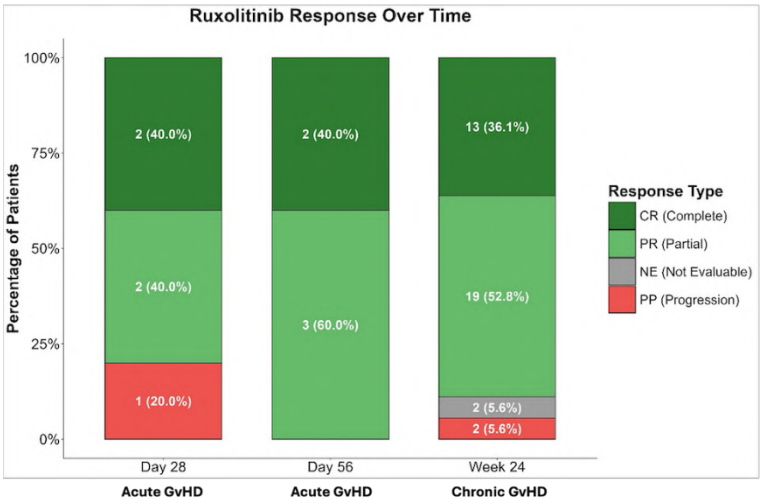
Background: Real-world evidence on the use of ruxolitinib for graft-versus-host disease is limited in Latin America, particularly within resource-limited healthcare systems such as those in Mexico.

Methods: We conducted a retrospective observational study of patients with acute and chronic graft-versus-host disease treated with ruxolitinib at the National Cancer Institute of Mexico between 2018 and 2025. Clinical and treatment data were collected from electronic medical records. Continuous variables were summarized as medians and interquartile ranges and compared using non-parametric tests, while categorical variables were compared using Chi-square or Fisher's exact test. Overall survival was estimated using the Kaplan–Meier method, and univariate logistic regression was used to explore factors associated with treatment response. A p-value <0.05 was considered statistically significant.

Results: A total of 36 patients with graft-versus-host disease treated with ruxolitinib were included. Median age at transplantation was 28 years (IQR 23–42), and most patients had acute leukemia as the underlying diagnosis. Among patients with acute GVHD, classic onset was observed in 85.7% of cases. In acute GVHD, skin was the most frequently involved organ, whereas gastrointestinal and hepatic involvement were uncommon. In chronic GVHD, the most frequently involved organs were the skin, liver, and oral mucosa, followed by ocular involvement.
In patients with acute GVHD, ruxolitinib induced rapid clinical responses, with an overall response rate of 80% at day 28 (CR 40%, PR 40%) and 100% at day 56 (CR 40%, PR 60%), with minimal progression. Overall survival in this subgroup remained favorable during follow-up.
In chronic GVHD, response assessment at week 24 demonstrated an overall response rate of 88.9%, including 36.1% CR and 52.8% PR, while progression or non-evaluable outcomes were infrequent. Long-term overall survival remained stable at approximately 80%, with

superior survival observed among patients achieving complete response compared with those with partial response.
Adverse events differed by GVHD type. In acute GVHD, toxicity was mainly infectious, whereas in chronic GVHD infections (52%) and cytopenias (40%) were the most frequent complications. No statistically significant factors associated with response were identified in univariate analyses, although concomitant calcineurin inhibitor use showed a trend toward improved response. In patients with acute GVHD, steroid discontinuation was achieved in 85.7% (6/7) of those receiving concomitant corticosteroids, and overall 83.3% (30/36) of patients were able to discontinue steroids during follow-up.

Variable	Total (N= 36)
Age, median (IQR), years	28 (23–42)
Sex, n (%) (female / male)	22 (61.1) / 14 (38.9)
Underlying diagnosis, n (%) (acute leukemia / other)	28 (77.8) / 8 (22.2)
GVHD presentation, n (%)	Chronic: 36 (100); Acute: 7 (19.4)
Organs involved in acute GVHD, n (%): skin / GI / liver	18 (85.7) / 3 (14.3) / 1 (4.8)
Organs involved in chronic GVHD, n (%): liver / skin / oral / eyes	23 (63.9) / 22 (61.1) / 22 (61.1) / 20 (55.6)
Steroid-refractory or steroid-dependent GVHD, n (%)	24 (66.7)
Steroid discontinuation, n (%)	Acute: 6/7 (85.7); Overall: 30/36 (83.3)
Concomitant calcineurin inhibitor use, n (%)	15 (41.7)



Conclusions: In this real-world experience from a national referral cancer center in Mexico, ruxolitinib was associated with high response rates, favorable survival outcomes, and an acceptable safety profile in patients with acute and chronic graft-versus-host disease. These findings provide valuable evidence from a resource-limited setting, where access to specialized treatments may be restricted. Despite healthcare system limitations, outcomes were comparable to those reported in other settings, highlighting the clinical value of ruxolitinib and supporting its use in routine clinical practice across Latin America.

Disclosure: Nothing to declare.

ETANERCEPT AS SECOND-LINE THERAPY FOR STEROID-REFRACTORY GVHD: FEASIBILITY, SAFETY, AND OUTCOMES

Michel Lu[1], *Barbara Withers*[1], *Wei Jiang*[1], *Jacinta Perram*[1], *Keith Fay*[1], *Samuel Milliken*[1], *John Moore*[1]
[1]*St Vincent's Hospital, Sydney, Australia*

Background: Graft versus host disease (GVHD) remains a significant cause of morbidity and mortality following allogeneic haematopoietic stem cell transplantation (alloHSCT). As supported by the 2024 European Society for Blood and Marrow Transplantation (EBMT) consensus recommendations, ruxolitinib is now first line for steroid refractory acute GVHD (SR-aGVHD) and chronic GVHD (SR-cGVHD). There is, however, no consensus treatment for SR-aGVHD beyond ruxolitinib with numerous agents trialed globally.

Methods: This retrospective cohort study evaluated etanercept as second-line therapy for SR-aGVHD following alloHSCT at a single metropolitan transplant centre in Australia between April 2020 and October 2025. All patients received calcineurin inhibitor–based GVHD

prophylaxis in combination with either antithymocyte globulin or post-transplant cyclophosphamide.
Eligible patients had glucocorticoid- and ruxolitinib-refractory disease. Failure to respond was defined according to EBMT guidelines: disease progression within 3–5 days of initiating therapy, incomplete response by 7–14 days or recurrence following dose reduction of the preceding treatment. The study timeframe reflected the availability of ruxolitinib through compassionate access programs and the Pharmaceutical Benefits Scheme (PBS), Australia's government-subsidised prescription medication program.

Results: A total of 9 patients (age range: 21–70 years; 5 female and 4 male) received etanercept as 2nd-line therapy following ruxolitinib for SR-aGVHD. The median interval between ruxolitinib and etanercept initiation was 22 days (range: 5-97 days). 66.7% presented with MAGIC Grade IV disease, predominantly involving the lower gastrointestinal tract (77.8%). At 30 days after initiating etanercept, 42.9% with SR-aGVHD achieved a ≥50% reduction in corticosteroid dose across skin, liver, and gastrointestinal GVHD phenotypes. All patients surviving to one year weaned off corticosteroids completely. Overall survival was 77.8% at 30 days and 62.5% at 1 year. Within 100 days post-transplant, only one patient had CMV reactivation despite no letermovir prophylaxis as is standard practice in Australia. Overall, 3 of 9 (33.3%) had CMV reactivation within three months of etanercept initiation. All were CMV-seropositive recipients with cumulative immunosuppression, including pulse steroids, prior to etanercept.

Conclusions: In this small, high-risk cohort, etanercept administered as a second-line agent following ruxolitinib for steroid-refractory GVHD demonstrated feasible use with treatment-related toxicity analogous to other immunosuppressants. Its introduction occurred early in the disease course as a rescue escalation rather than as prolonged salvage, as is reflected in etanercept's administration schedule as a subcutaneous injection given over an eight-week finite course. Among patients with SR-aGVHD, a meaningful steroid-sparing effect was observed, with over one-third achieving substantial corticosteroid reduction by 30 days and all 1-year survivors ultimately discontinuing steroids. Survival outcomes were acceptable given the predominance of MAGIC Grade IV GVHD with lower gastrointestinal involvement, though interpretation remains limited by the small sample size and absence of a comparator group. These findings suggest that etanercept may offer clinical benefit for selected patients with SR-aGVHD, warranting further evaluation in larger studies. Although those who received etanercept for SR-aGVHD and SR-cGVHD following ruxolitinib were both examined, meaningful analysis for SR-cGVHD was limited by small numbers at time of write up and our study is ongoing.

P130

IN VIVO T CELL DEPLETION IN COMPLETE REMISSION ACUTE LEUKEMIA PATIENTS RECEIVING PERIPHERAL STEM CELL TRANSPLANTATION FROM HLA IDENTICAL SIBLING WITH MYELOABLATIVE CONDITIONING REGIMEN

Luca Castagna[1], *Roberto Bono*[1], *Giuseppe Sapienza*[1], *Cristina Rotolo*[1], *Corinne Spoto*[1], *Carmelo Costanza*[1], *Antonino Mulè*[1], *Valeria Calafiore*[1], *Giulia Arrigo*[1], *Alessandra Santoroi*[1], *Laura Di Noto*[1], *Caterina Patti*[1]
[1]*AOR Villa Sofia Cervello, Palermo, Italy*

Background: A large metanalysis showed that the incidence of extensive chronic GVHD (cGVHD) was highest using conventional graft versus host disease (GVHD) prophylaxis after allogeneic hematopoietic cell transplantation (HCT) with peripheral blood stem cell (PBSC) from HLA identical sibling (SIB). At least 3 randomized studies showed the benefit to add ATG/ATLG reducing this complications. ATG/ATLG could blunt the graft versus leukemia effect and could be an obstacle spreading it in clinical practice.

Methods: From 2010 and 2025, we retrieved in our data set acute leukemia (AL) patients with the same characteristics of randomized trial with ATLG. ATG (Thymoglobuline) was administered at total dose of 5 mg/kg days -2 and -1. All patients were conditioned with transplant conditioning intensity (TCI) regimens intermediate/high and PBSC. Patients were in complete (CR) and donors were HLAid sibling. Before 2021, patients did not receive ATG.

Results: 89 patients were identified. Main patient characteristics were depicted in Table 1. The median follow-up was 5 years.
For the whole population, the 2-y OS, PFS, cumulative incidence of relapse (CIR), and 1-year non-relapse mortality were 63%, 55%, 33% and 14%. The 6-month CI of grade 2-4 and 3-4 acute GVHD were 25% and 10%. The CI of moderate-severe chronic GVHD was 19%.
In univariate analysis, we founded a trend to better 2-y OS (66% with ATG vs 62% without ATG) and 2-y PFS (62% with ATG vs 52% without ATG), and 2-y CIR was lower with ATH (21% vs 36%). Similarly, the 1-year NRM was lower with ATG (11% vs 15%). The 6M CI of aGVHD was similar while the 1-y CI of moderate/severe cGVHD was statistically higher without ATG than with ATG (0% vs 31%, p 0.01).

Conclusions: This retrospective single center study, with confounding factors due to the retrospective nature and low number of patients, show that ATG use, in HLAid sibling setting, improves the outcomes of AL. Only the CI of moderate/severe cGVHD was significant lower in ATG cohort.

Disclosure: Nothing to declare

P131

ECP BASED COMBINATIONS FOR TREATING ACUTE AND CHRONIC GRAFT VERSUS HOST DISEASE

Sasha Ollerenshaw[1], Arun Alfred[2], Jennifer Clay[1], Anjum Khan[1], Katja Kimberger[1], Suzanne Liebersbach[1], Francesca Padday[1], Janette Sampson[1], ***Simon Bulley***[1]
[1]*Leeds Cancer Centre, Leeds, United Kingdom of Great Britain and Northern Ireland (the),* [2]*The Rotherham NHS Foundation Trust, Rotherham, United Kingdom of Great Britain and Northern Ireland (the)*

Background: We present our experience using ECP in combination with ruxolitinib for steroid refractory aGvHD, and ECP in combination with belumosudil vs belumosudil alone for refractory cGvHD.

Methods: Patients treated with ruxolitinib or belumosudil were identified from pharmacy records. All other data were collected from medical records.
For aGvHD the outcomes presented are response rate and overall survival. For cGvHD accurate retrospective evaluation of response as per NIH criteria is very difficult. We therefore present two outcomes: Firstly, successful time on therapy defined as treatment duration until cGvHD progression, death, relapse of underlying disease, start of new systemic cGvHD treatment, or discontinuation due to toxicity; and secondly, the ability to successfully wean systemic corticosteroids.

Results: Twelve patients with steroid refractory / dependent aGvHD were treated with ECP in combination with ruxolitinib. Median age was 55 years. Five out of twelve patients had grade 2 aGvHD, four had grade 3 aGvHD, and three had grade 4 aGvHD. The skin was involved in nine patients, the lower GI tract in eight patients, the liver in three patients, and the upper GI tract in three patients.
Ten out of twelve patients (83%) achieved a partial or complete response, and nine patients (75%) successfully discontinued corticosteroids. Median overall survival has not yet been reached. Overall survival is 66% at 8 months median follow-up. Deaths were from aGvHD (two patients), cGvHD (one patient), and infection (one patient). Treating death as a competing risk, 33% of patients developed cGvHD. There have been no relapses of the underlying haematological disease.
The median time spent on ruxolitinib was 4.5 months, and the median time spent on ECP was 6 months. The median time until patients were on a physiological dose (5mg or less) of prednisolone was 6 weeks.
For cGvHD nine patients were treated with beluosudil, and eight with ECP plus belumosudil. Patient characteristics were balanced between the groups apart from cGvHD severity. In the belumosudil group four patients (44%) had severe cGvHD. In the ECP plus belumosudil group six (75%) had severe cGvHD. Median successful time on therapy as defined in the methods section was 4 months in the belumosudil group vs 13 months in the ECP plus belumosudil group. In the belumosudil group four patients were on systemic corticosteroids when belumosudil started and one (25%) was able to wean to a physiological dose of prednisolone. In the ECP plus belumosudil group five patients were on corticosteroids and three (60%) were able to wean to a physiological dose of prednisolone.
In the belumosudil group six patients (66%) discontinued treatment; three due to cGvHD

progression and three due to toxicity. In the ECP plus belumosudil group four patients (50%) discontinued treatment; one due to cGvHD resolution, two due to cGvHD progression, and one due to leukaemia relapse.

Conclusions: ECP combined with ruxolitinib for steroid refractory aGvHD appears to be a safe and efficacious combination. ECP combined with belumosudil to treat refractory cGvHD appears more efficacious than belumosudil alone. Further evaluation in prospective studies is warranted.

P132

BELUMOSUDIL FOR REFRACTORY CHRONIC GRAFT VERSUS HOST DISEASE IN CHILDREN AND YOUNG ADULTS: REPORT OF 4 CASES

Burcu Akıncı[1], *Seda Ozturkmen*[2], *Bülent Antmen*[3], *Hayriye Daloğlu*[1], *Suleimen Zhumatayev*[1], *Şefika Akyol*[2], *Vedat Uygun*[2], *Gülsün Karasu*[2,1], *Akif Yesilipek*[1,2]
[1]*Medicalpark Pendik Hospital, İstanbul, Turkey,* [2]*Mecicalpark Antalya Hospital, Antalya, Turkey,* [3]*Acibadem Adana Hospital, Adana, Turkey*

Background: Although significant progress has been obtained in donor selection, conditioning regimens, and graft versus host disease prophylaxis in recent years, chronic graft versus host disease (cGVHD) remains a serious complication and a major factor determining quality of life after hematopoietic stem cell transplantation (HSCT). cGVHD is an immune-mediated inflammatory disorder which causes fibrosis and sclerosis. Despite the medicines we currently use, there is still a need for new drugs. Belumosudil, an oral selective inhibitor of Rho–associated coiled–coil–containing protein kinase 2 (ROCK2). It mainly inhibits Th17 cells, reduces collagen/extracellular matrix production and cytokine production. It has been approved for the treatment of adults and pediatric patients aged >12 years with cGVHD after at least two systemic therapies.

Methods: We describe four cases of cGVHD who have been receving belumosudil. The assessment of the severity of the cGVHD, and treatment response were made based on the NIH 2014 criteria. Written consent was obtained.

Results: The first three patients underwent allo-HSCT for hematological malignancies, and the last one for thalassemia major. One of our patients was 5 years old, and off-label

approval was obtained before the medication was used. After myeloablative conditioning regimens, cyclosporin (CSA) and methotrexate were used for GVHD prophylaxis. All patients had severe cGVHD and had been received at least 4 lines of immunosuppressive treatment before starting belumosudil. Additionally, they underwent extracorporeal photopheresis. Belumosudil was used at a dose of 200 mg/day. No serious adverse event were reported. The findings of the patients related to cGVHD and details regarding to belumosudil treatment are shown in Table 1.

Table 1:Patient Characteristics

Age/ gender	Donör type	GVHD organ/ Grade	Previosuly used treatments	Belumosudil start date	Currently used treatments	Treatment response
21/ F	MUD 9/10	Skin-3 Eye-3 Mouth-2 Lung-2	Steroid CNI RUXO MMF Ibrutinib	08-08-2024	Belumosudil CNI	From the first month of treatment, hyperpigmentation and sclerosis began to decrease.
17 / F	MUD 10/10	Skin-3 Joints-3 Liver-2 Lung-3	Steroid CNI RUXO MMF Ibrutinib	23-07-2025	Belumosudil RUXO	An apparent improvement in skin and joint findings has been observed.
15 / F	MUD 10/10	Skin-3 Joints-3 Eye-3 GIS-3 Mouth-2	Steroid CNI RUXO MMF	30-07-2024	Belumosudil RUXO Steroid	There was complete recovery in GIS findings. Sclerosis disappeared. Joint contractures continue.
5 / F	MSD 10/10	Skin-3	Steroid CNI RUXO MMF	08-08-2024	Belumosudil RUXO	Ulcers on the skin were healed. Hyperpigmented areas on the upper and lower extremities were decreased. The lesions on the trunk have completely healed.

F:Female, M:Male, MUD: Matched unrelated donor, MSD:Matched sibling donor, CSA: cyclosporin, MTX: methotrexate, CNI: calcineurin inhibitor, RUXO: ruxolitinib, MMF: mycophenolate mofetil, GIS: gastrointestinal system

Conclusions: In all four patients who have been using belumosudil for severe cGVHD, marked clinical improvement was seen especially in the skin, fascia and joints. Additionally, steroid treatment could be discontinued in three patients. Belumosudil may effective for pediatric patients with severe cGVHD, especially the sclerotic subtype with acceptable toxicity profile. However, prospective studies involving a larger patient population are needed on this subject.

Disclosure: The Authors declare no conflict of interest.

P134

OCULAR GRAFT VERSUS HOST DISEASE AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION: A 10-YEAR SINGLE CENTER EXPERIENCE

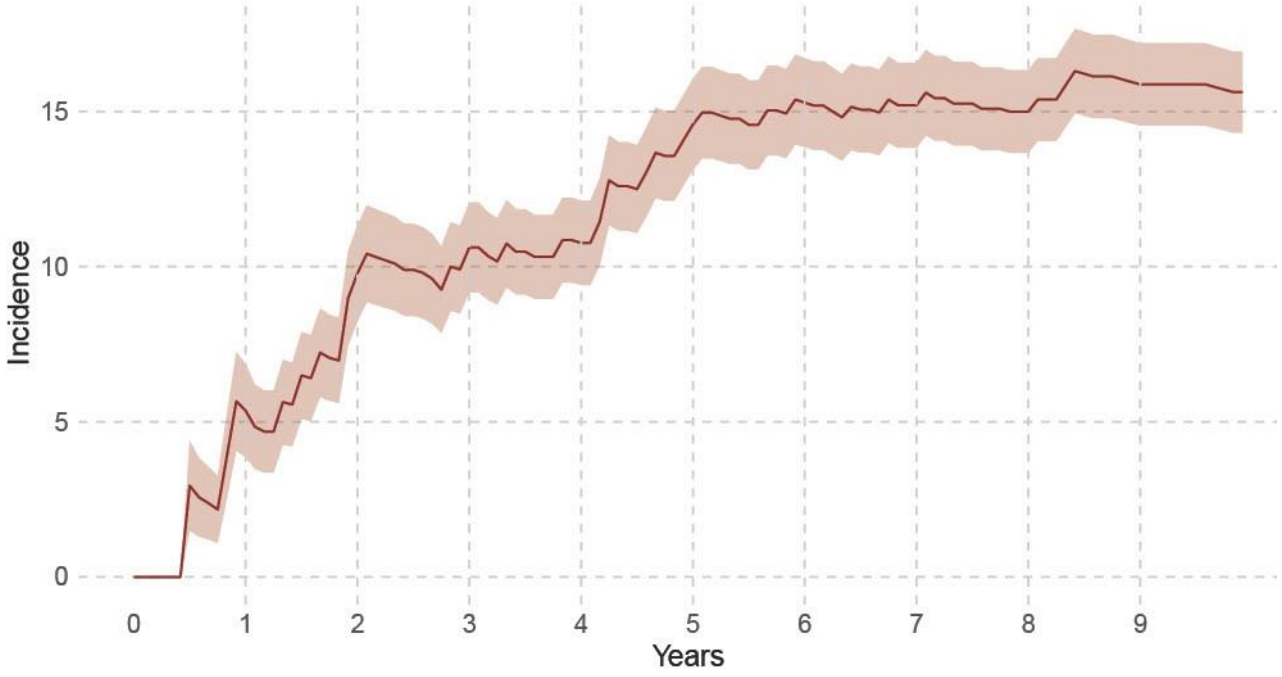
*Beatrice Bugnotto[1], Erika Bonacci[1], **Cristina Tecchio**[1], Emilio Pedrotti[1]*
[1]University of Verona, Verona, Italy

Background: Allogeneic hematopoietic stem cell transplantation (allo-HSCT) is currently the only curative option for several hematologic diseases. Among allo-HSCT associated ocular complications, ocular graft-versus-host disease (oGVHD) severely affects patient quality of life.
This study aimed to review oGVHD incidence, clinical presentation, risk factors, therapy, and outcome in 192 consecutive patients who underwent allo-HSCT at our center between January 2015 and January 2025.

Methods: Data were retrieved from hospital records upon patient informed consent. Ocular GVHD was diagnosed according to NIH 2014 criteria and treated by a dedicated in-hospital ophthalmology team. Slit-lamp examination, corneal fluorescein staining and tear breakup time were the main diagnostic tools.

Results: Thirty-two (16.7%) patients were affected by oGVHD, which occurred after a median time of 12 (1-72) months from allo-HSCT. At diagnosis, 18 (56%) patients were receiving systemic immunosuppression. oGVHD was isolated in 7 (22%) cases, associated to one or more additional GVHD-involved sites in 10 (31%) and 15 (47%) cases, respectively. Symptoms reported at presentation were ocular dryness (59% of patients), ocular hyperemia (31%), burning sensation (19%), ocular discharge (19%), photophobia (18%), decreased visual acuity (25%), foreign body sensation (13%), and ocular pain (1%). At onset, all patients were affected by keratoconjunctivitis sicca. Ocular adnexal involvement was observed in 24 (75%) cases. Four (12.5%) patients further developed corneal ulcers that were subsequently complicated by bacterial infections in 3 cases.
oGVHD severity was mild in 14 (44%) patients, moderate in 6 (19%), and severe in 12 (37%). Female recipient (OR 4.46, 95% CI 1.42–14.08, $p<0.05$), prior skin acute GVHD (OR 3.64, 95% CI 1.62–8.18, $p<0.05$), and female-to-male allo-HSCT (OR 4.37, 95% CI 1.08–17.7, $p<0.05$) independently increased the risk of oGVHD by multivariate analysis (AUC 0.766). Patients received at least one topical treatment which was eventually modified. Steroid drops were used in 22 patients, cyclosporin A 1% drops in 19, autologous serum drops in 6, amniotic membrane extract fresh drops in 9, and therapeutic contact lens in 12. The median number of topical treatments was 2.6 (1-4). Two patients underwent ocular surgery due to corneal ulceration with infectious keratitis.
Clinical remission with first-line topical therapy (steroid drops) occurred in 13/32 (41%) patients. Topical 0.1% cyclosporine A was used in 19 (59%) patients, who obtained a significant reduction of oGVHD severity in 12 (63%) cases. Nine (28%) patients received

amniotic membrane extract fresh drops (AMED), obtaining a significant oGVHD improvement in 7 (77%) cases at 1 month. Despite treatment, visual acuity decreased significantly (median Δ dpt last follow-up vs baseline −1.45/10, $p<0.05$), with 3 (9%) patients experiencing total blindness.



Conclusions: oGVHD was a relatively frequent complication of allo-HSCT, mostly occurring within the first year, with a moderate to severe presentation pattern in 56% of cases. Patients underwent a median of 2.6 lines of treatments, reporting on average a significant loss of visual acuity, and total blindness in 9% of cases. Overall, these findings indicate that a close interaction between transplant physicians and ophthalmologists is needed to provide early oGVHD assessment and prompt intervention.

P135

COMPARATIVE OUTCOMES OF THREE DIFFERENT ATLG REGIMENS IN ALLO-HSCT FOR PATIENTS WITH HEMATOLOGICAL MALIGNANCIES: A RETROSPECTIVE STUDY

Xiaohong Liu[1], *Min Xiong*[2], *Deyan Liu*[2,1], *Jian-Ping Zhang*[2]
[1]*Beijing Lu Daopei Hospital, Beijing, China,* [2]*Hebei Yanda Lu Daopei Hospital, Langfang, China*

Background: Anti–T-lymphocyte globulin (ATLG) is a rabbit-derived polyclonal antibody widely used for GVHD prophylaxis after allogeneic HSCT. However, the optimal dosing and combination strategy—balancing GVHD prevention with immune recovery and infection risk—remains uncertain.

Methods: We retrospectively analyzed 191 allo-HSCT recipients at Hebei Yanda Ludaopei Hospital and Beijing Ludaopei Hospital (July 2023–January 2025). All patients received ATLG-based GVHD prophylaxis and were assigned to three cohorts: ATLG 25 mg/kg, ATLG 20 mg/kg, or ATLG 20 mg/kg combined with anti-CD25 antibody on day +1 and/or +4. Primary endpoints were day-100 acute GVHD. Secondary endpoints included day-180 CMV/EBV reactivation, hemorrhagic cystitis, CIR, NRM, LFS, and OS.

Results: **Patient Characteristics and Outcomes**
A total of 191 allo-HSCT recipients were assigned to the CD25+ATLG20 (n = 61), ATLG20 (n = 92), and ATLG25 (n =38) groups. baseline variables—including disease status, sex, graft characteristics including $CD34^+$, MNC, and $CD3^+$ cell doses and letermovir use—were well balanced. With a median follow-up of 15.3 months (range, 0.4–28.3), long-term outcomes were comparable across groups. CIR remained low (3.39% for CD25+ATLG20 vs. 11.57% for ATLG20 vs. 6.59% for ATLG25; P=0.225). NRM showed no significant differences, though lower rates were observed with ATLG20-based regimens (9.8% and 8.9%) compared with ATLG25 (21.2%; P=0.106). LFS (86.9%, 79.5%, 71.9%; P=0.189) and OS (88.6%, 82.9%, 72.2%; P=0.109) followed a similar pattern, with CD25+ATLG20 showing numerically favorable but non-significant improvements.
Acute GVHD and Viral Reactivation
The day-100 cumulative incidence of grade II–IV aGVHD did not differ significantly among the CD25+ATLG20, ATLG20, and ATLG25 groups (26.7%, 28.5%, and 39.5%, respectively; P = 0.329) (Figure 1A). In contrast, a significant difference was observed in severe grade III–IV aGVHD. The CD25+ATLG20 group had the lowest incidence (5.0%), markedly lower than both ATLG20 (12.0%) and ATLG25 (26.3%) groups (P = 0.007)(Figure 1B). This finding indicates that ATLG 20 mg/kg provided aGVHD control comparable to 25 mg/kg, while adding CD25 antibody reduced severe aGVHD. In multivariable Fine–Gray regression for II–IV aGVHD (Table 1), the combined CD25+ATLG20 approach was associated with a markedly reduced risk of severe (grade III–IV) aGVHD (HR 0.14, 95% CI 0.04–0.53; P = 0.004), and remained the only protective factor in the multivariable model.
The day-180 cumulative incidence of CMV reactivation was 36.44% in the CD25+ATLG20 group, 32.21% in the ATLG20 group, and 43.24% in the ATLG25 group (P = 0.598). EBV reactivation was similarly low and not significantly different (15.2%, 11.0%, and 7.9%; P = 0.450). Neither ATLG dose escalation nor the addition of CD25 antibody increased viral susceptibility or early toxicity.

Figure 1. Cumulative incidence of aGVHD among CD25+ATLG20, ATLG20, and ATLG25 groups

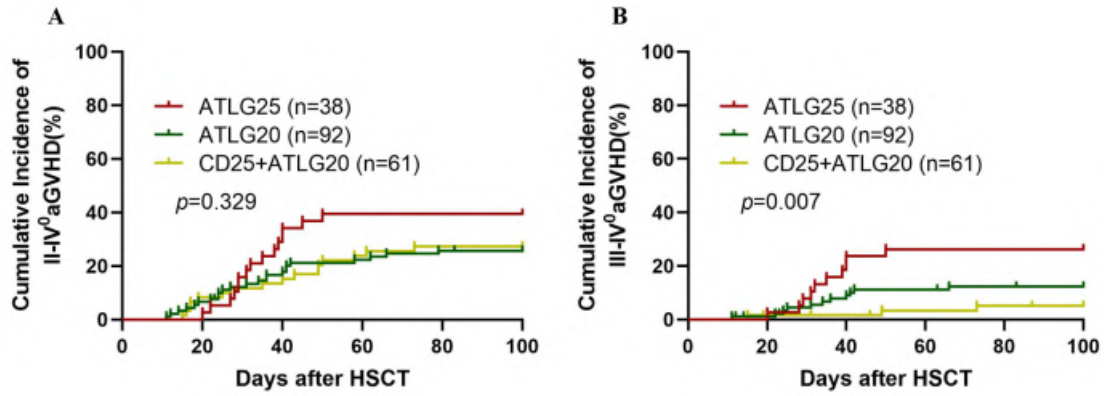

Table 1. Multivariable Fine–Gray regression for aGVHD

Characteristic	II-IV0aGVHD		III-IV0aGVHD	
	HR (95%CI)	p-value	HR (95%CI)	p-value

BU-based vs. TBI-based	0.91(0.50-1.65)	0.75	0.53(0.18-1.56)	0.25
CD34+ (≤6 vs. >6)	1.53(0.88-2.64)	0.13	1.92(0.77-4.81)	0.16
MNC (≤9 vs.>9)	0.82(0.47-1.43)	0.49	1.72(0.74-3.97)	0.21
CD3+ (≤2 vs.> 2)	1.30(0.78-2.19)	0.32	1.65(0.74-3.67)	0.22
ATLG25	1(reference)			
ATLG20	0.64(0.33-1.25)	0.19	0.45(0.18-1.15)	0.096
CD25+ATLG20	0.58(0.29-1.16)	0.12	0.14(0.04-0.53)	0.004
age (≤14Y vs. >14Y)	1.56(0.74-3.32)	0.25	1.28(0.40-4.13)	0.68

Conclusions: In this real-world cohort, ATLG at 20 mg/kg achieved aGVHD prophylaxis comparable to the 25-mg/kg dose across all efficacy and safety endpoints. Only the addition of CD25 monoclonal antibody to ATLG20 was associated with a significantly lower incidence of severe grade III–IV aGVHD, without increased viral reactivation or toxicity.

Disclosure: Nothing to declare

P137

BELUMOSUDIL IN SEVERE PROGRESSIVE OCULAR CHRONIC GRAFT-VERSUS-HOST DISEASE: A CASE SERIES

Filippo Frioni[1], *Maria Assunta Limongiello*[1], *Sabrina Giammarco*[1], *Elisabetta Metafuni*[1], *Roberto Maggi*[1], *Romina Fasciani*[2], *Simona Sica*[1], *Patrizia Chiusolo*[1]
[1]*Section of Hematology, Department of Laboratory and Hematological Sciences, Università Cattolica del Sacro Cuore, Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Rome, Italy,* [2]*Section of Ophtalmology, Università Cattolica del Sacro Cuore, Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Rome, Italy*

Background: Belumosudil is a selective ROCK2 inhibitor approved by the U.S. Food and Drug Administration for the treatment of chronic graft-versus-host disease (cGVHD) after failure of at least two prior systemic therapies. Through modulation of IL-21 and IL-17 secretion, upregulation of regulatory T cells, inhibition of pro-fibrotic pathways and TGF-β signaling, and reduction of choroidal neovascularization, belumosudil may represent a promising therapeutic option for ocular cGVHD.

Methods: We report a case series of five patients with severe, progressive ocular cGVHD treated with belumosudil for six months. All patients had undergone allogeneic hematopoietic stem cell transplantation more than 10 years before treatment initiation. Ocular cGVHD was graded as severe in all cases (NIH ocular score 3). Ophthalmologic assessments were performed according to NIH recommendations. Belumosudil was administered at a dose of 200 mg twice daily.

Results: Common ocular manifestations included corneal ulceration, eyelid thickening and irregularity, meibomian gland dysfunction, reduced tear meniscus, diffuse epithelial keratopathy, filamentary keratitis, early lens opacities, and severe dry eye with corneo-conjunctival epitheliopathy. All patients experienced significant impairment of daily activities, with vision loss reported in two cases. Concomitant cGVHD involvement included oral involvement in three patients and pulmonary involvement in two patients. All patients had previously received long-term topical cyclosporine, and two were on oral cyclosporine, without clinical benefit. The overall response rate for ocular cGVHD was 100%. All patients showed symptomatic improvement, confirmed by serial ophthalmologic evaluations performed every two months. After six months of therapy, three patients improved from NIH ocular score 3 to 1, and two patients from score 3 to 2.

Conclusions: Belumosudil demonstrated significant clinical activity in patients with severe, progressive ocular cGVHD and may represent an effective therapeutic option in this difficult-to-treat population.

Disclosure: Nothing to declare.

P138

EFFECTS OF EXTRACORPOREAL PHOTOPHERESIS (ECP) ON LEUKEMIA-SPECIFIC AND ANTI-LEUKEMIC IMMUNE CELL SUBSETS IN LEUKEMIA PATIENTS AFTER STEM CELL TRANSPLANTATION (HSCT) WITH ACUTE OR CHRONIC GRAFT-VERSUS-HOST-DISEASE

Cansu Karatas[1], Vivien Simon[1], Kristina Schreiner[1], Anying Huang[1], Julian Stein[1], Johannes Zimmer[1], Joudi Abdulmajid[1], Jan Weller[2], Christoph Schmid[3], Jochen Frietsch[4], Tobias Holderried[5], Helene Schmeller[5], Katrin Strauss[6], Elisa Sala[6], Giuliano Filippini[3], ***Helga Schmetzer***[1]
[1]LMU Munich, Munich, Germany, [2]UKE, Hamburg, Germany, [3]Uniklinik Augsburg, Augsburg, Germany, [4]Uniklinik Würzburg, Würzburg, Germany, [5]Uniklinik Bonn, Bonn, Germany, [6]Uniklinik Ulm, Ulm, Germany*

Background: Acute (a) or chronic (c) Graft-versus-Host-Disease (GvHD) are frequent, potentially life-threatening complications after HSCT and can be treated with ECP. How ECP influences the function and dynamics of leukemia-specific immune subsets remains unclear. We analyzed leukemia-specific subsets defined by CD107a$^+$ (DEG) or IFNγ$^+$ (INC) responses and "antitumor-directed" (Integrinβ7$^+$, γδ$^+$) T cells and TH cells in aGvHD, cGvHD, no-GvHD patients, and healthy donors (H). We correlated these profiles with clinical characteristics to identify ECP-, GvHD-, or relapse-associated signatures at baseline (d0) and after 3 months of ECP (d90).

Methods: ECP was performed using the TherakosTM CELLEXTM system. Flow cytometric analyses were performed on patient blood samples at d0 (pre ECP) and d90 (after ECP), focusing on leukemia-specific (DEG+/INC+), antitumor directed and Thelper cells. Statistical analyses were conducted.

Results: noGvHD d0 vs Healthy controls:

- TH cells H vs. noGvHD: TH17↑ TH1↑ TH2↑
- Integrinß7$^+$T^{4-}↓ and γδ$^+$ T^{4+}↓ in H

noGvHD d0 vs. d90:

- Degranulating cells: CIK cells ↓ NK cells ↓ Tem cells ↓
- INFγ producing cells: CIK↓ NK↑
- TH cells: TH17↑ TH1 and TH2 stable

cGvHD d0 vs. d90 under ECP:

- Degranulating cells: CIK cells ↓ NK cells↑ Breg↑ Tem↓ Tcm↑
- INFγ producing cells: CIK cells ↓ NK cells ↓ Tcm↑
- TH cells: TH17 stable, TH1↑ TH2↓

aGvHD d0 vs. d90 under ECP:

- Degranulating cells: CIK cells ↓ NK cells ↓
- INFγ producing cells: CIK cells↑ NK cells↑ Tem cells↑
- TH cells: TH17, TH1 and TH2 stable

cGvHD vs. noGvHD d0:

- Degranulating cells cGvHD vs. noGvHD: CIK cells↓ NK cells↓ Tcm↓ Tem↓ Breg↑
- INFγ producing cells cGvHD vs. noGvHD: CIK cells↓ NK cells↓ Tcm↓ Tem↑
- TH cells cGvHD vs. noGvHD: TH17↓ TH1↓ TH2↓

aGVHD vs. noGvHD d0:

- Degranulating cells aGvHD vs. noGvHD: CIK cells↑ NK cells↑ Breg ↑ Tcm↓ Tem↓
- INFγ producing cells aGvHD vs. noGvHD: CIK cells↓ NK cells↓ Tcm↓ Tem↓
- TH cells aGvHD vs. noGvHD: TH17↓ TH1↓ TH2↓

cGvHD under ECP vs. noGvHD d90:

- Degranulating cells cGvHD vs. noGvHD: CIK cells↑ NK cells↑ Breg↑ Tcm↓ Tem↓
- INFγ producing cells cGvHD vs. noGvHD: CIK cells↑ NK cells↑ Tcm↑
- TH cells cGvHD vs. noGvHD: TH17↓ TH1↑ TH2↓

aGvHD under ECP vs. noGvHd d90:

- Degranulating cells aGvHD vs. noGvHD: CIK cells↑ NK cells↑ Tem↑
- INFγ producing cells aGvHD vs. noGvHD: CIK cells↑ NK cells↑ Tcm↓ Tem↑
- TH cells aGvHD vs. noGvHD: TH17↓ TH1↑ TH2↓

Conclusions: At d0, both GvHD groups showed reduced degranulating and IFNγ-producing CIK, NK, and Tcm cells and lower TH17, TH1, and TH2 levels compared with noGvHD. Both groups also had decreased DEG/IFNγ$^+$ Tem and increased DEG-Breg cells. Intβ7$^+$T4$^-$ and γδ$^+$T4$^+$ subsets were lowest in healthy donors.
At d90, aGvHD and cGvHD patients showed higher degranulating and IFNγ-producing CIK andNK cells than noGvHD, along with reduced TH17/TH2 and increased TH1 levels. cGvHD patients additionally showed reduced DEG-Tcm and increased DEG-Breg cells.
Overall, noGvHD patients showed stable, GVHD patients under ECP variable immune subset compositions. Correlations of findings with clinical parameters will be presented.

Disclosure: FUNDING: This work was funded by an external collaborative research (ECR) grant provided by Therakos EMEA Limited.

P140

REDUCED-DOSE POST-TRANSPLANT CYCLOPHOSPHAMIDE FOR GVHD PROPHYLAXIS IN HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION: REAL-WORLD OUTCOMES FROM A LATIN AMERICAN TRANSPLANT CENTER

Guillermo Sotomayor Duque[1], Araceli Leal Alanis[1], Hernan Ramirez Duran[1], Dolores Catalina Cortes Flores[1], Martha Audelo Guzman[1], ***Severiano Baltazar Arellano***[1]
[1]*IMSS UMAE 25, Monterrey, Mexico*

Background: Post-transplant cyclophosphamide (PTCy), administered at high doses of 50 mg/kg/day on days +3 and +4, is a standard of care for graft-versus-host disease (GVHD) prophylaxis in haploidentical hematopoietic cell transplantation (HCT). Although highly effective, PTCy is associated with toxicities that may be dose-dependent, prompting dose-adjustment strategies aimed at reducing cardiovascular and infectious complications. We report the experience of a transplant center in Mexico using dose-adjusted PTCy as GVHD prophylaxis in haploidentical HCT.

Methods: Patients aged ≥16 years who underwent haploidentical hematopoietic cell transplantation between 2024 and 2025 at IMSS UMAE 25, Monterrey, Mexico, were included. Descriptive analyses were performed using measures of central tendency and percentages. Overall survival (OS) and relapse-free survival (RFS) were estimated using the Kaplan–Meier method, while non-relapse mortality (NRM) and graft-versus-host disease (GVHD) were analyzed using cumulative incidence functions.
Objective: Describe outcomes of patients receiving PTCy at 40 mg/kg/day on days +3 and +4 following haploidentical HCT at a single transplant center in Mexico.

Results: Patients aged ≥16 years who underwent haploidentical hematopoietic cell transplantation between 2024 and 2025 at IMSS UMAE 25, Monterrey, Mexico, were included. Descriptive analyses were performed using measures of central tendency and percentages. Overall survival (OS) and relapse-free survival (RFS) were estimated using the Kaplan–Meier method, while non-relapse mortality (NRM) and graft-versus-host disease (GVHD) were analyzed using cumulative incidence functions.
Results: A total of 21 patients were included (16 men and 5 women), with a median age of 27 years (range 16-50). The main indication for transplantation was malignancy (ALL 11, AML 3, MDS 2, NHL 1, PMF 1). Nine donors were male and 12 were female. The median CD34+ count was 11.27/kg (range 3-28.6), all obtained from peripheral blood by apheresis. Conditioning was performed using the MAC variant in 80% of cases. Engraftment was successful in 91% of cases; one patient experienced primary failure requiring a second transplant. The median chimerism at day 30 was 99% (0-99). The median neutrophil engraftment was on day 14 (range 12-20), and the median platelet engraftment was on day 15 (range 13-50).

The median follow-up was 200 days (range 20-455). Overall survival was 69%, and relapse-free survival was 90%. Only 8 (38%) patients developed GVHD during the follow-up period.

The cumulative incidence of acute GVHD was 24% (19% GII-IV) and of chronic GVHD was 12% (6% NIH moderate/extensive) at 400 days of follow-up.

CMV reactivation occurred in 10 patients (47%), none with clinical disease; BK virus reactivation in 4 patients (19%); hemorrhagic cystitis in 5 patients (23%), none in its severe form; and pneumonia in 5 patients (23%). Non-Relapse Mortality was 23% (1 patient graft failure, 3 Klebsiella sepsis, and 1 patient severe graft-versus-host disease).

Conclusions: The reduction of PTCy dose in our patient group demonstrated comparable efficacy to the conventional dose against GVHD prevention and a low incidence of severe/extensive forms.

Disclosure: No conflict of interest.

P142

CLINICAL CHARACTERISTICS AND SURVIVAL OUTCOMES OF GRAFT-VERSUS-HOST DISEASE AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION: A SINGLE-CENTRE COHORT ANALYSIS

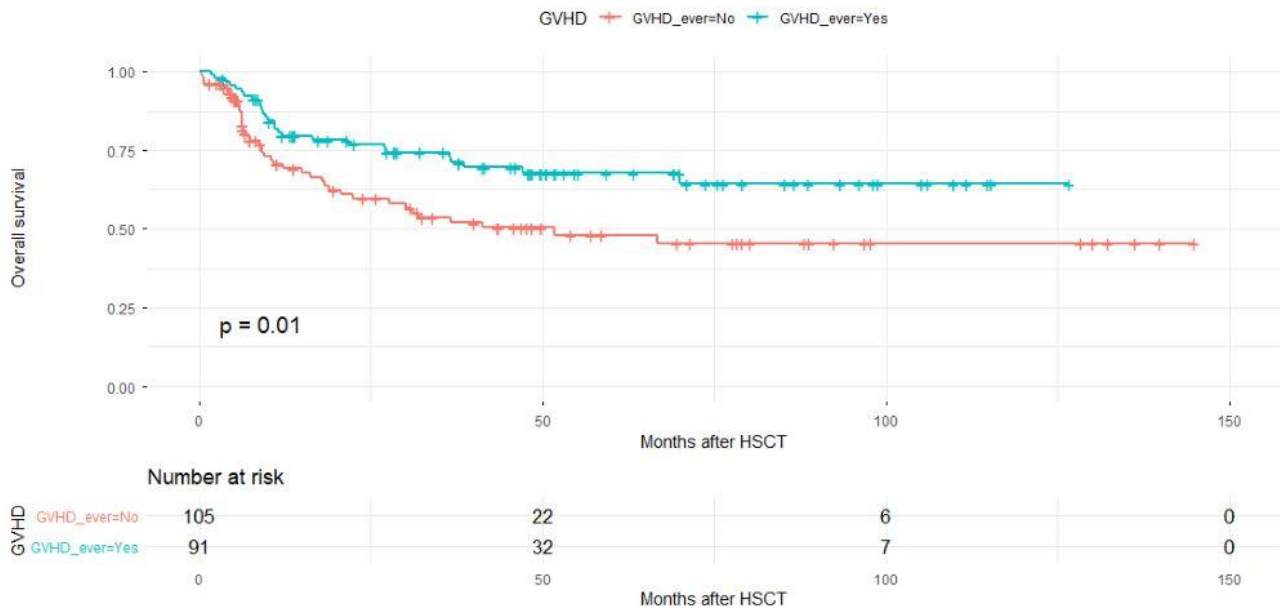
*Shirley Quintana-Truyenque[1], **Naty López-Córdova**[1], Cindy Alcarraz-Molina[1], Lourdes Lopez-Chavez[1], Victor Mallma-Soto[1], Jessica Meza-Liviapoma[1], Alexandra Saavedra Baron[1], Jorge Sánchez Alarcón[1], Armando Sánchez Yarlequé[1], Claudia Castillo Chilet[1], Tatiana Vidaurre[1], Jule Vasquez-Chavez[1]*
[1]Instituto Nacional de Enfermedades Neoplásicas, Lima, Peru

Background: Graft-versus-host disease (GVHD) remains an important complication after allogeneic haematopoietic stem cell transplantation (allo-HSCT), with a complex relationship to post-transplant outcomes. Characterising the clinical presentation of GVHD and its association with survival remains clinically relevant. We aimed to describe the incidence of GVHD in a real-world allo-HSCT cohort and to evaluate its association with overall survival (OS) and its relationship with selected baseline donor and recipient characteristics.

Methods: We conducted a retrospective cohort study including 235 adult patients who underwent allo-HSCT. OS was estimated using the Kaplan–Meier method. Survival outcomes were compared by GVHD status using the log-rank test. GVHD was defined based on documented clinical diagnosis and classified as acute or chronic. Acute GVHD severity was graded according to standard criteria (grades I–IV), while chronic GVHD was categorised as mild, moderate or severe. Baseline characteristics, including organ involvement, recipient sex, donor sex, and donor–recipient sex combinations, were summarised descriptively. Associations between categorical variables and GVHD occurrence were evaluated using Fisher's exact test.

Results: With a median follow-up of 49.8 months (range 0.8–140), patients who developed GVHD showed significantly improved overall survival compared with those without GVHD (Figure 1). Two- and five-year OS rates were 76.9% and 67.8% in patients with GVHD versus 59.6% and 48.1% in those without GVHD (log-rank p = 0.01).Among the 235

patients, 91 (38.7%) developed GVHD. Of these, 34 (37.4%) presented with acute and 57 (62.6%) with chronic GVHD. Acute GVHD was predominantly low-grade, with grade I being 58.1% of cases. Higher-grade acute GVHD was less frequent, with grades III–IV observed in 19.3% of patients. Chronic GVHD was mainly mild (40.7%) to moderate (53.7%), while severe chronic GVHD was uncommon, accounting for only 5.6% of cases.
Regarding organ involvement, hepatic GVHD was the most frequent manifestation, observed in 45.1% of cases, followed by skin involvement in 20.9%. Multiorgan GVHD was present in approximately one fifth of patients (22.0%), while mucosal (5.5%), pulmonary (4.4%) and gastrointestinal (2.2%) involvement were less frequent.
The distribution of donor–recipient sex combinations was balanced across the cohort. No significant differences in GVHD occurrence were observed among the four donor–recipient sex combinations (female donor–female recipient, female donor–male recipient, male donor–female recipient, and male donor–male recipient; Fisher's exact test, p = 0.65). Donor–recipient sex discordance was not associated with GVHD development. The classical female donor–male recipient combination was not associated with a higher frequency of GVHD when compared with other sex combinations.



Conclusions: In this cohort, GVHD occurrence was associated with improved overall survival, supporting the clinical relevance of the graft-versus-leukaemia effect. Acute GVHD was predominantly low grade, and chronic GVHD was mainly mild to moderate, with severe forms being uncommon. Hepatic and skin involvement were the most frequent clinical manifestations. No significant associations were observed between GVHD and donor–recipient sex combinations. These findings highlight the prognostic relevance of GVHD while emphasising the absence of detectable associations with baseline donor–recipient sex characteristics in this cohort.

Disclosure: Nothing to declare.

P143

DUPILUMAB AS EFFECTIVE TREATMENT IN ADULT AD-LIKE GVHD: A CASE REPORT

*Irene Bernareggi[1], Laura Lazzeri[2], Alessandro Bucalossi[1], **Margherita Malchiodi**[1], Mariapia Lenoci[1], Francesca Toraldo[1], Monica Tozzi[1]*
[1]Cellular Therapy and Blood Establishment Unit, AOUS, Siena, Italy, [2]Dermatology Unit, AOUS, University of Siena, Siena, Italy

Background: Atopic dermatitis (AD)-like graft-versus-host disease (GVHD) is a chronic form of cutaneous GVHD that may occur following allogeneic hematopoietic stem cell transplantation (allo-HSCT). Both for acute and chronic GVHD, systemic corticosteroids are considered first-line therapy, but responses may be temporary. Second-line options—including Ruxolitinib, extracorporeal photopheresis, Sirolimus, Mycophenolate mofetil and Rituximab—are variably effective but could often be toxic. Targeted therapies such as Dupilumab are emerging as promising options for cutaneous, AD-like chronic GvHD in pediatric patients. Dupilumab is a human IgG4 monoclonal antibody targeting the interleukin-4 receptor α subunit (IL-4Rα), thereby inhibiting IL-4 and IL-13 signalling and selectively modulating the Th2 axis involved in cutaneous inflammation and pruritus.

Methods: We report a case of an adult, 55-year-old woman, who underwent cord blood allo-HSCT for Acute Myeloid Leukaemia and was treated with Dupilumab for AD-like GVHD.

Results: The patient had a history of atopy (seasonal allergic rhinoconjunctivitis, skin reactions to fish and shellfish, family history of atopy) and was affected by high-risk Acute Myeloid Leukaemia FAB M4 diagnosed in 2009. After a suboptimal response to multiple induction and consolidation chemotherapy regimens (FLAIE, IDA-AraC, HD-AraC, MEC-My) and persistence of minimal residual disease, she underwent an allo-HSCT. In 2010, she received a cord blood unrelated donor transplantation (4/6 mismatched, ABO major incompatible, infused dose TNC/kg 3.61×10^7) after a myeloablative conditioning therapy including Thiotepa, Fludarabine and Busulfan with a GVHD prophylaxis including anti-thymocite globulin, mycophenolate mofetil and cyclosporine. No acute GHVD signs occured. One year after transplant, the patient developed erythematous-scaling skin lesions with an eczematous appearance at the base of the neck, in the elbow folds and breast region, associated with dry, pruritic skin, excoriations and facial erythema. Histological picture was compatible with Atopic Dermatitis, with a transient response to topical corticosteroid therapy, emollients and cyclosporine. Following the loss of therapeutic response, a new skin biopsy led to a diagnosis of chronic cutaneous GVHD; therefore the patient was treated with cyclosporine and extracorporeal photopheresis, continued for nearly ten years with moderate clinical benefit, despite seasonal flare-ups. After immnosuppressive therapy was interrupted, in 2022 a new worsening of skin condition was observed. New histological evaluation documented moderate-to-severe Atopic Dermatitis with GVHD features. Resuming cyclosporine resulted in an unsatisfactory clinical response; therefore, in light of the evidence of a concomitant EBV infection, the patient received two administrations of rituximab, resulting in both a reduction in EBV viral load and an improvement in the cutaneous findings.

Subsequently, second-line biologic therapy with Dupilumab was started in December 2023, at a dosage of 300 mg s.c. every two weeks, obtaining a good disease control, with disappearance of skin lesions. Dupilumab was well tolerated, with no drug-related toxicities reported.

Conclusions: As reported in pediatric setting, Dupilumab seems to be a promising, well-tolerated option also in adult patients with steroid-refractory cutaneous GvHD with AD-like features. Its use may reduce immunosuppressive burden and improve quality of life.

Disclosure: Nothing to declare.

P146

VERY LATE ONSET ACUTE GVHD AFTER COVID19 VACCINE AND INFECTION: A CASE REPORT

Margherita Malchiodi[1], *Alessandro Bucalossi*[1], *Irene Bernareggi*[1], *Mariapia Lenoci*[1], *Francesca Toraldo*[1], *Monica Tozzi*[1]
[1]*Cellular Therapy and Blood Establishment Unit, AOUS, Siena, Italy*

Background: Late onset acute graft-versus-host disease (aGVHD) is defined by the presence of acute GVHD beyond 100 days post allogeneic hematopoietic stem cell transplantation (allo-HSCT).
These findings present clinical and pathological features of aGVHD without any representative chronic GVHD findings. Of note, they usually present more severe symptoms, frequently unresponsive to immunosuppressive therapy. Cutaneous late onset aGVHD is the most common form, characterized by pruritic and erythematous rash with basal keratinocyte apoptosis, perivascular lymphocytic infiltration and dyskeratosis.

Methods: We report a case of a 63-year-old female affected by Myelofibrosis post Polycythemia Vera (PPV-MF), JAK2 mutated, who received an allo-HSCT in 2014 and developed a late onset aGVHD 8 years post-transplant.
In 2001 our patient was diagnosed with Polycythemia Vera, and she started treatment with hydroxyurea and phlebotomies. In 2009 she experienced an increasing spleen volume, and she underwent bone marrow (BM) biopsy which documented the evolution to PPV-MF, and she started Ruxolitinib with improvement of symptoms.
In April 2014 she underwent haploidentical allo-HSCT. GVHD prophylaxis included post-transplant cyclophosphamide, mofetil mycophenolate (MMF) and cyclosporine. At day +24 she developed grade I cutaneous aGVHD, which responded to increased cyclosporine and prolonged MMF until day +35. BM evaluations, performed up to two and a half years after allo-HSCT, confirmed CR, JAK2 negative and complete donor chimerism.
In April 2022, 8 years after allo-HSCT, she developed a widespread pruritic erythroderma some weeks after COVID-19 vaccination and subsequent infection. She underwent skin biopsy which documented apoptotic keratinocytes and lymphocityc infiltration, histopathological features consistent with aGVHD rather than lichenoid or sclerotic chronic GVHD. Furthermore, we performed BM evaluation, 8 years after allo-HSCT, which

documented Myelofibrosis JAK2 mutated and mixed chimerism with 30,9% donor and 69,1% recipient.

Results: Corticosteroid therapy was eventually initiated, without clinical improvement, thus cyclosporine and extracorporeal photopheresis were introduced, however, these interventions also proved ineffective. An improvement in the cutaneous findings was finally obtained with the JAK1/JAK2 inhibitor ruxolitinib, a particularly effective treatment in steroid-refractory aGVHD.
During this therapy our patient developed pancytopenia, so we performed another BM biopsy, which showed persistence of JAK2 mutation and chimerism improvement with 89,5% donor and 10,5% recipient. Despite being evaluated for a second allo-HSCT, she withdrew consent and, today, 3 years after, she continues Ruxolitinib with hematological recovery.

Conclusions: This case shows a very rare entity of late onset aGVHD occurred 8 years after transplantation, triggered by COVID-19 vaccination and infection. Despite its complexity was aggravated by the concurrent Myelofibrosis relapse and chimerism loss, Ruxolitnib appears to be an effective treatment.

Disclosure: Nothing to declare.

P147

COMPOSITION OF PERIPHERAL BLOOD IMMUNE-CELLS IN PATIENTS WITH LEUKEMIA AFTER ALLOGENEIC STEM-CELL-TRANSPLANTATION(HSCT) IN PATIENTS WITH VS. WITHOUT CHRONIC(C) OR ACUTE(A) GRAFT-VERSUS-HOST-DISEASE(GVHD) AND HEALTHY DONORS

Vivien Simon[1,2,3], Cansu Karatas[1,2], Kristina Schreiner[1,2], Anying Huang[1,2], Alyia Tasdemir[1,2,3], Kerstin Gruber[1,2,4], Clyde Boppel[1,2,4], Julian Stein[1,2], Annalena Frischhut[1,2], Jan Weller[5], Christoph Schmid[2,6], Jochen Frietsch[7], Tobias Holderried[8], Anne Brandenburg[8], Elisa Sala[9], Giuliano Filippini[6], ***Helga Schmetzer***[1,2]
[1]Ludwig Maximilian University of Munich, Munich, Germany, [2]Bavarian Center for Cancer Research (BZKF), Munich, Germany, [3]University of Bielefeld, Bielefeld, Germany, [4]University of Applied Sciences, Esslingen, Germany, [5]University of Hamburg, Hamburg, Germany, [6]University of Augsburg, Augsburg, Germany, [7]University of Würzburg, Würzburg, Germany, [8]University of Bonn, Bonn, Germany, [9]University of Ulm, Ulm, Germany*

Background: aGvHD/cGvHD are common and potentially life-threatening autoimmune complications after HSCT, mediated by immune cells. Treatment aims to suppress excessive immune activity while maintaining graft versus leukemia effects. The impact of treatment on the provision of inflammatory or inhibitory immune cell subsets is poorly understood. We compared myeloid, adaptive and innate immune cell compositions in aGvHD/cGvHD vs non-GvHD HSCT patients or healthy controls before treatment (baseline) and correlated findings with clinical patients' characteristics. Finally, we deduced knowledge about immune cells involved in patients after HSCT that did not develop GvHD ('NoGvHD') vs GvHD patients.

Methods: Flow cytometric cell analyses of blood samples (H=10, NoGvHD=19, cGvHD=18, aGvHD=6) were observed at baseline. Statistical analysis was performed.

Results: Cells in cGvHD compared to NoGvHD

- Myeloid: ↓ DCtol/MDSCs, ↑ myeloid dysfunction
- Adaptive: ↑ effector-memory, ↓ regulatory/anti-tumor subsets
- Innate: ↑ differentiated/exhausted NK/CIK

Cells in aGvHD compared to NoGvHD

- Myeloid: ↓ inhibitory monocytes/DCtol
- Adaptive: ↑ strong late T-cell proliferation, ↓ Tregs/B cells
- Innate: ↓ NK56bri, ↑ destabilized/exhausted NK/iNKT

Cells in aGvHD compared to cGvHD

- Myeloid: acute collapse (aGvHD) vs. chronic dysfunction (cGvHD)
- Adaptive: extreme effector proliferation (aGvHD) vs. persistent activation (cGvHD)
- Innate: loss of early NK regulators (aGvHD) vs. NK56dim dominance (cGvHD)

Cells in NoGvHD compared to GvHD development

- Myeloid: ↑ tolerogenic DC/MDSC
- Adaptive: ↑ T/Treg, ↓ activation/proliferation
- Innate: ↓ NK/CIK exhaustion

Cells in skin aGvHD compared to no-skin aGvHD

- Myeloid: ↓ tolerogenic signatures
- Adaptive: ↑ activation/homing markers, ↓ regulatory subsets
- Innate: ↑ NK/CIK exhaustion, ↑ TH1/TH17 skewing

Cells in overlap cGvHD compared to non-overlap cGvHD

- Myeloid: ↓ tolerogenic myeloid cells
- Adaptive: ↑ PD-L1/TIGIT, ↓ Tregs
- Innate: ↑ NK/CIK exhaustion

Cells in severe cGvHD compared to mild cGvHD

- Myeloid: ↑ activated/CTLA-4^{+} MDSC/DC
- Adaptive: ↑ proliferating/gut-homing T cells, ↓ Th1/Treg
- Innate: ↑ NK/CIK exhaustion

Cells in multi organ cGvHD compared to single organ cGvHD

- Myeloid: ↑ inflammatory monocytes/MDSCs
- Adaptive: ↑ γδ⁺/Intβ7⁺ activation, ↓ Tregs
- Innate: ↑ checkpoint-positive NK/CIK, ↓ NK56bri

Cells in DLI-exposed compared to non-DLI exposed cGvHD

- Myeloid: ↓ tolerogenic myeloid function
- Adaptive: ↑ activation/gut-homing, ↓ Tregs
- Innate: ↑ NK/CIK exhaustion

Conclusions: Post-HSCT, NoGvHD patients who did not develop GVHD maintain regulatory myeloid and adaptive features with limited T/NK activation, whereas GvHD patients, with especially skin aGvHD, severe cGvHD, multi-organ cGvHD, or DLI-treated cGvHD, showed myeloid suppression, T-cell hyperactivation, and NK/CIK exhaustion, reflecting distinct inflammatory and tissue-homing immune signatures.

Disclosure: This work was funded by an external collaborative research (ECR) grant provided by Therakos EMEA Limited.

P148

DYNAMIC MODULATION OF NATURAL KILLER (NK) AND CYTOKINE INDUCED KILLER (CIK) CELLS BY EXTRACORPOREAL PHOTOPHERESIS IN CHRONIC GRAFT-VERSUS-HOST DISEASE AFTER HEMATOPOETIC STEM CELL TRANSPLANTATION

Anying Huang[1], *Kristina Schreiner*[1], *Cansu Karatas*[1], *Vivien Simon*[2], *Kerstin Gruber*[3], *Aliya Tasdemir*[2], *Julian Stein*[1], *Johannes Zimmer*[1], *Christoph Schmid*[4], *Jochen Frietsch*[5], *Helene Schmeller*[6], *Tobias Holderried*[6], *Elisa Sala*[7], *Giuliano Filippini*[4], *Helga Schmetzer*[1]
[1]*University Hospital of Ludwig-Maximilian-University, Munich, Germany,* [2]*University of Bielefeld, Bielefeld, Germany,* [3]*University of Applied Sciences, Esslingen, Germany,* [4]*University Hospital of Augsburg, Augsburg, Germany,* [5]*University Hospital of Würzburg, Würzburg, Germany,* [6]*University Hospital of Bonn, Bonn, Germany,* [7]*University Hospital of Ulm, Ulm, Germany*

Background: NK cells are central to immune reconstitution after Hematopoetic Stem Cell Transplantation**(**allo-SCT) and contribute to Chronic Graft vs Host Disease(cGvHD) pathophysiology. Altered NK maturation and inhibitory phenotypes have been linked to persistent inflammation in cGVHD. Extracorporeal Photopheresis (ECP) is widely used in steroid-refractory cGvHD, but its effects on NK-cell subset composition remain poorly defined. Aims**:** To compare NK and checkpoint-expressing NK/CIK subsets between patients without GvHD ('No-GvHD', controls) and cGVHD patients receiving ECP at baseline and after 12 weeks.

Methods: ECP was administered using the THERAKOS™ CELLEX™ Photophoresis system. Peripheral Blood samples from cGvHD (n=14) and no-GvHD (n=14) allo-SCT recipients were analyzed at baseline and after 12-weeks follow-up. NK and CIK subsets were quantified by flow cytometry. Statistical analyses were performed.

Results: 1. cGVHD displayed vs no-GvHD (baseline):
↑ **Cytokine-producing NK** ($CD56^{bri}$) cells
↓**TIGIT-expressing NK** cells
↓**KLRG1-expressing and TIM3-expressing CIK** cells
2.After 12 weeks from baseline, cGVHD patients displayed vs no-GvHD:
↓**Cytotoxic NK** ($CD56^{dim}CD16^{+}$, $CD56^{dim}CD57^{+}$) cells
↓**TIGIT-expressing and KLRG1-expressing NK** cells
↓**KLRG1-expressing CIK** cells
3. cGVHD patients displayed after 12 weeks ECP treatment:
↓**Cytokine-producing NK** ($CD56^{bri}$) cells
↑**TIGIT-expressing ,KLRG1-expressing NK cells** and **$2B4^{+}$ expressing NK** cells
↓**TIGIT -expressing** and **KLRG1-expressing CIK** cells

Conclusions: cGVHD patients showed reduced cytotoxic NK signatures at follow-up compared with no-GVHD controls. During ECP, NK cells shifted toward increased inhibitory/stimulatory phenotypes and reduced cytokine-producing subsets, while CIK cells displayed an opposite trend. These data suggest differential NK/CIK remodeling as part of ECP's immunomodulatory mechanism. Clinical correlations will be presented at the meeting.

REPORT ON THE EFFICACY OF MESENCHYMAL STROMAL CELLS (MSC–OBTINIX™) IN STEROID AND RUXOLITINIB-REFRACTORY GVHD (SRR-GVHD) WITHIN A COMPASSIONATE USE PROGRAM: AN ITALIAN SINGLE-CENTER EXPERIENCE

*Gabriele Magliano[1], Enrico Morello[1], Vera Radici[1], Mirko Farina[1], Silvia Zanon[1], Rachele De Domenico[1], Marco Galli[1], Riccardo Marnoni[1], Paolo Clementi[1], Francesca Bonati[1], Laura Donatoni[1], Simona Bernardi[1,2], Federica Re[1,2], Alessia Cavalleri[1,2], Alessandro Leoni[1,2], Domenico Russo[1], Michele Malagola[1], **Daniele Avenoso**[1]*
[1]Unit of Blood Diseases and Bone Marrow Transplant, University of Brescia, ASST Spedali Civili, Brescia, Italy, [2]Centro di Ricerca Emato-Oncologica AIL, Brescia, Italy

Background: Graft-versus-host disease (GVHD) remains a major complication of allogeneic hematopoietic stem cell transplantation (allo-HSCT) and a leading cause of morbidity and mortality. Although corticosteroids represent first-line therapy and ruxolitinib is currently the standard second-line treatment for steroid-refractory disease, a substantial proportion of patients develop GVHD that is refractory to both agents (SRR-GVHD). In this setting,

therapeutic options are limited, and clinical management remains poorly defined, representing a significant unmet medical need. Mesenchymal stromal cells (MSCs), due to their immunomodulatory and anti-inflammatory properties, have emerged as a potential therapeutic strategy for patients with multi-refractory GVHD.

Methods: We conducted a retrospective single-center analysis of patients with refractory acute and chronic GVHD treated with third-party mesenchymal stromal cells (MSCs-Obnitix™). Clinical and transplant-related variables, prior GVHD therapies, and MSC dosing were collected. Response was assessed according to EBMT criteria one week after the last MSC infusion, and post-treatment complications were recorded. Descriptive analyses were performed to explore associations between baseline characteristics and outcomes.

Results: Three patients with an average age of 55 years at the time of transplantation were included in the analysis (Table 1).
The first patient, female, affected by primary myelofibrosis, developed acute gut GvHD which persisted after day +100 post HSCT. She was initially treated with corticosteroids and ruxolitinib achieving only a partial response followed by an exacerbation of symptoms. One week after the infusion of the fourth and final dose of MSCs, she showed a marked clinical improvement, with a reduction in daily stool volume from 1500 to 200ml (Image 1).
The second patient, male, affected by T lymphoblastic lymphoma, developed acute gut GvHD on day +49 post HSCT. After achieving an only partial response to steroids, ruxolitinib and vedolizumab, he experienced a marked clinical improvement along the course of MSCs infusion, with a progressive resolution of the fecal volume (from 3000 ml/day to about 300 ml/day).
The third patient, male, affected by B lymphoblastic leukemia, developed acute cutaneous GvHD on day +15 that evolved to chronic on day +280 post HSCT characterized by lichenoid lesions and diffuse pruritus. The treatment with corticosteroids, ruxolitinib, imatinib, tacrolimus and belumosudil resulted in only limited benefit. A notable amelioration was achieved after the last dose of the MSC-based treatment, with pruritus improving to CTCAE grade 2, BSA involvement decreasing from 80% to 50% and full resolution of the oral lichenoid manifestations.
MSCs infusions were well tolerated and no complications or adverse events were observed in any of the patients.

	Patient 1	**Patient 2**	**Patient 3**
Sex	F	M	M
Age	58	58	48
Diagnosis	MF	T-ALL	B-ALL
Sorror score	0	5	1

Donor type	MUD	Haplo	Sibling
GvHD prophylaxis	ATG, MMF, cyclosporine	PTCY, MMF, tacrolimus	ATG, MTX, cyclosporine
Type of GVHD	Acute, severe	Acute, severe	Chronic, moderate
Involved organs	GI tract	GI tract	Skin
Symptoms	Diarrhea	Diarrhea	Lichenoids lesions, diffuse pruritus
Previous therapy for GvHD	Corticosteroids, ruxolitinib	Corticosteroids, ruxolitinib, sirolimus, vedolizumab	Corticosteroids, ruxolitinib, imatinib, tacrolimus, belumosudil
Pre-MSC severity	Fecal output of 1500 ml/day	Fecal output of 3000 ml/day	CTCAE grade 3, BSA involved of 80%
Post-MSC severity	Fecal output of 200 ml/day	Fecal output of 300 ml/day	CTCAE grade 2, BSA involved of 50%, oral lichen resolution

Table 1

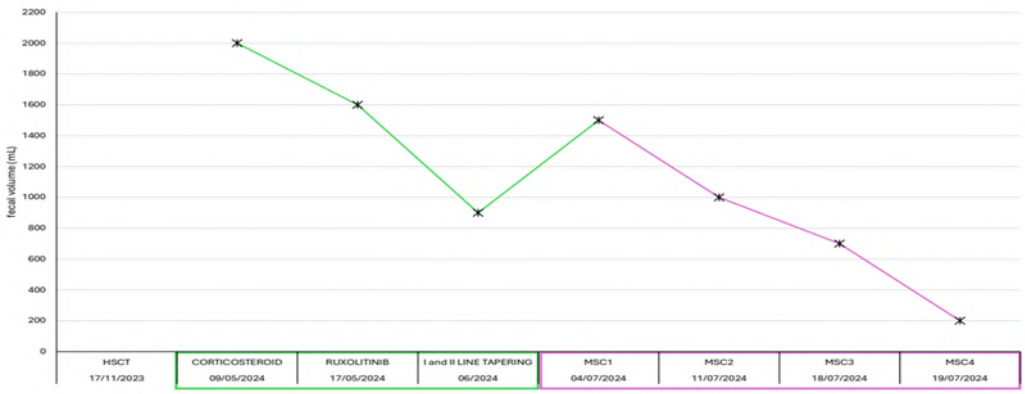

Image 1

Conclusions: Our data show that MSC cell therapy provides a clear improvement in GVHD-related clinical manifestations, both gastrointestinal and cutaneous, and notably without

evident adverse events.
Based on our observations, MSCs may represent a valuable therapeutic option for patients with therapy-refractory acute and chronic GvHD. In all treated cases, MSCs were associated with meaningful clinical improvements, without any treatment-related toxicities or complications. Although limited by the sample sample size, these results encourages further exploration of MSCs as a backbone to current treatment options.

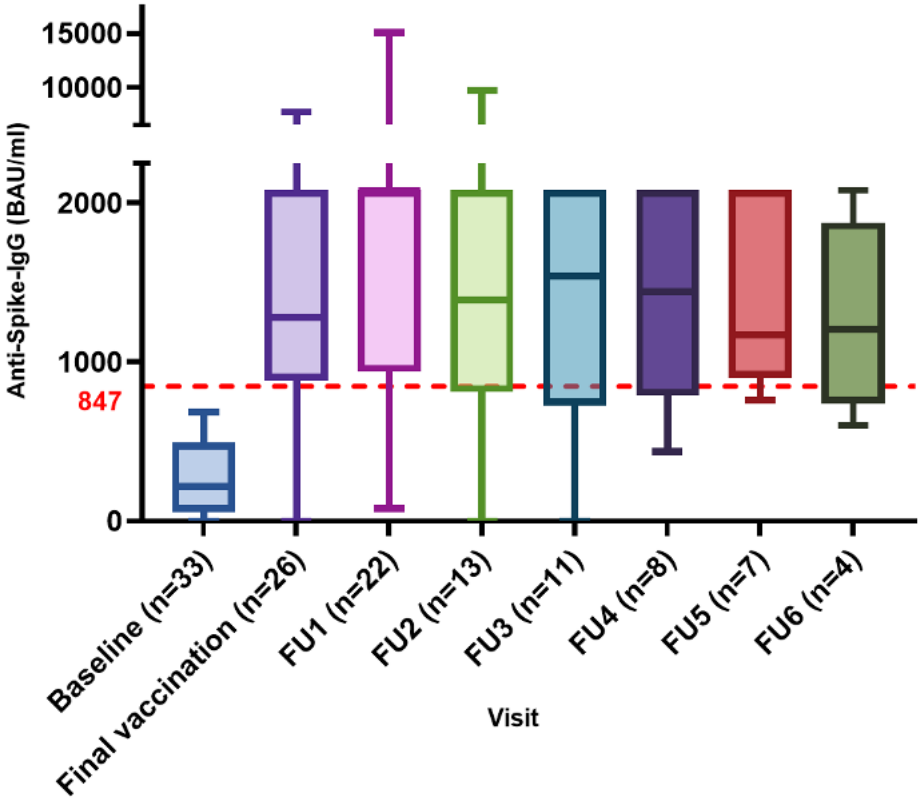
Background: Immunocompromised patients are at an ongoing high risk for severe COVID-19 infections. Vaccination has been proven to be an effective measure in preventing severe SARS-CoV-2 infections, while data on B-cell and T-cell responses are lacking in this population.

Methods: This multicentre, prospective, non-interventional study aimed to determine the immunogenicity and reactogenicity of a COVID-19 vaccination strategy in immunocompromised patients with a focus on patients after autologous HSCT and CAR-T cell recipients. Immunocompromised patients received up to eight COVID-19 vaccinations in 4-week intervals depending on their individual anti-SARS-CoV-2-spike-IgG level as standard of care (SOC). Patients after autologous HSCT and CAR-T cell recipients received a minimum of three vaccinations to re-complete basic immunization. Blood samples were drawn immediately before each vaccination and during a 6-months follow-up.

At each study visit, the humoral and cellular immunity was analysed. Humoral immunity was investigated by measuring anti-SARS-CoV-2-spike-IgG, anti-SARS-CoV-2-nucleocapsid-IgG and Omicron-BA.1-specific neutralising serum activity. Cellular immunity was measured by T-cell-specific IFN-y and IL-2 secretion upon SARS-CoV-2-spike-protein stimulation using IFN-y release assay, FluoroSpot- and FACS analysis. All invasive procedures were performed as SOC.

Results: The study has enrolled 49 patients. Antibody responses were measured in all patients after each visit. Anti-spike-IgG levels show a steady incline in most patients following repeated vaccinations and remained stable during follow-up (Figure 1).
With regard to cellular response, preliminary results show an increase in T-cell immune response in most patients following vaccinations. However, CAR-T cell recipients have lower T-cell responses compared to patients after autologous HSCT during the vaccination and follow-up phase.
Two female patients (31 and 55 years old) with an aggressive B-cell lymphoma, who received CAR-T cell therapy, failed to reach an anti-spike-IgG level ≥847 BAU/ml, which was defined as an adequate immune response in this study, after eight vaccine doses. However, in one of these patients T-cell response increased, while antibody levels declined despite repeated vaccinations.

Figure 1 – SARS-CoV-2 antibody titres before vaccination, at the last vaccination visit and during the follow-up phase



Anti-spike-IgG levels were measured by the LIAISON SARS-CoV-2 TrimericS IgG test on the LIAISON XL (DiaSorin, Vicenza, Italia).
BAU = Binding antibody units, FU = Follow-Up

Conclusions: Our preliminary findings show a boosted B-cell response following repeated vaccinations in most patients. However, even with minimal antibody response, T-cell response may still offer protection. Results will be used to optimize vaccination and booster schedules for immunocompromised patients and to increase rates of protection against severe COVID-19. Further, results may identify risk and treatment factors leading to low immune responses in immunocompromised patients vaccinated against COVID-19, as well as the impact of repeated vaccinations on B-cell and T-cell responses.

IMPACT OF EBV-DRIVEN POST-TRANSPLANT LYMPHOPROLIFERATIVE DISEASE (EBV-PTLD) ON DONOR T-CELL CHIMERISM IN ALLOGRAFT RECIPIENTS RECEIVING THYMOGLOBULIN AS GVHD PROPHYLAXIS

[1]*Oxford University Hospital, Oxford, United Kingdom of Great Britain and Northern Ireland (the),* [2]*Royal Adelaide Hospital, Adelaide, Australia,* [3]*Westmead Hospital, Sydney, Australia,* [4]*Royal Melbourne Hospital, Melbourne, Australia,* [5]*Royal Prince Alfred Hospital, Sydney, Australia,* [6]*Royal North Shore Hospital, Sydney, Australia,* [7]*Fiona Stanley Hospital, Perth, Australia,* [8]*Austin Hospital, Melbourne, Australia*

Background: EBV-PTLD is a well-recognized complication of allogeneic transplant when thymoglobulin is used for GVHD prophylaxis. A single case report described T-cell chimerism loss in this context (Guo et al., World J Radiol 2024). We investigated the association between PTLD and donor T-cell chimerism in a large cohort.

Methods: We analysed 405 patients who underwent allograft from matched sibling (n=37), matched unrelated (n=364), or mismatched (n=4) donors between 2015–2023. GVHD prophylaxis consisted of thymoglobulin 4.5 mg/kg in divided doses (days −3 to −1), predominantly with methotrexate and cyclosporine (n=395). Myeloablative conditioning (MAC) was used in 105 (25%). $CD3^+$ chimerism was measured using short tandem repeat analysis and categorised as complete (100%), near-complete (95–100%), mixed (51–94%), or predominant recipient (<50%). PTLD was diagnosed according to WHO criteria. Comparisons were made between D30 and D100 CD3 chimerism, with D60 substituted where D30 data were missing. Severe, moderate and minor chimerism loss were defined as ≥50%, 20–50% and 10–20% respectively. Clinically significant EBV reactivation (csEBVR) was defined as requiring intervention: reduction in immunosuppression and/or rituximab.

Results:

Chimerism (%): median(IQR)	No EBV (n=125)	csEBV(n=144)	PTLD (n=61)	p-value
$CD3^+$baseline	100 (98-100)	100 (98-100)	100 (99-100)	0.45
$CD3^+$day 100	99(95-100)	98(90-100)	96(75-100)	0.89
Severe loss (≥50%), n (%)	5(4)	8(5)	10(16)	0.009
Moderate loss (20-50%), n (%)	6(5)	17(12)	5(8)	.084

Minor Loss (10-20%), n(%)	12(11)	9(7)	5(9)	0.419
$CD3^-$ day 100**:** **data** available in 110	100(99-100)	100(98-100)	100(98-100)	0.89

csEBVR occurred in 161 patients (40%), managed with immunosuppression reduction alone (n=54) and/or rituximab (n=107). Of these, 70 developed PTLD (43%) at a median of 47 days post-allograft (IQR 36–64). Diagnosis was by CT (n=15) or PET (n=55), with biopsy confirmation in 36 cases (51%). Treatment comprised immunosuppression reduction plus rituximab (n=68) or chemotherapy (n=4). PTLD resolved in 68 patients; two died (one PTLD, one respiratory failure).
Serial $CD3^+$ chimerism data were available in 330 patients, including 61 with PTLD. Severe, moderate and minor $CD3^+$ chimerism loss occurred in 26 (7%), 29 (8%) and 23 (7%) patients, respectively. Patients were stratified into no csEBVR (n=126), csEBVR without PTLD (n=145), and PTLD (n=61). Severe chimerism loss occurred in 4%, 5.5% and 16.4%, respectively (p=0.009), with a similar trend for moderate loss (4.8%, 12.4%, and 24.6%:p=0.084): no difference in minor loss (table 1).
$CD3^-$ chimerism (available in 110/329 cases) remained stable with median day-100 chimerism of 100% in patients with (n = 36: IQR 98-100) and without (n=74: IQR 99-100%) PTLD. In all but one patient $CD3^-$ chimerism remained above 80%; the outlying patient had moderate $CD3^+$chimerism loss and developed secondary graft failure.
In multivariable logistic regression adjusting for age, conditioning intensity, and diagnosis, PTLD remained independently associated with severe (OR 3.74, 95% CI 1.41–8.84, p=0.007) and moderate chimerism loss (OR 2.04, 95% CI 1.00–4.15, p=0.048). After adjustment for age, conditioning regimen, and diagnosis, survival analysis showed that <50% donor $CD3^+$ chimerism conferred increased mortality (adjusted HR 2.31, 95% CI 1.27–4.21, p=0.006), while PTLD was not independently associated with mortality after chimerism adjustment (HR 1.37, p=0.210).

Conclusions: EBV-driven PTLD is independently associated with loss of donor T cell engraftment, conferring four times the risk of major chimerism loss. While the causal mechanism remains unclear, subsequent $CD3^+$ chimerism status—rather than PTLD itself—is a strong independent predictor of survival. These findings highlight the critical importance of intensive chimerism monitoring in EBV-driven PTLD post allograft

LOW T-CELL RESPONSES TO PHYTOHEMAGGLUTININ ARE ASSOCIATED WITH INCREASED RELAPSE AND MORTALITY AT 1-YEAR POST-CAR-T CELL THERAPY

Francesco Peracchi[1,2,3], *Hu Xie*[3], *Mandeep K. Sekhon*[3], *Julian Munoz*[3], *Molly Briggs*[3], *Wendy Leisenring*[3], *Mazyar Shadman*[3,4], *Terry L. Stevens-Ayers*[3], *Michael J. Boeckh*[3,4], *Eleftheria Kampouri*[5], *Joshua A. Hill*[3,4]
[1]*University of Milano-Bicocca, Milan, Italy,* [2]*University of Milan, Milan, Italy,* [3]*Fred Hutchinson Cancer Center, Seattle, United States of America (the),* [4]*University of Washington, Seattle, United States of America (the),* [5]*Lausanne University Hospital and University of Lausanne, Lausanne, Switzerland*

Background: T-cell responses to phytohemagglutinin (PHA), a polyclonal activator used as positive control in interferon-γ (IFN-γ) release assays, provide an accessible measure of global T-cell function. Low or indeterminate PHA-induced IFN-γ responses in the QuantiFERON TB assay have been associated with reduced overall survival, higher non-relapse mortality, and worse outcomes in hematopoietic cell transplant recipients. Assessing T-cell function in chimeric antigen receptor (CAR)-T cell therapy (CARTx) recipients could serve as a global marker of T cell activity and immune competence to identify patients at high risk for adverse outcomes.

Methods: We prospectively enrolled adult CMV-seropositive patients treated with CD19, CD20, or BCMA-targeted CARTx for hematologic malignancies at Fred Hutch Cancer Center from August 2021 through March 2023. We assessed CMV cell-mediated immunity using an IFN-γ release assay (T-SPOT®.CMV) pre- and at week 2 and 4 post-CARTx. T-cell responses to PHA were quantified. A low PHA value at two weeks post CARTx was defined as below the median value of the cohort (185 spot counts) and indeterminate responses as those that fail the positive control. Cox regression was used to assess the association of PHA T-cell responses and other clinically relevant variables (included in Table 1) with 1-year disease relapse and overall mortality. Data on CAR-T cell expansion, including peak PCR values and persistence, were collected when available (n=23) and compared by PHA category (high versus low) at week 2 post-CARTx

Results: 89 patients were enrolled; demographic and clinical characteristics are summarized in Table 1. Disease relapse occurred in 35% (n=31) of patients, and 27% (n=24) died within 1 year. Low and indeterminate PHA T-cell responses (combined) at week 2 post-CARTx were associated with lower peak and persistence of CAR-T cells (Figure 1A-B). Concordant with this observation, low and indeterminate PHA T-cell responses at week 2 post-CARTx were independently associated with increased disease relapse (low PHA: adjusted hazard ratio [aHR], 5.22; 95% confidence interval [CI], 1.98-13.8; p<0.001; indeterminate PHA: aHR, 4.45; 95% CI, 1.48-13.4; p=0.01, respectively). Low PHA T-cell responses at week 4 post-

CARTx remained significantly associated with an increased risk of overall mortality (aHR 3.14; 95% CI, 1.11-8.90; p= 0.003), in addition to the use of corticosteroids for >3 days (aHR, 7.14; 95% CI, 1.96-26.0; p=0.003).

Table 1. Demographic and clinical characteristics of the included patients

Characteristic	Total (N=89)
Age at time of CARTx (years), median (IQR)	65.0 (57.0-71.0)
Female sex, n (%)	40 (45%)
Underlying hematologic malignancy, n (%)	
ALL	3 (3%)
CLL	4 (4%)
Lymphoma	60 (67%)
Multiple Myeloma	19 (21%)
Waldenstrom macroglobulinemia	3 (3%)
Number of prior chemo treatment regimens ≥6, n (%)	24 (27%)
CARTx target, n (%)	
BCMA	19 (21%)
CD19/CD20	70 (79%)
CAR-HEMATOTOX score ≥2, n (%)	29 (33%)
PHA at 2-week post infusion, Median (IQR)	237.0 (110.0-456.0)
PHA at 4-week post infusion, median (IQR)	448.0 (238.0-554.0)
Any steroid use >3 days after day 14, n (%)	7 (8%)
ALC value at 2-week post infusion, median (IQR)	450.0 (260.0-910.0)
Maximum ICANS grade≥2 or CRS grade≥2, n (%)	42 (47%)

Characteristic	Total (N=89)
High risk disease for relapse/progression post CART infusion, n (%)	27 (30%)

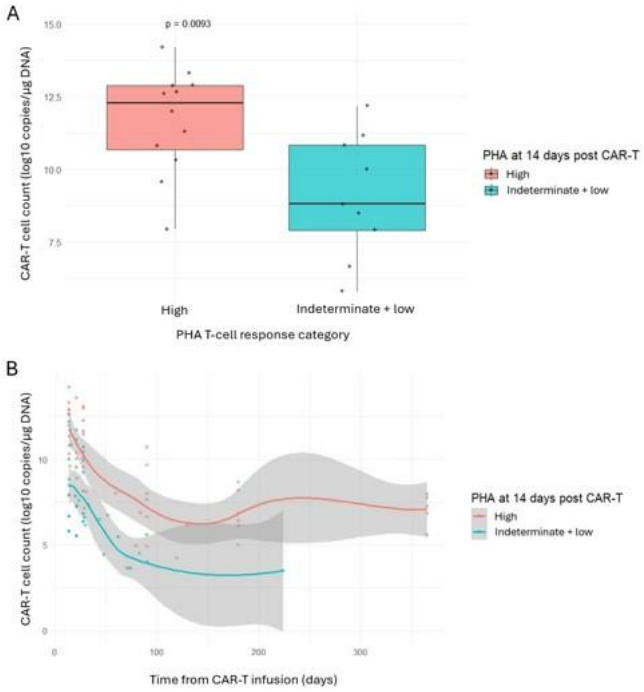

Figure 1. *A)* Distribution of peak CAR-T cell counts (log_{10}) according to PHA response at 14 days post-CARTx. *B)* CAR-T cell counts kinetics from day 14 through 1 year after CARTx, stratified by PHA response at 14 days post-CARTx. In both panels, the 'Indeterminate+low' category includes participants with values below the median (n=8) in addition to indeterminate responses (n=1) at week 2 post-CARTx.

Conclusions: PHA T-cell responses could represent a promising and accessible marker of T-cell function, correlating with CARTx efficacy, disease response, and survival. Low PHA responses following CARTx identify patients at higher risk of disease relapse and mortality, highlighting their potential as an early biomarker of impaired global T-cell function.

Background: Findings of retrospective studies suggested that cytomegalovirus (CMV)-specific cell-mediated immunity (CMV-CMI) might reduce clinically significant CMV infections (cs-CMVi) after letermovir withdrawn in allogeneic hematopoietic stem cell transplantation (allo-HCT). In this study, we aimed to evaluate the efficacy and safety of CMV-CMI guided letermovir prophylaxis for decreasing the late-onset cs-CMVi in patients following allo-HCT.

Methods: We conducted an open-label, randomized phase 3 trial at seven transplantation centers in China. Eligible patients (aged 18–70 years) underwent their first allo-HCT and received letermovir for CMV prophylaxis were enrolled. Randomization was performed using an electronic data capture (EDC) system with a stratified randomization ratio of 1:1, based on patient age and transplantation type at the transplantation day. The participants were divided into two groups: the CMV-CMI guided group (n=125), where letermovir was discontinued after achieving the CMV-CMI recovery, with a maximum treatment duration of 270 days post-transplantation; and the fixed-duration group (n=125), where letermovir was discontinued at day 100 after allo-HCT. Letermovir was given orally or intravenously at a dose of 480 mg daily from day 1, or 240 mg daily when in conjunction with cyclosporine A. CMV-CMI was evaluated with CMV-ELISPOT at at the 3rd, 5th, 6th, and 9th month post-HCT. The primary endpoint of this study was the cumulative incidence of late-onset cs-CMVi after letermovir withdrawal. This study was registered with ClinicalTrials.gov, NCT06449586, and is complete.

Results: Between July 2024 and May 2025, 250 patients were randomly assigned to the CMV-CMI guided group (n=125) or the fixed duration group (n=125). Median follow-up was 355 days (IQR 283, 436). The median age of the cohort was 42 (IQR 32, 54) years old, and 80.5% of the recipients received haploidentical related donor (HID) grafts were included in the study. The primary endpoint, cumulative incidence of late-onset cs-CMVi after letermovir withdrawal was significantly lower in the CMV-CMI guided group (9.2% [95% *CI:* 4.6%–

16.0%]) compared to the fixed duration group (26.7% [95% *CI:* 18.8%–35.2%], *P*=0.002) within the first year after allo-HCT. Additionally, the cumulative incidence of cs-CMVi within the first year after allo-HCT was also lower in the CMV-CMI guided group (13.0% [95% *CI:* 7.6%–19.9%]) compared to the fixed duration group (26.7% [95% *CI:* 19.0%–35.0%], *P*=0.02). In the multivariate analysis, reduced intensity conditioning (HR 2.97, 1.25–7.03; *P*=0.01) was a risk factor for late-onset cs-CMVi. Conversely, CMV-CMI guided strategy (HR 0.43, 0.21–0.88; *P*=0.02) was a protective factor against late-onset cs-CMVi. The most common adverse events among participants in the CMV-CMI guided group versus the fixed duration group were acute graft versus host disease (20 [16.9%] *vs*. 28 [23.7%]), poor appetite (14 [11.6%] *vs*. 18 [15.2%]) and EBV reaction (15 [12.7%] *vs*. 14 [11.8%]). There were no treatment-related deaths.

Conclusions: The CMV-CMI-guided strategy of letermovir use for CMV prophylaxis after allo-HCT is effective and safe in reducing the cumulative incidence of late-onset cs-CMVi after letermovir withdrawal.

PREDICTORS OF PROTECTIVE ANTIBODY LEVELS IN ALLOGENEIC HCT RECIPIENTS FOLLOWING A STANDARDIZED POST-TRANSPLANT VACCINATION SERIES INCLUDING TWO DOSES OF MMR

Kareem Jamani[1], *Megan Kinzel*[1], *Carmen Charlton*[2], *Faisal Khan*[1], *Poonam Dharmani-Khan*[1], *Jan Storek*[1]
[1]*University of Calgary, Calgary, Canada,* [2]*University of Alberta, Edmonton, Canada*

Background: Without vaccination, levels of antibodies against vaccine-preventable diseases decline after allo-HCT so that by 1-5 years after HCT, a substantial fraction of patients have the specific antibody levels undetectable or under the limit for protection. For measles, it is known that <80% achieve protective levels after one MMR dose. Little is known about the factors influencing the likelihood of achieving protective antibody levels after routine post-HCT vaccination, which in Alberta includes two doses of MMR, and whether the immunity achieved by the vaccination is durable and reaches the immunity of the general population.

Methods: Antibody levels to measles, hepatitis B and tetanus were measured before allo-HCT, and at 3 and 5 years after allo-HCT in recipients receiving a uniform vaccination series that included 2 doses of the MMR vaccine, 3 doses of the hepatitis B vaccine and 3 doses of a

tetanus containing vaccine, with the entire series typically completed by 2.5 years post-transplant. Donor antibody levels were measured at the time of donation. Univariable and multivariable analyses were undertaken to elucidate predictors of non-protective antibody levels in recipients.

Results: *Measles*
At 3 years post-transplant, 178 of 196 recipients (91%) had protective antibody levels versus 67 of 81 donors (83%) at the time of donation (p=0.06). Antibody levels were durable with 49 of 53 (92%) recipients with available levels at 5 years remaining with protective levels. In univariable analyses, non-protective antibody levels at 3 years post-transplant was associated with donor age <50 (i.e. born after 1970) (p=0.02), lower IgG levels at 6 months post-transplant (p=0.05), and possibly non-protective antibody levels in donors (p=0.06).
Hepatitis B
At 3 years post-transplant, 149 of 198 recipients (75%) had protective antibody levels versus 44 of 89 donors (49%) at the time of donation (p <0.01). Antibody levels were somewhat durable with 45 of 65 (69%) recipients with available levels at 5 years remaining with protective levels. In multivariable analyses, non-protective antibody levels at 3 years post-transplant was associated with receipt of immunosuppression beyond 1-year post-transplant (OR 0.21, p=0.02), recipient age >50 (OR 0.24, p=0.04), and possibly non-protective donor antibodies (OR 0.31, p=0.07).
Tetanus
At 3 years post-transplant, 226 of 259 recipients (87%) had protective antibody levels versus 93 of 109 donors (85%) at the time of donation (p=0.62). Antibody levels were somewhat durable with 57 of 76 (75%) recipients with available levels at 5 years remaining with protective levels. In multivariable analyses, non-protective antibody levels at 3 years post-transplant was associated with receipt of immunosuppression beyond 1-year post-transplant (OR 0.03, p<0.01) and receipt of rituximab in the first-year post-transplant (OR 0.05, p=0.03).

Conclusions: After 2 doses of MMR vaccination, 91% of allo-HCT recipients experience protective antibody levels against measles, with the proportion protected exceeding the proportion of donors protected. Protective antibody levels to measles at 3 years appear to be durable to at least 5 years post-transplant. Donors with probable natural immunity to measles through exposure (born before 1970) are associated with protective antibody levels in recipients.

Background: With the improved life expectancy of people living with HIV (PLWH), the prevalence of hematological diseases and, therefore, the need for hematopoietic cell transplantation (HCT) is increasing. Despite initial reluctance, advance in supportive care has progressively improved HCT outcomes and expanded the number of patients considered eligible, including for allogeneic HCT. Despite these advances, uncertainty remains regarding safety and efficacy of HCT in PLWH with very limited data.

Methods: We retrospectively evaluated outcomes of autologous and allogeneic HCT in adult PLWH and compared them with negative controls in the EBMT registry. PLWH were defined as adults with HIV from EBMT member centres who received their first autologous or allogeneic

HCT between 2010 and 2023 and were HIV-positive at the time of transplant. The primary endpoint was 100-day non-relapse mortality (NRM). Secondary endpoints were 1-year NRM, relapse incidence (RI), progression-free survival (PFS), overall survival (OS), in HIV-positive and negative patients.

Results: Baseline characteristics were well balanced between cases and controls (Table 1). Among HIV-positive patients we identified 159 who underwent autologous HCT and were compared with 21,284 controls. The median age of cases was 48.5 (range 39.9-55.5) years, and 139 (87.4%) were male. Diagnosis was Non-Hodgkin B cell lymphoma in 96 (60.4%), and 87 (54.7%) were in complete remission (CR) at HCT. The conditioning regimen was BEAM in 79 (53.7%). NRM at 100 days was not significantly different among HIV-positive patients and negative controls (2% [95%CI 1-2%] and 3% [95%CI 0-6%], p=0.237). OS was significantly higher for HIV-negative controls than HIV-positive cases (92% [95%CI 92-92%] vs 85% [95%CI 79-92%] at 1 year, p=0.002) (figure 1a). PFS was similar between HIV cases and controls (81% [95%CI 74-89%] vs 80% [95%CI 79-80%] at 1 year, p=0.920).
We identified 52 HIV-positive adults who underwent allogeneic HCT and compared them with 16,211 controls. The median age was 44.1 (36.4-55) years and 36 (69.2%) were male. Diagnosis was acute myeloid leukemia in 21 (40.4%) and 38 (73.1%) underwent allogeneic HCT in CR. Myeloablative conditioning was used in 30 (57.7%) and graft source was peripheral blood in 44 (84.6%). The most frequent donor type was a matched unrelated donor in 16 (30.8%). The 100-day NRM did not differ significantly between groups (9% [95%CI 8-9%] for controls and 12% [95%CI 3-21%] for cases, p=0.776). One-year OS was also similar between HIV-positive patients and negative controls (68% [95%CI 54-81%] vs 68% [95%CI 68-69%], p=0.620) (figure 1b). PFS and RI were also not significantly different between the two groups.

	GROUP	control auto-HCT	case auto-HCT	control allo-HCT	case allo-HCT
		21284	159	16211	52
Patient sex	male female	12610 (59.2%) 8674 (40.8%)	139 (87.4%) 20 (12.6%)	9067 (55.9%9 7144 (44.1%)	36 (69.2%9 16 (30.8%)
Age at HCT (years)	median (IQR)	57.9 (49.1-64)	48.5 (39.9-55.5)	50.9 (37-60.8)	44.1 (36.4-55)
Disease	acute leukemia multiple myeloma lymphoma MDS/MPN	11347 (53.3%) 9937 (46.7%)	17 (10.7%) 142 (89.3%)	12879 (79.4%) 751 (4.6%) 2581 (15.9%)	31 (59.6%) 13 (25%) 8 (15.4%)

Disease status at HCT	complete remission other	8240 (38.7%) 13044 (61.3%)	87 (54.7%) 72 (45.3%)	12706 (78.4%) 3505 (21.6%)	38 (73.1%) 14 (26.9%)
conditioning (alloHCT)	RIC MAC			6716 (42.2%9 9210 (57.8%)	22 (42.3%9 30 (57.7%)
conditioning (autoHCT)	BEAM other	6380 (34.4%) 12168 (65.6%)	79 (53.7%) 68 (46.3%)		

Conclusions: This is one of the largest reported series of HCT for PLWH. We observed a modestly lower OS for autologous HCT in the HIV group though rates remained acceptable. No differences were detected in any other outcomes. Overall, these findings support the inclusion of carefully selected HIV-positive patients in standard transplant pathways for both autologous and allogeneic HCT, highlighting the need for continued data collection and reinforcing that HIV infection is no longer a contraindication to HCT.

Background: Pritelivir is a novel oral helicase-primase inhibitor, active against HSV-1 and HSV-2, including strains resistant to nucleoside analogues and foscarnet. PRIOH-1 evaluated the safety and efficacy of pritelivir vs. investigator's choice therapy (ICT) in immunocompromised (IC) patients with refractory herpes simplex virus (HSV) infection, with or without resistance (R±R).

Methods: In this randomized (1:1), controlled, open label trial, 101 IC patients (≥16 years) with R±R HSV mucocutaneous infection received oral pritelivir (100 mg daily; 400 mg loading dose) or ICT (IV foscarnet, IV/topical cidofovir, or topical imiquimod) for up to 28 days, extendable to 42 days. Eligibility criteria included hematopoietic cell transplant, solid organ transplant, HIV, malignancy, or chronic use of immunosuppressive treatment with refractory/clinical failure (defined as no clinical improvement of lesions after ≥7 days of standard of care nucleoside analogue therapy or confirmed acyclovir resistance). The primary endpoint was complete lesion healing within 28 days. Secondary endpoints included safety and tolerability.

Results: The mean age of patients was 52.6 years (range 19-84 years) and 52.5% were male. Refractory HSV was diagnosed in 71.3%, and acyclovir resistant infection in 28.7%. HSV-1 and HSV-2 were identified in 31.7% and 45.5% of patients, respectively. Immunocompromised conditions included transplant (43.6%), oncology and other indications (including autoimmune, primary immunodeficiency disorders, and use of chronic immunosuppressive agents) (33.7%), and HIV infection (22.8%). Pritelivir demonstrated superior lesion healing of 62.7% vs. 34.0% for ICT up to 28 days, resulting in an adjusted treatment difference of 28.4%, p=0.0047 [95% CI: 9.6, 47.3] (Fig.1). The most common TEAEs are presented in Table 1. The majority of events are lower for pritelivir vs. ICT. Pritelivir was associated with fewer renal, electrolyte events and drug-related TEAE discontinuations (2.0%) compared with ICT (20.0%).

Conclusions: Pritelivir met the Phase 3 primary endpoint, demonstrating statistically superior efficacy compared with ICT, with a favorable safety and tolerability profile. These findings support pritelivir as a promising oral agent to address the unmet needs of refractory HSV infections in IC patients.

Figure 1 Summary of lesion healing rate: primary efficacy endpoint (28 days)

Background: Letermovir is widely used in adult allogeneic haematopoietic stem cell transplantation (HSCT) for CMV prophylaxis and has recently been authorised for paediatric use. However, data remain limited for children under 12 years treated in real-world settings. We report outcomes of letermovir prophylaxis in a large multicentre paediatric HSCT cohort.

Methods: We performed an updated multicentre retrospective analysis (2019–2025) within the PDWP and IEWP of the EBMT. A total of 146 HSCT recipients under 12 years (median age 7.2 years; range 0.1–11.9) received letermovir as primary (n=115) or secondary (n=31) prophylaxis (Table 1). Letermovir was administered orally (82.2%), intravenously (13.7%), or via both routes (4.1%). Conditioning regimens included treosulfan-based (44.5%), TBI-based (32.2%), busulfan-based (15.1%), and other (8.2%). In-vivo T-cell depletion (TCD) was used in 34.2% of patients (ATG 27.4%, Campath 6.8%), and ex-vivo TCD in 11.6%.

Table 1: Patient and transplant characteristics

Characteristics	Primary prophylaxis N = 115	Secondary prophylaxis N = 31	Overall N = 146

Unknown	4	3	7

Results: With a median follow-up of 1 year (95% CI: 0.9–1.1), the 1-year cumulative incidence of CMV reactivation was 23.8% (95% CI: 16–30) overall, 21.4% (95% CI: 13.6–29.2) during primary prophylaxis, and 32.6% (95% CI: 13.1–45) during secondary prophylaxis (Figure 1). One-year overall survival was 87.3% (95% CI: 79.5–92.2), with comparable outcomes between primary 88.2% (95% CI: 79.5–93.4) and secondary 83.9% (95% CI: 61.9–93.8) prophylaxis.

Among CMV-seropositive recipients with seronegative donors (n=56), CMV reactivation occurred more frequently than in seropositive donor-recipient pairs (32.1% versus 17.8%). In the seropositive recipient with seronegative donors group, seven patients died without prior CMV-reactivation (1-year incidence 13.3% [95% CI: 5.1–25.4]). Among the patients with seropositive donors (n=82), 14 patients experienced CMV reactivation (17.8% [95% CI: 10.2–27]) and 7 died without reactivation (9.1% [95% CI: 3.6–17.7]).

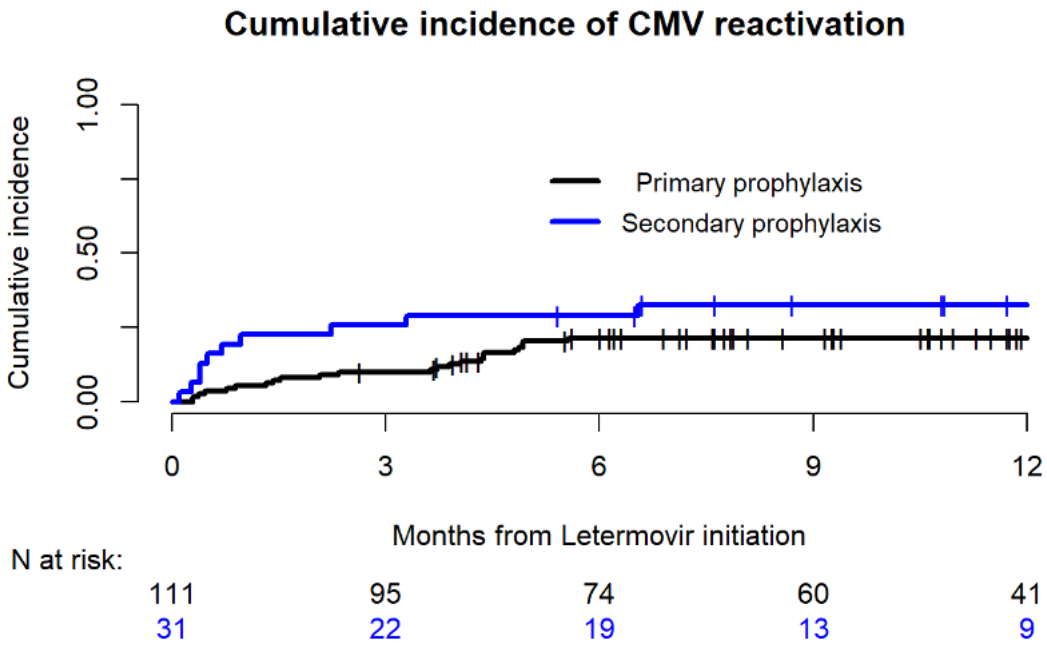
Of the 17 CMV-seronegative patients, two received grafts from CMV-negative donors and letermovir as secondary prophylaxis; both are alive at last follow-up, one with and one without CMV reactivation.

Causes of death included relapse (5), non-CMV infections (3), GvHD (2), hypovolaemic shock (1), pulmonary vascular event (2), and veno-occlusive disease (1). Among patients with CMV reactivation, one death was attributed to relapsed disease.

Letermovir was well tolerated with only two patients experiencing mild gastrointestinal toxicity, and no additional significant adverse events reported.

CMV reactivations were managed using standard antiviral strategies, including valganciclovir (n=10), ganciclovir (n=8), foscarnet (n=7), and cidofovir (n=1) or continued letermovir alone (n=8). All but one patient achieved complete viral clearance by end of follow-up. There were no CMV-related deaths in the cohort.

Figure 1: Cumulative incidence of CMV reactivation



Conclusions: In this large real-world pediatric HSCT cohort in children under 12 years of age, letermovir demonstrated high efficacy and excellent tolerability in both primary and secondary prophylaxis. Breakthrough reactivations were infrequent and generally manageable, supporting routine use of letermovir in paediatric HSCT recipients.

Clinical Trial Registry: Not applicable.

Background: CMV is among the most frequent infections early after CAR-T therapy, but only incidental CMV disease cases have been reported. The impact of CMV on non-relapse mortality (NRM) and survival after CAR-T treatment is largely unexplored.

Methods: In this registry-based study, we analysed CMV infection (CMVi) (defined as a positive CMV-PCR) in adult patients with lymphoma who received their first CAR-T infusion between 2019-2024, and in whom at least one CMV-PCR test was performed after CAR-T infusion and the result reported as negative or positive. CMV-PCR monitoring was not standardized across centers, and testing frequency was heterogeneous and center-dependent . The primary endpoint was the impact of CMVi on NRM at 1 year after CAR-T. Because most CMVi occur early, a 50-day landmark analysis was performed, comparing outcomes between patients who developed CMVi by day 50 and those who did not.

Results: 1,429 patients were reported from 22 countries. Baseline characteristics are shown in Table 1.
A CMVi developed in 205 patients, with a median time of 23 days after CAR-T (min-max:0-1282). 73% occurred ≤ 50 days after CAR-T. The cumulative incidence at 100 days was 10% (95%CI 9-12%), higher in CMV seropositive than in seronegative patients (19% (95%CI 15-23%) vs 1% (95%CI 0-3%), p<.001).
The NRM at 1 year was 8% (95%CI 7-10%) for all patients, and 11% (95%CI 6-17%) for those with CMVi. In the Cox model, CMVi was associated with higher NRM (HR 2.51, 95%CI 1.56, 4.01; p <.001) (Figure 1).
In the Kaplan-Meier(KM) landmark analysis at 50 days, the overall survival(OS) at 1 year was significantly lower in those with vs without CMVi (62% (95%CI 52-71%) vs 74% (95%CI 71-76%) p=.003). In the Cox model, CMVi was associated with lower survival (HR 2.11; 95%CI 1.65,2.70; p<.001), as were male sex (HR 1.29; 95%CI 1.07,1.55; p=.0008), relapse/progression at CAR-T (HR 1.59; 95%CI 1.30,1.94; p<.001), ECOG ≥2 (HR 2.68; 95%CI 2.05,3.51; p<.001), and year of CAR-T (lower for 2023-2024 (HR 1.46, 1.67) vs 2019-2020; p<0.03).
In the KM landmark analysis at 50 days, the relapse/progression rate at 1 year was no different in those with vs without CMVi (36% vs 37%, p .75). In the Cox model, CMVi was associated with higher risk of relapse/progression (HR 1.36; 95% CI 1.01-1.84; p=.043), as were male sex (HR 1.23;p=.021), relapse/progression at CAR-T (HR 1.71;p<.001), ECOG ≥2 (HR 1.81;p<.001), use of tisagenlecleucel(Kymriah®) (HR 1.37;p=.006), and year of CAR-T infusion (higher for 2022-2024 (HR 1.92, 2.60, 3.35) vs 2019-2020, p<.001).
In a Cox model landmark analysis at 50 days, CMVi was associated with a significantly lower OS at 1 year (HR 1.43; 95%CI 1.04,1.96, p=.026) but did not significantly affect NRM (HR 1.43 95%CI 0.78,2.63, p=.2) or relapse/progression (HR 1.0; 95%CI 0.71,1.41; p>.9).

Conclusions: In this large series of lymphoma patients treated with CAR-T, CMVi was associated with a significantly higher NRM, relapse/progression and lower OS at 1 year after CAR-T infusion. In the 50-day landmark analysis, CMVi continued to adversely affect OS, although its impact on NRM and relapse/progression was no longer significant.

Background: Cytomegalovirus (CMV) infection and disease remain major causes of morbidity and mortality among immunocompromised patients, and limited existing treatment options are either associated with renal or bone marrow toxicities or can rapidly select for resistance. Brincidofovir (BCV) is a lipid conjugate of cidofovir that overcomes cidofovir's dose-limiting nephrotoxicity while enhancing antiviral activity against CMV and other double-stranded DNA viruses. Here, we report data from CMV Cohorts of the Phase 2a ATHENA study (BCV-PA01: NCT04706923) that evaluated multiple ascending doses of intravenous (IV) BCV for safety, tolerability and antiviral activity against adenovirus or CMV.

Methods: Eligible immunocompromised patients ≥2 months of age with CMV plasma levels ≥ 500 IU/ mL, with or without evidence of tissue invasive CMV disease, were enrolled. Dosing consisted of IV BCV 0.4 mg/kg twice weekly (BIW; max 20 mg) in Cohort A and 0.5 mg/kg BIW (max 25 mg) in Cohort B for ≤14 weeks. Treatment emergent and treatment related adverse events (TEAEs/TRAEs) and virologic response (measured as change in plasma CMV DNAemia) were assessed throughout the study. CMV was quantified weekly using the Eurofins CMV qPCR (plasma) 5500 assay with a limit of quantitation (LOQ) of 96 IU/mL (2.0$\log_{10}$).

Results: Of 19 treated patients (primarily hematopoietic cell transplant recipients), 18 (9 in each Cohort) received more than one dose of BCV and were evaluated for virologic response. Most patients (7/9 per Cohort) had failed ≥1 prior CMV antiviral (n=12 GCV or valGCV, 4 foscarnet, 4 letermovir, and 2 maribavir). Mean baseline CMV DNAemia was 3.99 $\log_{10}$ IU/mL in Cohort A and 3.39 $\log_{10}$ IU/mL in Cohort B. Most patients in Cohort A (8/9) and Cohort B (6/9) received 4 weeks of treatment with BCV. At this timepoint, CMV DNAemia decreased to <LOQ for 2/9 (22%) and 5/9 (56%) subjects in Cohort A and B, respectively. This difference is likely influenced by higher baseline viral load in Cohort A as the mean decline in CMV DNAemia was approximately 1.3 $\log_{10}$ IU/mL for both cohorts (Figure 1). Within 8 weeks, CMV DNAemia decreased to <LOQ for 4/9 (44%) and 8/9 (89%) subjects in Cohort A and B,

respectively. The average decrease in CMV DNAemia after 8 weeks was -1.67 log_{10} IU/mL in Cohort A and -1.80 log_{10} IU/mL in Cohort B (Figure1). As expected for this population, TEAEs were common (Table 1), and possible drug related AEs included mild diarrhea (1 in Cohort A and 1 in Cohort B), liver enzyme elevations (2 in Cohort B), and an allergic reaction (1 Cohort B). There were two deaths in Cohort A, both considered unrelated to IV BCV.

Figure 1. Plasma CMV (DNA log IU/mL) Change from Baseline

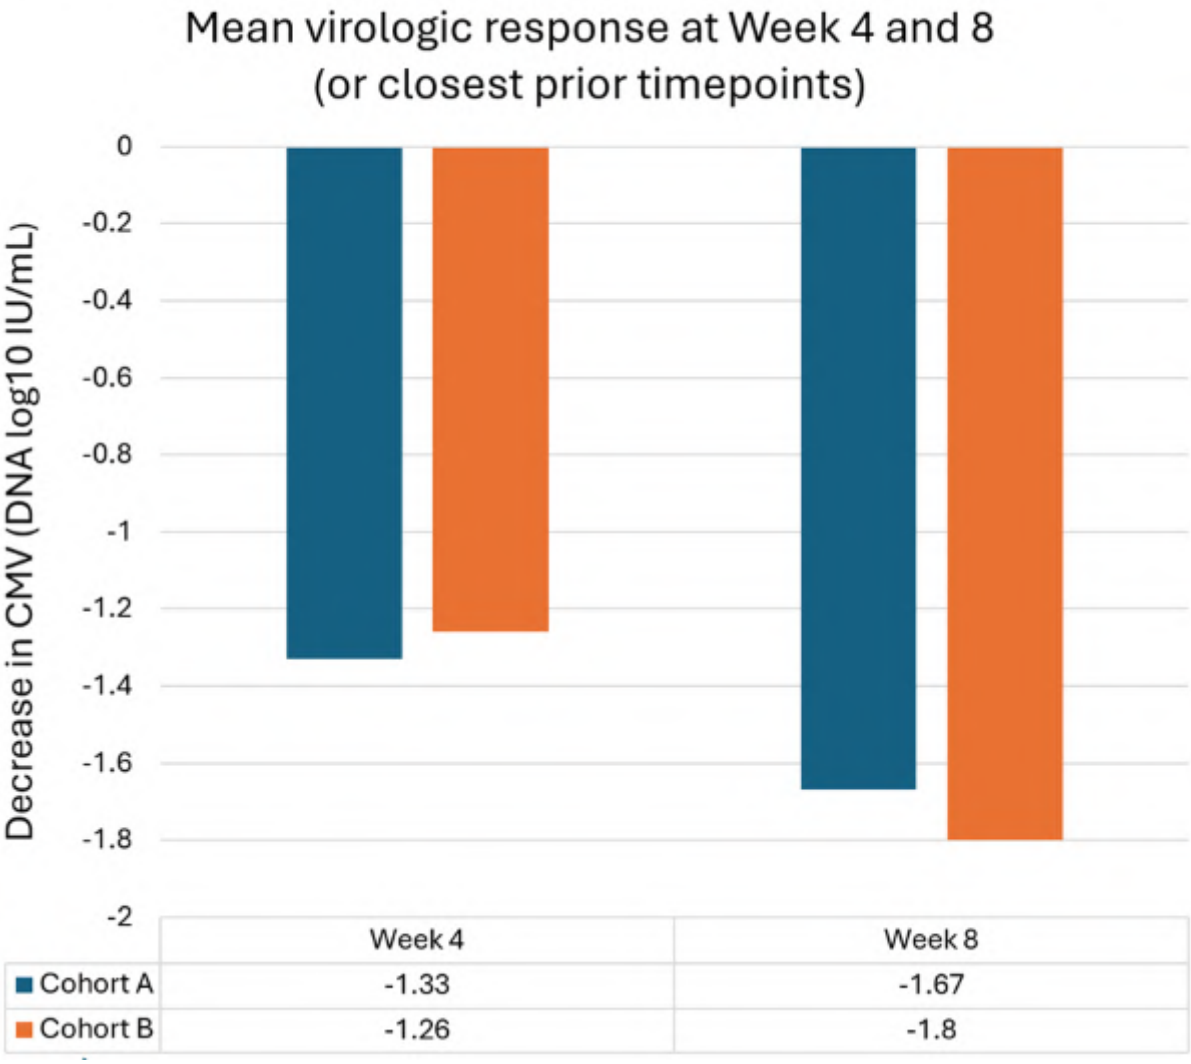

Table 1. Treatment Emergent Adverse Events

	Cohort A – 0.4 mg/kg BIW n=9 (%)	Cohort B – 0.5 mg/kg BIW n=10 (%)

Table 1. Treatment Emergent Adverse Events

TEAEs, Total	7 (77.7%)	7 (70%)
TRAEs	3 (33%)	5 (50%)
Serious TEAE (SAEs)	1 (11.1%)	6 (60%)
Treatment Related SAE	0	1 (10%)*
TEAEs leading to discontinuation	1 (11.1%)	6 (60%)
Drug Related TEAEs leading to discontinuation	1 (11.1%)	4 (40%)
Death	2 (22.2%)	0
		*Allergic Reaction

Conclusions: IV BCV was effective in reducing CMV DNAemia and was reasonably well tolerated in this population of pre-treated immunocompromised patients with CMV viremia. IV BCV is a potential treatment option for these patients with limited treatment options. These data support further study of IV BCV for treatment of CMV infections in immunocompromised patients.

Clinical Trial Registry: Clintrials.gov NCT04706923

Disclosure: Fareed Khawaja, Genovefa Papanicolaou, Michael Grimley, Carlos Gomez, Kris Mahadeo, Caitlin Elgarten, Gabriela Maron, and Roy Chemaly served as clinical investigators on NCT04706923. Roy Chemaly also serves as an advisor to Symbio. Randall Lanier, Inger Nielsen-Orzeck, Rochelle Maher, and Nkechi Azie were employed by Symbio during the conduct of NCT04706923.

Background: Despite letermovir prophylaxis, refractory or resistant (R/R) Cytomegalovirus (CMV) infections occur. Maribavir (MBV) was approved in Europe in November 2022 for the treatment of R/R CMV in adults who undergone allogeneic hematopoietic stem cell (allo-HCT) or solid organ transplantation, but real-world data in allo-HCT recipients remain scarce.

Methods: We conducted a retrospective multicenter study in EBMT centers, including adult and pediatric allo-HCT recipients who received MBV for CMV infection or disease after its approval in Europe (including off-label use). Compassionate use was excluded. The primary endpoint was clinical outcome after MBV initiation; secondary endpoints included reasons for discontinuation, overall survival (OS), and non-relapse mortality (NRM) at 12 weeks.

Results: One hundred six adults and 9 pediatric patients were included. Eight patients had more than one MBV course for a total of 123 MBV courses with a median duration of 7.8 (min-max 0.6-26.6) weeks. Acute leukemia was the most common disease (n=61, 53%) and most of the patients underwent a haploidentical HCT (n=41, 36%). The graft-versus-host disease prophylaxis was post-transplant cyclophosphamide-based in 63 (55%); 60 (52%) had received prophylaxis with letermovir. Treatment with MBV was given as: first line pre-emptive (PET) in 24 (20%), second line PET in 60 (49%), third or more line PET in 22 (18%), first line treatment for CMV disease in 1 (1%), second line in 6 (5%) and third line or more in 10 (8%) courses. A test for resistance before starting MBV was reported for 8 courses. Mutations identified were: UL54 in one, UL54 and UL97 in two, UL56 in two, UL97 in two, and UL56 + UL97 in another one.
Among the 106 PET courses, 87 (83%) had CMV resolution, 11 (10%) progressed on MBV, 6 (6%) had response and rebound, and in 2 cases (1%) response was not evaluable due to

death or lost to follow-up. A CMV viremia requiring antiviral treatment within 12 weeks from MBV initiation was observed in 17 courses. In 5 cases a CMV end organ disease (EOD) developed. One patient had a proven CMV pneumonia, two had proven CMV gastrointestinal disease (GID), one had a probable CMV retinitis and another had a probable CMV encephalitis.
Among the 17 courses given for CMV disease, all were proven: 12 patients had CMV GID, two had a CMV GID and pneumonia, one had a pneumonia, in one case a CMV skin disease (biopsy-proven), and in one case a combination of CMV cystitis, GID, hepatitis and pneumonia. Response was not evaluable in 3 cases, 12 (71%) responded to MBV and progression was observed in two cases.
OS and NRM were 82% (95% CI 74–89%) and 16% (95% CI 9-22%) at 12 weeks.
Discontinuation was due to planned therapy completion (n=88, 72%); failure (n=14, 13%) including no response (n=8, 6%) or response and rebound (n=6, 5%), death (n=13, 11%), side effects (n=4, 3%), supply problem (n=3, 2%), other (n=1, 1%).

Conclusions: This large real-world study confirms MBV as an effective and well-tolerated option for CMV infection and disease in allo-HCT recipients

TOXOPLASMOSIS SCREENING, PROPHYLAXIS AND TREATMENT PRACTICES ACROSS EBMT CENTERS: A SURVEY ON BEHALF OF THE INFECTIOUS DISEASES WORKING PARTY

Fabio Andreozzi[1,2], *Aspasia Georgala*[1], *Juana Schwartz*[3], *Nina Knelange*[3], *Gloria Tridello*[3], *Malgorzata Mikulska*[4,5], *Jan Styczynski*[6], *Dina Averbuch*[7,8]
[1]*HUB - Jules Bordet Institute, Brussels, Belgium,* [2]*VIB-KU Leuven, Leuven, Belgium,* [3]*EBMT, Leiden Study Unit, Leiden, Netherlands (the),* [4]*IRCCS Ospedale Policlinico San Martino, Genoa, Italy,* [5]*University of Genoa, Genoa, Italy,* [6]*University Hospital, Collegium Medicum UMK, Bydgoszcz, Poland,* [7]*Hebrew University of Jerusalem, Jerusalem, Israel,* [8]*Hadassah Medical Center, Jerusalem, Israel*

Background: Toxoplasmosis is a potentially life-threatening complication after allogeneic stem cell transplantation (allo-HSCT). In 2024, new ECIL guidelines were published on the management of *Toxoplasma gondii* infection and disease in this setting.

Methods: On behalf of the Infectious Diseases Working Party (IDWP), we conducted a survey addressing current practices in EBMT centers and alignment with ECIL guidelines.

Results: Overall, 140 EBMT centers performing allo-HSCT participated in the survey. Responses and ECIL recommendations are reported in table 1.
PCR technique for *T. gondii* detection is widely available (132/140, 94%), reimbursed for toxoplasmosis screening and diagnostic purpose in 87/140 (62%) centers, only for disease diagnosis in 17/140 (12%), not reimbursed in 35/140 (25%). Screening after allo-HSCT is offered in 67/140 (48%) centers, beginning either on the day of transplant (38/66, 57%) or after engraftment (28/66, 42%) and continued variably: more frequently until engraftment (19/63, 30%), during first 3mo after allo-HSCT (18/63, 28%), during immunosuppressive therapy (14/63, 22%), until CD4+>200/µL (13/63, 20%).
Prophylaxis is offered in 127/140 (91%) of centers, in most cases to all recipients in 90/127 (71%), whereas in 20/127 (16%) it is restricted to IgG-positive, in 9/127 (7%) only in presence of additional risk factors.
Prophylaxis is generally started after engraftment (94/126, 75%) and variably continued: at least 6mo in 31/126 centers (25%), 1y in 22/126 (17%), until CD4+>200/µL in 38/126 (30%), >400 CD4+/µL in 24/126 (19%), until immunosuppression discontinuation in 23/126 (18%). In 99/100 (99%) of centers, prophylaxis is trimethoprim-sulfamethoxazole. If trimethoprim-sulfamethoxazole is contraindicated, most employed alternatives are atovaquone ± pyrimethamine (45/126, 36%) or nothing (27/126, 21%).
In asymptomatic patients, anti-toxoplasma therapy is initiated after a single positive blood PCR in 19/67 (28%) centers, in 2/67 (3%) only if the patient is considered high-risk, in 7/67 (10%) only if the PCR-value is very high. In 24/67 (36%) two consecutive positive PCR-results are required. Specific assessments are variably performed: cerebral MRI (49/67, 73%), lung CT (42/67, 63%), ophthalmic examination (43/67, 64%), lumbar puncture (20/67, 30%) and bone marrow assessment (10/67; 15%).
Anti-toxoplasma therapy relies on trimethoprim-sulfamethoxazole, pyrimethamine-sulfadiazine and pyrimethamine-clindamycin with similar distribution for infection (73/134, 54%; 49/134, 37%; 10/134, 7%) and disease (66/132, 50%; 54/132, 41%; 9/132, 7%). The preferred regimen for neuro-toxoplasmosis is pyrimethamine-sulfadiazine (61/129, 47%) or trimethoprim-sulfamethoxazole (45/129, 35%).
Treatment for infection is continued in 71/132 (54%) centers until two negative PCRs, in 10/132 (8%) until one. A fixed duration criteria is often considered (< 4w in 5/133, 4% of centers; 4-7w in 32/133, 24%; 8-12w in 16/133, 12%) and more frequently applied while treating toxoplasmosis disease (< 4w in 7/131, 5% centers; 4–7w in 64/131, 49%; 8–12w in 41/131, 31%; >12w in 19/131, 15%). Imaging resolution of pathologic finding is often required (88/131, 67%) before treatment discontinuation.

Toxoplasmosis management – Survey results (n = 140). Number of centers are presented	**ECIL guidelines recommandations, graded for the level of proof and**

			strength of recommandation [Aerts et al., Lancet Inf Dis 2024]
Screening	Screening with qPCR	Yes- 67/140 (48%); no- 73/140 (52%).	qPCR screening recommended for seropositive recipients. A-B II
	Start	Day 0 - 38/66 (58%); after engraftment -28/66 (42%).	PCR screening should start from day 0. A II
	Frequency	<1x week - 17/66 (26%); 1x week - 33/66 (50%); 2x week - 4/66 (6%); > 2x week - 12/66 (18%).	The screening should be at least once per week until day 100, then at least every 2 weeks until day 180, adapted to the schedule of patient follow-up and the intensity of immunosuppression. B II
	Duration (one or more possible answers)	Until engraftment - 19/63 (30%) ; during first 3 months - 18/63 (28%); until IS discontinuation - 14/63 (22%); until CD4+ count > 200/µL - 13/63 (20%); during first 6 months - 9/63 (14%); other 5-63 (8%).	
Prophylaxis	Prophylaxis administration	Yes 127/140 (91%), No 13/140 (9%) For all patients - 90/127 (71%); Only for IgG-positive - 20/127 (16%); Only for IgG-positive patients plus additional risk factors - 9/127 (7%); No specified – 7/127 (6%).	All seropositive recipients before allo-HCT should receive primary toxoplasma prophylaxis. A II
	First-line Drug	TMP- SMZ 99/100 (99%). Posology : 80/400 mg 1 pill every day - 8/99 (8%); 160/800 mg 1 pill 3x days/week - 70/99 (70%); 160/800 mg 1 pill every day- 3/112 (3%); other	First choice: oral or intravenous TMP-SMZ (80–400 mg) per day or 160 mg-800 mg, three times per week regimen. A II

		schedule - 18/99 (18%); Other than TMP- SMZ - 12/99 (12%).	
	Alternative if TMP-SMZ contraindicated	Atovaquone ± pyrimethamine - 45/126 (36%); dapsone ± pyrimethamine - 21/126 (17%); pyrimethamine monotherapy - 15/126 (12%); other - 11/126 (9%); unknown - 8/126 (6%); none, 27/126 (21%).	Alternate options: Pyrimethamine–sulfadiazine with folinic acid. No grade; oral atovaquone 1500 mg/day. C III; dapsone, azithromycin, or clindamycin only in combination with pyrimethamine and folinic acid. No grade
	Start	Before/during conditioning without discontinuation - 14/126 (11%); During pre-engraftment phase - 7/126 (5%); after engraftment - 94/126 (75%); more than 1 month after allo-HCT - 6/126 (5%); other - 13/126(10%).	Prophylaxis should ideally be started as soon as feasible after transplant, but no later than neutrophil engraftment. A II Given the potential for marrow toxicity, it is advised not to start TMP-SMZ prophylaxis during the pre-engraftment period. B II
	Criteria Stop (one or more possible answers)	CD4+ count > 200/µL - 38/126 (30%) centers; ≥6 to < 12 months from the day of allo-HCT - 31/126(25%) centers; CD4+ count > 400/µL - 24/126 (19%) centers; IS discontinuation - 23/126 (18%) centers; ≥12 to < 24 months from the day of allo-HCT - 22/126 (17%) centers; ≥3 to < 6 months from IS discontinuation -	At least 6 months; During immunosuppression ; Until the CD4 cell count significantly increases, when IS is discontinued. B II

		14/126 (11%) centers; ≥6 to < 12 months from IS discontinuation - 12/126 (10%) centers; other 45/126 (36%).	
Toxoplasma gondii Infection/asymptomatic patient with positive blood PCR	Pre-emptive therapy	PCR positive in asymptomatic patient is sufficient for starting treatment - 19/67 (28%); PCR positive in asymptomatic patient is sufficient for starting treatment, only when a single value is very high - 7/67 (10%); only after a second positive PCR or evidence of increasing toxoplasma DNA copies over time - 24/67 (36%); only if the patient is considered high-risk - 2/67 (3%); case by case decision - 15/67 (22%).	Resampled for qPCR within 48–72 h. Concomitantly and without delaying the treatment by waiting for the second qPCR result, the patient should be assessed for any toxoplasma disease. A II If the second qPCR is negative, it is the clinician's choice to either continue the treatment or to stop treatment. However, this patient should at least receive an efficient toxoplasmosis prophylaxis and be monitored with qPCR. B III
	First line	TMP-SMZ - 73/134 (54%); pyrimethamine/sulfadiazine - 49/134 (37%); pyrimethamine/clindamycin - 10/134 (7%); pyrimethamine/atovaquone - 1/134 (1%); other - 1/134 (1%).	If already under TMP-SMZ prophylaxis: increase the dose or switch to an alternative. If not under TMP-SMZ as prophylaxis: start TMP-SMZ prophylactic, intermediate, or therapeutic dose or pyrimethamine plus sulfadiazine

			/clindamycin. No grade
	PCR monitoring frequency	Less than 1x week - 21/133 (16%); 1x week - 82/133 (62%); 2x week - 19/133 (14%); More than 2x week - 11/133 (8%).	qPCR monitor at least once per week. B III
	Duration of treatment (one or more possible answers)	PCR-guided: Until one negative PCR - 10/132 (8%); until two negative PCRs - 71/132 (54%); not based on PCR result(s) - 51/132 (39%). Fixed-duration: < 4 weeks - 5/133 (4%), 4-7 weeks - 32 /133(24%), 8-12 weeks -16/133 (12%); not based on fixed duration - 80/133 (60%).	After starting, pre-emptive treatment should be continued until at least the second negative qPCR, 7 days apart. B II
Toxoplasmosis disease	First line	TMP-SMZ - 66/132 (50%); pyrimethamine–sulfadiazine-54/132 (41%); pyrimethamine–clindamycin - 9/132 (7%); pyrimethamine–atovaquone - 2/132 (2%); pyrimethamine–azithromycin - 1/132 (1%). In case of neurotoxoplasmosis: Pyrimethamine–sulfadiazine 61/129 (47%) - TMP-SMZ 45/129 (35%); pyrimethamine–atovaquone - 1/129 (1%); pyrimethamine–azithromycin - 2/129 (2%); pyrimethamine–clindamycin -16/129 (12%); other - 4/129 (3%).	Pyrimethamine plus folinic acid plus sulfadiazine (A II) or clindamycin (A II) or atovaquone (C II); TMP-SMZ with or without clindamycin whether either pyrimethamine is not available or oral route is not feasible, irrespective of previous trimethoprim–sulfamethoxazole prophylaxis A II ; Atovaquone might also be used in combination with sulfadiazine. C II

	PCR monitoring frequence	<1x week - 25/129 (19%); 1x week - 75/129 (58%); 2x week - 21/129 (16%); ≥2x week - 8 /129 (6%).	
	Duration of treatment (one or more possible answers)	PCR-guided: Until one negative PCR - 7/130 (5%); until two negative PCRs - 52/130 (40%); not based on PCR result - 71/130 (55%). Fixed-duration: < 4 weeks- 7/131 (5%); 4-7weeks - 64/131 (49%); 8-12 weeks - 41/131 (31%); >12 weeks - 19/131 (15%).	Minimum duration of therapy is 6 weeks or until clinical resolution, or both, and two negative PCR tests in blood, 7 days apart, or one qPCR negative in a previously qPCR-positive cerebrospinal fluid; longer courses might be required if clinical disease or radiological findings are extensive or response is incomplete at 6 weeks. B II
		Complete resolution of radiological/ophthalmological findings required before treatment discontinuation Yes - 88/131 (67%); No - 43/131 (33%).	

Table 1 - Survey responses and ECIL recommendations. Allo-HCT – hematopoietic stem cell transplantation IS- Immunosuppression; TMP-SMZ – trimethoprim-sulfamethoxazole

Conclusions: This survey highlights significant variability across EBMT centers in toxoplasmosis management, underscoring the need for ongoing harmonization, in line with recent ECIL guidelines. Notably, pre-emptive strategy with PCR screening is offered in 48% of centers and pyrimethamine-based regimens remain less commonly used than trimethoprim–sulfamethoxazole in toxoplasmosis infection and disease treatment.

PROGNOSIS OF INVASIVE ASPERGILLOSIS AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Mathilde Ruggiu-Goirand[1], *Alexandre Alanio*[1], *Marie Robin*[1], *Flore Sicre de Fontbrune*[1], *David Michonneau*[1], *Eleonore Kaphan*[1], *Blandine Denis*[1], *Amira Benattia*[1], *Florian Chevillon*[1], *Matthieu Jestin*[1], *Nathalie Dhedin*[1], *Regis Peffault de Latour*[1], *Aliénor Xhaard*[1]
[1]*Hopital Saint-Louis, Paris, France*

Background: After allogeneic hematopoietic stem cell transplantation (allo-HSCT), triazole antifungals significantly improve short-term survival in patients with invasive aspergillosis (IA). However, few recent cohorts have described the long-term prognosis of these patients.

Methods: To address this issue, we retrospectively analyzed all consecutive patients receiving an allo-HSCT from 2012 to 2023 at Saint-Louis Hospital, Paris, France. Transplant characteristics were extracted from the EBMT Promise registry. We identified patients diagnosed with proven or probable IA according to the 2020 EORTC/MSGERC criteria. Clinical data were collected from electronic medical records. The primary objective was to compare overall survival (OS) between allo-HSCT recipients with vs. without proven or probable IA. To account for the delay between transplantation and aspergillosis diagnosis, we performed a Mantel-Byar test.

Results: Among the 1,495 allo-HSCT recipients, 61 (4%) developed IA after transplantation. The characteristics of IA patients were generally similar to those without IA, except for higher rates of late (>D30) neutropenia and steroid-resistant acute GvHD in IA patients ($p = 0.003$ and < 0.001, respectively). Notably, pre-transplant IA was not associated with an increased risk of post-transplant IA. IA was diagnosed a median of 95 days after allo-HSCT (Q1-Q3 = [25 – 230]).
We detailed the clinical, mycological, and CT scan findings of IA cases, with pulmonary IA representing the large majority (n = 58). Among patients with pulmonary IA, 21 only had positive respiratory samples, 21 only had positive blood samples and 13 had both. Twenty-one patients developed breakthrough IA, defined as IA occurring while receiving anti-mold triazole therapy. The characteristics of breakthrough and non-breakthrough IA are presented in the **Table**. First-line treatments were mainly liposomal amphotericin B and voriconazole. Treatment response was observed in 50% of the patients after first-line therapy and 60% after second-line (including oral continuation after first-line response, treatment toxicity, or failure). Despite these encouraging response rates, IA remained associated with a very poor prognosis after allo-HSCT. Median OS was 165 days after IA diagnosis (95% CI = [70 – 286]). Death was directly attributable to IA in 23% of cases and possibly related in 19%. Patients who died due to IA had significantly shorter survival than those who died from other causes: OS was 33 days (95% CI = [13–62]) vs 189 days (95% CI = [81–286]), $p < 0.001$. Other causes of death were mainly relapse (23%) and GvHD (27%).
When analyzing IA as a time-dependent variable after allo-HSCT, the 2-year OS was 9% (95% CI = 4–17) in patients with IA, compared with 68% (95% CI = 66–77) in those without IA (**Figure**, $p < 0.001$). Multivariate analysis demonstrated that IA as a time-dependent variable was strongly associated with increased post-allo-HSCT mortality (HR 3.20, 95% CI = [2.32-4.41], ($p < 0.001$)).

Table	Breakthrough IA (n = 21)	No breakthrough IA (n = 40	p
Neutropenia	9 (43%)	23 (58%)	0.03
Systemic steroids	12 (57%)	15 (38%)	0.14
Systemic immunosuppressive treatment (except steroids)	15 (71%)	37 (93%)	0.02
Pulmonary lesions on CT scan (n = 58) - Consolidations - Nodules - Other lesions	 10 (50%) 10 (50%) 0	 12 (32%) 17 (46%) 9 (24%)	0.05
Mycological criteria* - Positive only in respiratory samples - Positive only in blood samples - Positive both in respiratory and blood samples	 8 (42%) 5 (26%) 6 (32%)	 13 (35%) 17 (46%) 7 (19%)	0.3
***Aspergillus* species identification in culture (n = 32)** - *Aspergillus fumigatus* - *Aspergillus fumigatus associated with other species* - *Aspergillus non fumigatus*	 10 (67%) 0 5 (33%)	 10 (63%) 2 (2%) 5 (25%)	0.6
First line treatment - Liposomal amphotericin B - Liposomal amphotericin B + isavuconazole - Liposomal amphotericin B + caspofungine - Caspofungine - Isavuconazole - Posaconazole - Voriconazole - No treatment	 10 (48%) 1 (5%) 1 (5%) 1 (5%) 2 (9.5% 2 (9.5%) 3 (14%) 1 (5%)	 10 (30%) 0 0 2 (5%) 0 4 (10%) 22 (55%) 0	0.007
Survival after IA diagnosis (median, [$_{95}$CI]), days	180 days [49 – 697]	123 days [55 – 306]	0.88

* Positive galactomannan, positive *Aspergillus* PCR or culture positive for *Aspergillus*

Conclusions: Despite recent therapeutic advances, IA remains associated with substantial long-term mortality in allo-HSCT recipients. Although part of this mortality is directly caused by IA, the infection mainly reflects clinical frailty characterized by profound immunosuppression (e.g. systemic corticosteroid therapy, prolonged neutropenia) or relapse of the underlying hematological malignancy.

OS19-03

INFECTION RATES ACROSS THE FIRST-YEAR POST-TRANSPLANT IN PTCY AND NON-PTCY-BASED GVHD PROPHYLAXIS: A POST-HOC ANALYSIS OF A RANDOMIZED PHASE II STUDY

Jennifer I. Jensen[1], *Yehseo Jung*[1], *Xinyi Fan*[2], *Ted A. Gooley*[2], *Michael Boeckh*[1,2], *Marco Mielcarek*[2,1], *Brenda M. Sandmaier*[2,1], *Masumi Ueda Oshima*[1,2]
[1]*University of Washington School of Medicine, Seattle, United States of America (the),* [2]*Fred Hutchinson Cancer Center, Seattle, United States of America (the)*

Background: A prior randomized phase II trial (NCT03246906) of graft-vs-host disease (GVHD) prophylaxis with sirolimus and cyclosporine combined with either post-transplant cyclophosphamide (PTCy) or mycophenolate mofetil (non-PTCy) showed superior GVHD-free relapse-free survival and extremely low rates of moderate to severe chronic GVHD (3% vs. 33% at 1-year post-transplant) but delayed neutrophil engraftment and higher rates of early (day 0-100 post-transplant) grade ≥3 (CTCAE) infections with PTCy (Ueda Oshima, *JCO* 2025). There was no definitive difference in 1-year non-relapse mortality (NRM) between arms. In this post-hoc analysis, we hypothesized that the lower rates of chronic GVHD and associated reduced need for immunosuppression later post-transplant leads to overall lower infection burden across the first-year post-transplant in PTCy-treated patients.

Methods: We retrospectively evaluated all infections by CTCAE version 4.03 and by BMT CTN Infection Grading System between day 0 and 365 post-transplant in patients treated on the trial. The number of unique infections per patient in each arm was calculated by time intervals post-HCT: Day 0-30, 30-100, 100-180, 180-365, and 0-365. Poisson regression was used to compare infection rates between arms across the first year post-transplant. Time at risk for infection was taken as the beginning of the appropriate interval to the earliest of relapse, death, last contact, or end of the relevant interval. For each time interval, the rate of infection per patient and rate ratios (RR), which measures the average infection rate for the PTCy arm relative to the non-PTCy arm, were calculated for different severities of BMT CTN and CTCAE infections.

Results: In the first year post-transplant (days 0-365), 266 and 175 unique infections occurred in 72 PTCy and 72 non-PTCy treated patients, and PTCy-treated patients had higher rates of infection compared to non-PTCy for all infection severity categories (Table 1, Figure

1). When examining specific time periods, the early (days 0-30) and late (days 180-365) post-transplant period showed higher rates of infection in PTCy patients across all infection severities, with the magnitude of difference in PTCy vs. non-PTCy being most pronounced in days 180-365 particularly for severe infections (BMT CTN 2+: RR 3.02, 95% CI 1.16-9.34, p=0.0339 and CTCAE 2+: RR 3.45, 95% CI: 1.35-10.55, p=0.0156; Table 1). For time intervals days 30-100 and 100-180, infection rates with PTCy were numerically higher for every infection severity (Table 1).

Time Interval	Grade	RR	conf.low	conf.high	p.value
Day 0-30	ALL				
	BMT 1+	1.64	1.24	2.19	0.0007
	BMT 2+	1.65	1.24	2.20	0.0006
	CTCAE 2+	3.47	1.93	6.71	0.0001
	CTCAE 3+	1.68	1.23	2.32	0.0014
		1.86	1.28	2.73	0.0013

	BMT 1+	1.32	0.93	1.89	0.1182
	BMT 2+	1.32	0.93	1.89	0.1182
	CTCAE 2+	1.13	0.61	2.08	0.6962
	CTCAE 3+	1.20	0.79	1.81	0.3934
		1.57	0.83	3.08	0.1725
Day 100-180	ALL				
	BMT 1+	1.74	0.99	3.12	0.0564
	BMT 2+	1.74	0.99	3.12	0.0564
	CTCAE 2+	2.24	0.88	6.36	0.1032
	CTCAE 3+	1.81	0.99	3.41	0.0594
		2.29	1.07	5.30	0.0387
Day 180-365	ALL	1.81	1.08	3.12	0.0270
	BMT 1+	1.90	1.12	3.30	0.0188
	BMT 2+	3.02	1.16	9.34	0.0339
	CTCAE	2.97	1.57	5.98	0.0013
		3.45	1.35	10.55	0.0156

	2+ CTCAE 3+				
Day 0-365	**ALL BMT** **1+ BMT** **2+ CTCAE** **2+ CTCAE 3+**	 1.57 1.58 2.06 1.64 1.90	 1.30 1.31 1.46 1.32 1.44	 1.90 1.92 2.94 2.04 2.52	 <0.0001 <0.0001 <0.0001 <0.0001 <0.0001

Table 1. Poisson Model
RR = Rate Ratio represents the average infection rate for the PTCy group relative to the non-PTCy group

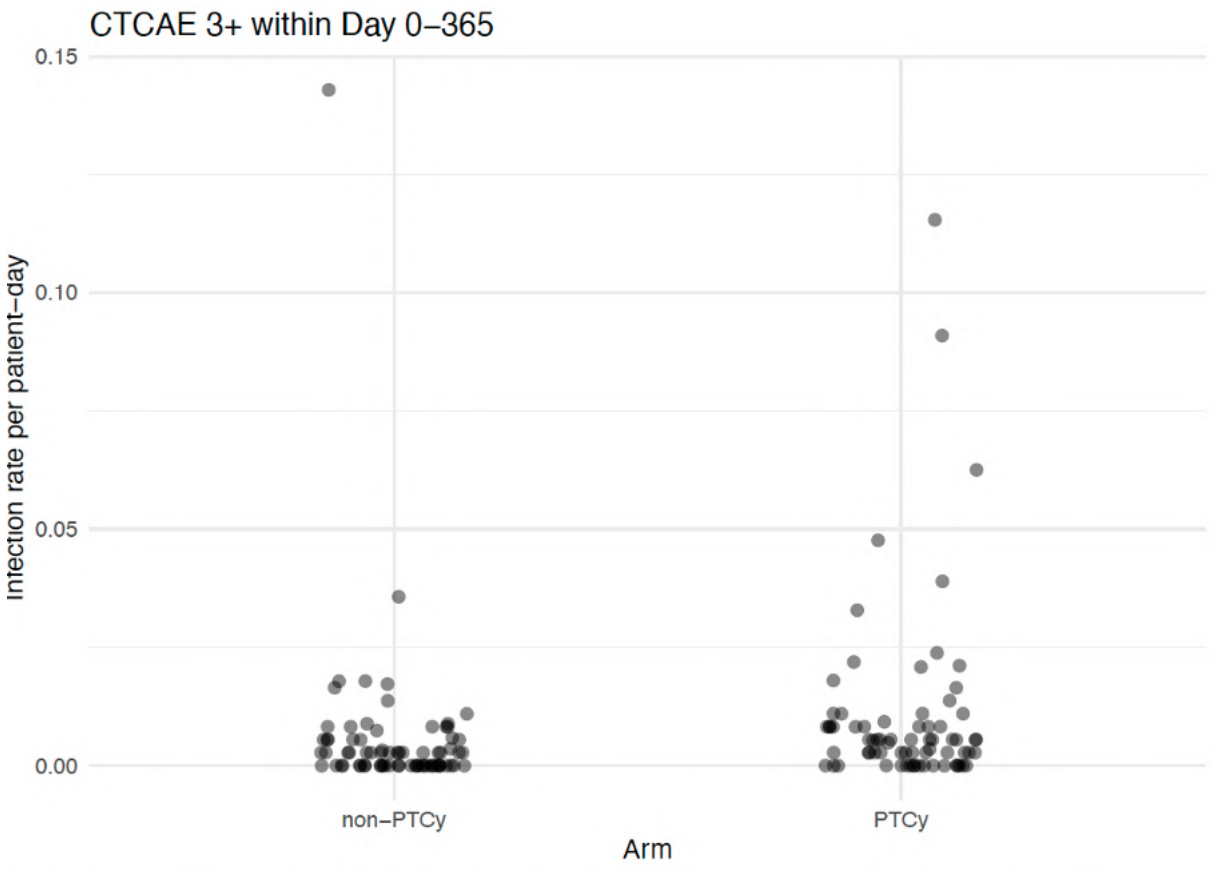

Figure 1. Jittered dot plot of infection rate per patient by arm day 0-365 post-transplant for

CTCAE grade 3+ infections. Each gray dot represents the infection rate per patient per days at risk (Note: overlapping gray dots appear black).

Conclusions: Despite significantly lower rates of GVHD and immunosuppressive treatment, PTCy-treated patients had higher rates of infection even beyond the initial pre-engraftment period and throughout the entire first year post-transplant compared to non-PTCy-treated patients. This suggests continued compromise to immune reconstitution extending beyond initial delay in neutrophil engraftment with PTCy. Targeted infection surveillance and prevention, as well as further optimization of PTCy-based GVHD prophylaxis, is needed to better balance GVHD reduction with infection risk.

Background: Vaccine studies focused on the population undergoing therapies with chimeric antigen receptor T-cells (CAR-T) are limited and, in most centres, the vaccination strategies are adopted from the transplantation protocols.
To optimize the vaccine-preventable protection, some authors propose immunizing patients against some pathogens prior to lymphodepleting therapy. Immunisation with killed/inactivated/recombinant vaccines (non-live; NLV) is recommended ≥3 months after CAR-T and with live attenuated vaccines (LAV) ≥12 months.

Methods: To obtain an overview of current vaccination practices, we launched a survey across EBMT-affiliated CAR-T centres. The differences between the center's prioritized vaccines were investigated using Fisher's exact test.

Results: The response rate was 38% (99/261) from adult centres (n=73), paediatric centres (n=9) and mixed centres (n=17). 56/99 (57%) centres reported a specific vaccination protocol for CAR-T recipients. Vaccinations before lymphodepleting therapy are performed in 18/99 (18%; in 5% routinely) centres (mainly against influenza and SARS-CoV-2 viruses). The vaccination strategies do not differ by CAR-T type (anti-CD19 or anti-BCMA). The fixed timing for beginning immunisation with NLV at 3-6 months and >6 months post-CAR-T is used in 34/88 (39%) and 17/88 (19%) centres, respectively. For LAV, a fixed timing of >12 months post-CAR-T is used in 42/99 (42%) centres. The immune reconstitution-dependent (CD4+ or CD19+ or CD20+ >0.2x10^9/L) strategy for NLV and LAV initiation is declared by 41/99 (41%) centres. Regarding the time elapsed since the last immunoglobulin supplementation as a strategy for NLV initiation, no specific time is reported by 72/88 (82%) centres, and 2-3 months by 12/88 (14%). For the LAV initiation, no particular time is declared by 69/99 (70%) centres, while 5-6 months, >6-12 months and >12 months by 13/99 (13%), 10/99 (10%), and 7/99 (7%) centres, respectively. Assessment of the specific vaccine-preventable humoral immunity before initiation of post-CAR-T vaccination is performed in 27/99 (27%) centres (mainly for hepatitis B virus (HBV), and varicella-zoster virus). Post-vaccine antibody response assessment in patients immunised after CAR-T therapy is performed in 29/99 (30%) centres (mainly for pneumococcal and HBV vaccines). To assess the durability of protection, the post-vaccine antibody maintenance after seroconversion is monitored in 20/99 (20%) centres.
The prioritized vaccines recommended in >80% of CAR-T centres, regardless of patients' age and the centre's geographical location, include influenza and pneumococcal vaccines (Table 1). The significant differences between the numbers of centres recommending specific vaccines in children vs adults were observed regarding papillomavirus (p=0.021) and zoster (p=0.004) vaccines, and between the CAR-T centres' regions (Western Mediterranean and Central Europe and Benelux versus West Asia–Southeast Asia) regarding vaccines against hepatitis A virus (p=0.012), HBV (p=0.049), and mumps, measles, rubella (p=0.005). Almost all responders (95%) expressed a need for vaccination guidelines for patients undergoing CAR-T cell therapy.

Table 1 Vaccines recommended in the CAR-T centres according to the treated population (paediatric, adult, or both) and the centres' geographic location.

Type of recommended vaccine	**Patient population**				**Regions**

OS19-05

INCIDENCE AND OUTCOME OF INFECTIONS AFTER TREATMENT WITH CAR-T CELLS VERSUS BISPECIFIC ANTIBODIES IN PATIENTS AFFECTED BY HEMATOLOGICAL MALIGNANCIES

Daniele Mannina[1], *Davide Chizzoniti*[1], *Chiara De Philippis*[1], *Jacopo Mariotti*[1], *Barbara Sarina*[1], *Daniela Taurino*[1], *Armando Santoro*[1], *Michele Bartoletti*[1], *Linda Bussini*[1], *Stefania Bramanti*[1]
[1]*IRCCS Humanitas Research Hospital, Rozzano, Italy*

Background: Novel immunotherapies such as chimeric antigen receptor T-cells (CAR-T) and bispecific antibodies (BsAbs) have significantly improved long-term outcomes in heavily pre-treated hematological malignancies. Both therapies are associated with cytopenia, hypogammaglobulinemia, and prior extensive treatment exposure, factors known to increase infectious risk. Although infection incidence after CAR-T and BsAbs has been increasingly investigated, comparative data between these approaches remain limited, with controversial results. Recent evidence shows that infectious risk is high with both CAR-T cells and bispecific antibodies, with severe infections occurring predominantly early after CAR-T therapy, whereas bispecific antibodies are associated with a sustained and cumulative infectious burden over time, particularly with continuous treatment. [1–3]

Methods: We conducted a retrospective analysis of all consecutive patients who received CAR-T cell therapy or bispecific antibodies at our institution, evaluating the incidence and spectrum of viral, bacterial, and fungal infections, as well as infection-related outcomes such as hospitalization rate and duration, ICU admission, and infection-related mortality. We retrospectively analyzed 237 patients treated with CAR-T (n=110), bispecific antibodies (BsAbs, n=81) or both (n=46). Table 1 describes patients characteristics.

Results: Across the 3 groups of CAR-T, bispecifics, or both, at least one infectious event occurred in 49%, 57% and 61% of patients, respectively. A total of 95, 109, and 46 infectious events were recorded in the CAR-T, bispecific antibody, and dual-therapy cohorts, respectively. Among infection episodes, early infections (<100 days) accounted for 34.7% after CAR-T and 20.0% after bispecific antibodies (p=0.018), while late infections predominated in the bispecific cohort (80.0% vs 65.3%). Across all groups, viral infections were the most frequent (46–49%), followed by bacterial (28–33%) and fungal infections (3–

10%). Infection-related hospitalization and mortality were significantly higher in patients treated with bispecific antibodies compared with CAR-T recipients (p=0.044 and p=0.009, respectively). Overall infection incidence and ICU admission did not differ significantly between groups.

Variable	**CAR-T (n=110)**	**Bispecifics (n=81)**	**Both therapies (n=46)**	
Sex (Male)	63 (57.3%)	47 (58.0%)	35 (76.1%)	0.069
Age at treatment (mean ± SD)	57.9 ± 13.1	61.7 ± 15.9	58.3 ± 12.0	0.074
Charlson Comorbidity Index (mean ± SD)	3.84 ± 1.40	4.14 ± 1.88	3.65 ± 1.46	0.386
ECOG PS (median, IQR)	0 (0–2)	0 (0–3)	0 (0–1)	0.174
Prior therapy lines (mean ± SD)	3.34 ± 1.15	3.54 ± 1.41	3.17 ± 0.82	0.401
Prior transplant	24 (21.8%)	8 (9.9%)	4 (8.7%)	0.030
Underlying disease				0.001
– Lymphoma	98 (89.1%)	73 (90.1%)	40 (87.0%)	
– Acute Leukemia	1 (0.9%)	8 (9.9%)	2 (4.4%)	
– Multiple Myeloma	11 (10.0%)	0	4 (8.7%)	
CAR-T product type				
– Tisagenlecleucel	44 (40.0%)			
– Axicabtagene ciloleucel	34 (30.9%)			
– Brexucabtagene autoleucel	16 (14.6%)			
– Idecabtagene vicleucel	11 (10.0%)			
– Lisocabtagene maraleucel	2 (1.8%)			

– Other / investigational	3 (2.7%)			
CAR-HEMATOTOX score, median (IQR)	3 (3–4)			
CAR-HEMATOTOX score ≥1 n (%)	101 (91.8%)			

Conclusions: Despite the limitations of this retrospective analysis, in a cohort predominantly composed of lymphoma patients we reported a later onset of infections and poorer infection-related outcomes after treatment with BsAbs compared with CAR-T, likely attributable with continuous exposure and sustained immunosuppression associated with ongoing BsAb therapy.

MANAGEMENT OF BLOODSTREAM INFECTION SECONDARY TO BACTERIAL TRANSLOCATION DURING THE NEUTROPENIC PHASE OF STEM CELL TRANSPLANT. A NO–CENTRAL LINE REMOVAL STRATEGY IN 73 EPISODES

Amado Karduss-Urueta[1,2], Guillermo Herrera[3], Santiago Manrique[2], Angelica Cardona[4], ***Angela Trujillo***[3]*, Hilda Deossa*[1]
[1]*Instituto de Cancerologia Las Americas, Medellin, Colombia,* [2]*University of Antioquia, Medellin, Colombia,* [3]*Instituto de Cancerologia las Americas, Medellin, Colombia,* [4]*AUNA IDEAS, Medellin, Colombia*

Background: Bacteremia secondary to bacterial translocation from injured mucosa during the neutropenic phase after stem cell transplant (SCT) is a frequent event. It has been well described and is classified by the CDC as mucosal barrier injury laboratory-confirmed bloodstream infections (MBI-LCBI) (1). However, controversy persists over whether the central line (CL) should be removed. In our transplant center, by protocol, we did not remove the CL in cases of MBI-LCBI. We present our experience with this approach.

Methods: From Jan 2023 to Oct 2025, we identified all bloodstream infections (BSI) that occurred during the neutropenic phase of SCT. Patients aged 18 years or older who met the CDC criteria for MBI-LCBI (1) and had a CL were included. We assessed: 1) resolution of infection after 7 days of treatment, 2) ICU transfer, 3) recurrence of BSI with the same organism, 4) overall mortality at 30 days, and 5) the percentage of CL that was finally removed.
In each episode of fever and neutropenia, a set of blood cultures was obtained, and empiric antibiotic (meropenem or ceftazidime/avibactam) was initiated within the first hour. Later, the therapy was de-escalated to cefepime according to the results and evolution. The CL was removed only in cases of thrombosis, exit site infection, or persistence of BSI.

Results: During the study period, 112 bloodstream infections were identified. A total of 73 of them (65.1%), occurring in 71 patients, met the inclusion criteria. (See Table 1 for the characteristics of the group). The median time to the first bacteremia was 7 days after transplant (-2 to 20), and for the second, it was 13 days (+12 to 15). In 5 episodes, the BSI was polymicrobial. Pathogens identified were E. coli (43.5%), Klebsiella spp. 32.0%, Enterococcus spp. 10.2%, Streptococcus spp. 10.2%, and others Gram negatives, 4.0%. The pattern of drug resistance was ESBL 26,9%, carbapenemase 17.9% and VRE 2.5%.
The 30-day mortality rate was 2.8%. Persistent infection with the same bacterium was observed in 2.7% of cases, catheter removal was required in 4.1% of instances, and 12% of episodes necessitated transfer to the ICU. Finally, 69 out of 71 patients (97,2%), corresponding to the 73 episodes, were alive at D+30.

Table 1 **Characteristics of patients**

Age	50.3 (20-75)
Gender	Men: 37, Women: 34
Type of Transplant	
	Autologous: 21 (29.5%)
	Allogeneic: 08 (11.2%)
	Haploidentical: 42 (59.1%)
Diagnosis	
	AML/MDS: 26 (36.6%)
	ALL: 13 (18.3%)
	Lymphomas: 14 (19.7%)
	Myeloma: 11 (15.5%)
	Other: 07 (9.85%)

Table 1 **Characteristics of patients**

Neutrophil number	100 (0-300)
Total patients	71

Conclusions: 1-More than 50% of bacteremia occurring during the neutropenic phase of SCT meet the CDC criteria of MBI-LCBI.
2- Given that the central line (CL) is not the source of the infection, a strategy involving early initiation of antibiotics and salvage of the catheter is feasible and seems safe.
3- This strategy saves resources and avoids invasive procedures in patients at risk of complications

OS19-07

THIRD PARTY FUNGUS-SPECIFIC T CELL THERAPY FOR INVASIVE FUNGAL INFECTION AFTER ALLOGENEIC STEM CELL TRANSPLANTATION

David Gottlieb[1,2,3], *Karen Maddock*[2], *Lan Mi*[4,2], *Barbara Withers*[4], *Wei Jiang*[4], *Louis Do*[5], *Catelyn Cashion*[2], *Stephanie Isaac*[2], *Mary Sartor*[3], *Deekshitha Dhulipati*[1], *Emily Blyth*[1,2,3], *Shafqat Inam*[2], *Renee Simms*[1,3], *Selmir Avdic*[1,3], *Gaurav Sutrave*[1,2,3]
[1]University of Sydney, Sydney, Australia, [2]Westmead Hospital, Sydney, Australia, [3]Westmead Institute of Medical Research, Sydney, Australia, [4]St Vincent's Hospital, Sydney, Australia, [5]Calvary Mater Hospital, Newcastle, Australia

Background: The global immune deficit that follows allogenic stem cell transplantation (HSCT) predisposes to multiple infections including invasive fungal infections (IFIs) with yeasts and moulds. The incidence of IFIs after transplant is 5 to 15% depending on factors including the severity of post-transplant neutropenia and the intensity of immune suppression. Despite optimal antifungal drug therapy, mortality for IFIs after transplant varies from 20% for primary invasive Candidiasis to over 60% for breakthrough mould infections. Defects in innate and adaptive immunity contribute to the development and progression of post-HSCT IFIs.

Methods: We generated a bank of cryopreserved fungus-specific T cells (FSTs) from the G-CSF primed apheresis product of allogeneic stem cell donors. Fungus-specific T cells were predominantly CD4+ and targeted fungal antigens mainly through HLA DR restriction. In a phase 1 trial, we treated 8 patients with possible, probable or proven IFI with one or more

infusions of FSTs with which they shared an HLA DR antigen. A 9th patient was treated off study but on the trial protocol. Patients received traditional antifungals at the discretion of their treating physicians.

Results: From August 2020 to September 2025, nine patients aged 24-71 years received FSTs 24 to 224 days (median 40) after HSCT for AML (n=3), MDS (1), ALL (2), T-LBL (1), NHL (1) and Vexas syndrome (1). Transplants were performed using haploidentical (n=4), matched unrelated (3), matched sibling (1) and mismatched related donors (1). GVHD prophylaxis consisted of post-transplant cyclophosphamide/tacrolimus/MMF (n=5) and thymoglobulin/ciclosporin/methotrexate (4). All patients had fungal lung disease, with additional disease in sinuses (n=4), brain (3), orbit (1) and blood (1). IFIs were proven (n=5), probable (3) and possible (1). Fungi identified were *Lomentospora prolificans (2), Candida albicans (2), Scedosporium aurantiacum, Clavispora lusitaneae, Candida parapsilosis, Purpureocillium lilacinum and Naganishia spp.* Three patients had infections with multiple fungal species. All infections occurred as breakthrough in patients receiving prophylactic antifungals. Two patients received 2 FST infusions. FST doses were $1x10^6/m^2$ (5), $10x10^6/m^2$ (3) and $100x10^6/m^2$ (3). There were no acute infusion related toxicities. Of eight currently evaluable patients including two with deep CNS infections, seven cleared or effectively controlled IFIs. One patient transplanted for Vexas syndrome developed persistent Lomentospora prolificans fungemia and died despite receiving FSTs in conjunction with antifungals including olorofim. One patient cleared his IFI but died with disseminated atypical Mycobacteria. GVHD occurred in 4 patients (1 pre-FST only, 1 pre- and post-FST, 2 post-FST only). Post-FST only GVHD was mild, did not require systemic steroids and fully resolved. At a median of 753 days (range 12-1772) post FST infusion, 7 patients are alive and well, 4 off all antifungal treatment.

Conclusions: FSTs infused after HSCT appear safe and were not associated with infusion related toxicity or excess GVHD. Eight of nine patients resolved IFIs including those with severe sinopulmonary and deep CNS mould infections. Fungus-specific adoptive T cell therapy may complement traditional antifungal drug treatment in immunodeficient HSCT patients with IFIs and result in improved outcomes without adversely affecting transplant safety. A larger study is required to confirm these encouraging preliminary findings.

Background: Invasive aspergillosis (IA) is an important infectious cause of morbidity and mortality in patients with hemato-oncological malignancies and those undergoing allogeneic stem cell transplantation (allo-SCT). Although IA may be a cause of transplant-ineligibility, a recent prospective study in patients with acute leukemia undergoing alloSCT showed that more than two thirds of patients with pre-SCT IA were alive one year after allo-SCT. We analyzed the pediatric population from this cohort to assess the influence of pre-SCT IA in children undergoing allo-SCT.

Methods: The data of children with acute leukemia undergoing allo-SCT and recruited in a prospective EBMT-IDWP study were analyzed to assess the impact of a prior history of probable or proven IA (pre-SCT P/P-IA) on 1-year overall survival (OS) and non-relapse mortality (NRM), relapse incidence and occurrence of infectious complications, and graft-versus-host disease (GvHD). Kaplan-Meier estimator was applied to estimate the OS, whilst the cumulative incidence method was used for NRM, relapse incidence and GvHD. Risk factors analysis was performed by using the Cox regression model. All the analyses were performed by using the RStudio software.

Results: Among the 449 children included between 2016 and 2021, the incidence of pre-SCT P/P-IA was 6.5% (N=29). The interval between diagnosis of P/P-IA and allo-SCT was median 125 days (range 17 – 1391 days). The incidence of 1-year NRM was significantly higher in children with pre-SCT P/P-IA (28% NRM, 95% CI 11-44%) versus children without pre-SCT P/P-IA (9% NRM, 95% CI 6-11%) (p = 0.003) (Figure 1A). Consequently, 1-year OS was lower in children with pre-SCT P/P-IA (62% OS, 95% CI 44-80%) versus children without pre-SCT P/P-
IA (83%, 95% CI 79-86%) (p<0.001) (Figure 1B). In the multivariate model, among the variables analyzed for OS (sex, age, underlying disease, disease status, pre-SCT P/P-IA, recipient-donor (R/D) sex, donor age, TBI, conditioning (RIC/MAC), stem cell source, donor type,T-cell depletion, R/D CMV, diagnosis-SCT interval), pre-SCT P/P-IA (HR 2.26, C.I. 1.28-3.97, *p* 0.005), stem cell source (PB+CB) (HR 2.01, C.I. 1.38-2.93, $p < 0.001$)), and longer diagnosis-SCT interval (HR 1.53, C.I.1.05-2.24, p=0.028) were significantly associated with a worst OS. Causes of death in children with pre-SCT P/P-IA compared to children without pre-SCT P/P-IA were more often related to bacterial infections (6.9% versus 1.7%), viral infections (3.4% versus 2.1%) and infection-related disease with unknown etiology (6.9% versus 0.7%).

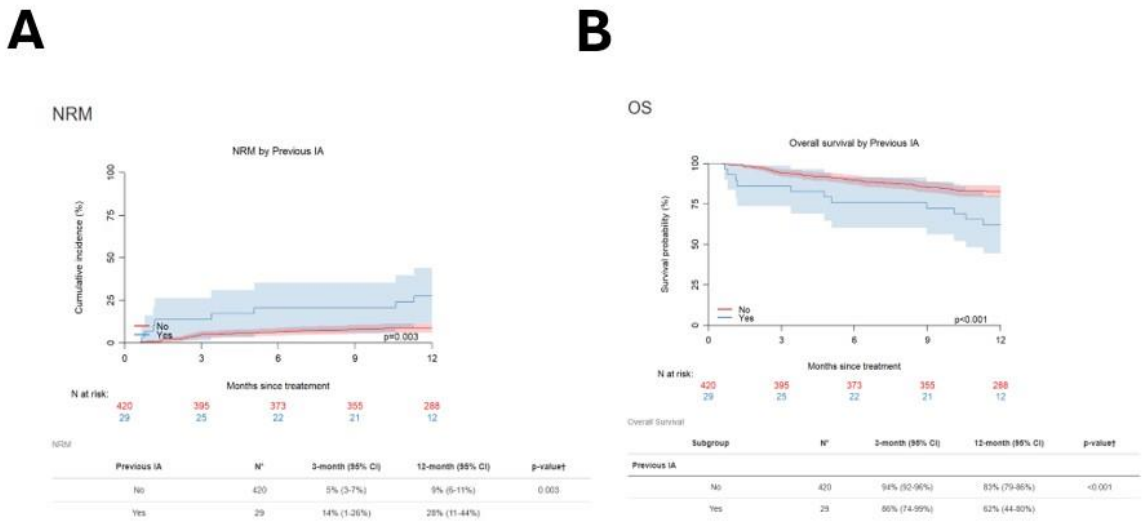

Figure 1A-B: Cumulative incidence of (A) 1-year non-relapse mortality (NRM) and (B) overall survival (OS) in children with and without invasive aspergillosis (IA) prior to allogenic stem cell transplantation.

Conclusions: In children, pre-SCT P/P-IA is significantly associated with worse allo-SCT outcomes. In addition, we observed a lower overall survival in the pediatric population with pre-SCT P/P-IA compared to the previously published cohort including both children and adults with pre-SCT P/P-IA undergoing allo-SCT. Nonetheless, allo-SCT represents a valuable

therapeutic option also in patients with prior IA, being successful in more than half of the patients.

RISK STRATIFICATION SYSTEM FOR CMV MONITORING AFTER AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION

Alicja Sadowska-Klasa[1,2], *Hu Xie*[1], *Leona Holmberg*[1], *Alpana Waghmare*[1,3], *Wendy Leisenring*[1], *Michael Boeckh*[1]
[1]*Fred Hutchinson Cancer Center, Seattle, United States of America (the),* [2]*Medical University of Gdansk, Gdansk, Poland,* [3]*Seattle Children's Hospital, Seattle, United States of America (the)*

Background: Autologous hematopoietic cell transplantation (auto-HCT) is a standard consolidation therapy for hematologic malignancies. However, the incidence and clinical impact of cytomegalovirus (CMV) infection post-auto-HCT remain poorly defined, as current guidelines do not recommend routine CMV monitoring in recipients of unmodified grafts. We aimed to characterize CMV reactivation patterns and identify pre- and post-transplant risk factors to develop a predictive model for targeted CMV monitoring.

Methods: We retrospectively analyzed 1,000 CMV-seropositive (all ages), non-CD34-selected auto-HCT recipients transplanted between 2011 and 2021 at Fred Hutchinson Cancer Center who underwent CMV monitoring between days +20 and +60. To assess the impact of CMV serostatus, 846 concurrently transplanted CMV-seronegative recipients were also analyzed. Preemptive therapy (PET) was initiated at ≥5 antigen-positive cells per slide or viremia ≥150 IU/mL, or at any positive antigenemia/viremia ≥50 IU/mL during high-dose steroid use (≥1 mg/kg) or anti-thymocyte globulin (ATG) administration. Clinically significant CMV infection (csCMV) was defined as viremia requiring PET or CMV disease. Time-to-event and Cox proportional hazard analyses were performed for CMV infection, CMV disease, and high-risk CMV infection (viremia ≥500 IU/mL, antigenemia ≥7, or CMV disease).

Results: By day 100 post-HCT, 29% (95% CI 26.6–32.3%) experienced any CMV viremia, while high-risk infection occurred in 4.4% (95% CI 3.2–5.8%). csCMV incidence was 12.7% (95% CI 10-14%), with CMV disease diagnosed in 1% of patients. Reactivation was most frequent in non-malignant disorders treated with ATG and in lymphomas (Figure 1A). Pre-HCT CMV reactivation (7.8% of 190 tested) predicted markedly post-HCT high-risk infection rates (33% vs 5%). By day 100, 24 deaths (2.4%) occurred among CMV-seropositive and 15 (2%) among CMV-seronegative patients; CMV contributed to death in 3 cases. CMV serostatus did not affect non-relapse mortality at day 100 (Figure 1B) or overall survival at 3 years.
In univariable models, HIV infection was associated with CMV disease (HR 16.1; 95% CI 2.03- 128) and pre-HCT CMV viremia (among patients with available data) was associated with increased risk of post-HCT CMV infection (HR 11.6; 95% CI 3.63-36.8). Multivariable

models identified elevated pre-HCT creatinine (>1.5 mg/dL), hypoalbuminemia (<3.4 g/dL), and lymphoma diagnosis as significant predictors of high-risk CMV reactivation (Figure 1C). A risk model incorporating these factors stratified patients by cumulative incidence of high-risk infection (1.4% with no risk factors vs. 9.4% with ≥2), Figure 1D. Adding pre-HCT CMV variable to the model further increased incidence of high-risk infection (30% with ≥2 risk factors). Post-HCT systemic steroid use (>0.5 mg/kg) was a significant predictor of high-risk infection (HR 4.7; 95% CI 1.86-11.9).

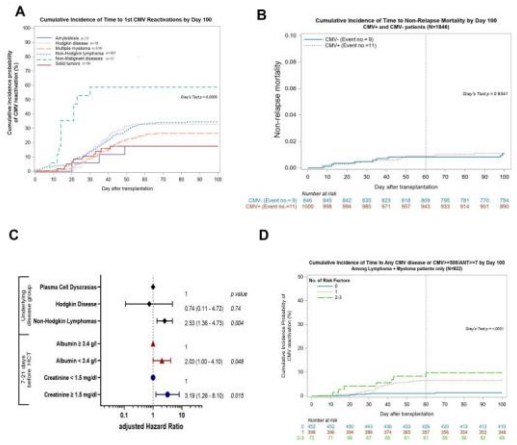

Figure 1. A) Cumulative incidence by 100 days post-transplant of CMV viremia by underlying disease (amyloidosis – solid purple line, Hodgkin disease – dotted line, multiple myeloma – long dashed line, non-Hodgkin lymphoma– short dashed line, non-malignant diseases – medium dashed line, and solid tumor – red solid line); B) Cumulative incidence of non-relapse mortality by day 100 post-transplantation among CMV seronegative (solid line) and CMV seropositive (dotted line) HCT recipients. Analyses of risk factors among patients diagnosed with plasma cell dyscrasias and lymphomas: C) Multivariable Cox regression model for high-risk CMV infection (≥500 IU/mL, ≥7 antigen-positive cells per slide, or CMV disease) among HCT recipients. D) Risk stratification model based on a number of risk factors (0 to 3, hypoalbuminemia, renal dysfunction, lymphoma diagnosis) for high risk infection.

Conclusions: We identified key pre- and post-transplant risk factors for CMV reactivation and developed a risk stratification model to guide targeted PCR monitoring, enabling more precise prevention and diagnostic stewardship after auto-HCT. CMV monitoring should be performed in patients with pre-HCT viremia, ATG exposure, HIV infection, or those receiving post-HCT steroid treatment, regardless of the underlying disease. Among patients with lymphoma and myeloma, PCR monitoring is recommended for those with at least two risk factors including hypoalbuminemia, renal dysfunction, or lymphoma diagnosis.

REAL-WORLD USE, EFFECTIVENESS AND SAFETY OF MARIBAVIR IN HEMATOPOIETIC CELL TRANSPLANT RECIPIENTS WITH REFRACTORY/RESISTANT CMV OR INTOLERANCE TO ANTI-CMV AGENTS: INTERIM ARISE RESULTS

Johan Maertens[1], *Arancha Bermúdez*[2], *Karl Stuart Peggs*[3], *Milena Todorović Balint*[4], *Fanny Vuotto*[5], *Francesca Cassanelli*[6], *Bojana Milovanović*[7], *Ilaria Albieri*[7], *Tien Bo*[8]

Background: Maribavir was approved in Europe in 2022 for treatment of post-transplant refractory/resistant (R/R) cytomegalovirus (CMV) infection/disease. Real-world data are needed to characterize its use, effectiveness and safety in routine practice. We report interim data from hematopoietic cell transplant (HCT) recipients in the ARISE study.

Methods: ARISE is a multinational, retrospective cohort study evaluating the use, effectiveness and safety of maribavir in adult (≥18 years) HCT or solid organ transplant recipients with R/R CMV or intolerance to anti-CMV agents. This analysis includes allogeneic HCT recipients who initiated maribavir between the start of country-specific commercial availability/early access program and 4 months before data abstraction (i.e., the eligibility period). The primary objective was to describe CMV clearance at maribavir discontinuation (i.e., last negative CMV quantitative PCR before maribavir discontinuation). Secondary objectives included maribavir treatment patterns, safety and healthcare resource utilization (HCRU). Outcomes were summarized using descriptive statistics and Kaplan-Meier (KM) analysis.

Results: This interim analysis included 89 allogeneic HCT recipients (R/R, n=56; intolerant, n=33) from nine European countries. Mean (SD) age at transplant was 50.5 (17.1) years, 52.8% were male, and 74.2% recipients had CMV-positive serostatus at transplant. Median (Q1-Q3) duration of follow up was 14.6 (9.1-21.2) months. Median (Q1-Q3) time from transplant to maribavir initiation and from maribavir initiation to end of follow up was 143 (70-189) days and 228 (122-512) days, respectively. Among evaluable patients at maribavir discontinuation (n=74), CMV clearance was achieved in 38/47 (80.9%; 95% CI: 66.7-90.9) HCT recipients with R/R CMV and in 25/27 (92.6%; 95% CI: 75.7-99.1) recipients with intolerance to anti-CMV agents. Median (Q1-Q3) time to CMV clearance from maribavir initiation was 50 (26–71) and 44 (18-56) days in the R/R and intolerant groups, respectively; KM analysis shown in Figure. Median (Q1-Q3) duration of maribavir treatment courses (n=94) was 49.5 (22-61) days. Maribavir was initially administered at home in 51/96 (53.1%) treatment courses. Adverse events of special interest and HCRU are shown in the Table. Before and after maribavir initiation, respectively, incidence rates per person-year for myelosuppression were 0.623 and 0.181 in the R/R group, and 1.409 and 0.218 in the intolerant group, while for nephrotoxicity were 0.147 and 0.052 in the R/R group, and 0.634 and 0.054 in the intolerant group. Hospitalization rates per person-year before and after

maribavir initiation were 1.36 and 0.91 in the R/R group and 1.27 and 0.46 in the intolerant group, respectively. All-cause mortality was 41.1% in the R/R group and 42.4% in the intolerant group.

Figure. Time to CMV clearance from start of maribavir therapy

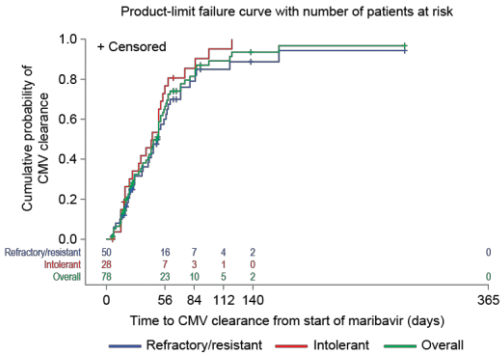

Table. Adverse events of special interest (AESI) and health care resource utilization, n (%)

	R/R (n=56)		Intolerance to anti-CMV agents (n=33)	
	Prior to maribavir initiation	After maribavir initiation	Prior to maribavir initiation	After maribavir initiation
Overall AESIs	21 (37.5)	10 (17.9)	23 (69.7)	9 (27.3)
Myelosuppression	17 (30.4)	7 (12.5)	19 (57.6)	7 (21.2)
Nephrotoxicity	4 (7.1)	2 (3.6)	9 (27.3)	2 (6.1)
Taste disturbance	4 (7.1)	2 (3.6)	1 (3.0)	1 (3.0)
ER visits	2 (3.6)	4 (7.1)	1 (3.0)	4 (12.1)
Inpatient hospitalizations	28 (50.0)	20 (35.7)	16 (48.5)	10 (30.3)

Table reports number (%) of patients with ≥1 events.
CMV, cytomegalovirus; ER, emergency room; R/R, refractory/resistant CMV

Conclusions: Interim results of this European retrospective study support the real-world effectiveness and safety of maribavir in adult HCT recipients with refractory/resistant CMV or

intolerance to anti-CMV agents. CMV clearance rates at maribavir discontinuation appeared to be higher than previously observed in the HCT population within the phase 3 SOLSTICE trial. The lower incidence of myelosuppression and nephrotoxicity after versus before maribavir initiation is in line with the lower hematologic and renal toxicity of maribavir compared with ganciclovir/valganciclovir and foscarnet in the overall SOLSTICE transplant population.

Background: Favorable one year overall survival was noted in the mismatched unrelated donor (MMUD) ACCESS trial (NCT04904588) (PMID 40523209). However, 60% of adult

patients experienced 275 clinically significant infections (CTCAE Grades 2-5) within the first 100 days (D100), with similar frequences in infections for patients receiving either myeloablative (MAC, 56%) or non-myeloablative/reduced intensity conditioning (NMA/RIC, 64%). Using combination reduced dose post-transplant cyclophosphamide (PTCy 25 mg/kg Days 3 and 4), tacrolimus, and mycophenolate mofetil as graft-versus-host disease (GvHD) prophylaxis, the OPTIMIZE (NCT06001385) trial aims to improve D100 infection free survival (IFS). As part of the trial's secondary objectives, we describe infections in the initial cohort of patients enrolled in OPTIMIZE.

Methods: Infection data was aggregated from 157 adult patients (n=75 MAC, n=82 RIC/NMA), who were fully evaluable for the primary endpoint and comprised patients enrolled in both stages of the 2-stage trial design, stratified by conditioning intensity. Infection surveillance and prophylaxis were according to institutional guidelines. Infections were graded using Blood and Marrow Transplant Clinical Trial Network (BMT CTN) criteria. Infection density was calculated as number of infections per 100 days at risk for enrolled patients. Infections occurring within 30 days after acute GvHD diagnosis were considered GvHD-related. Infection density with 95% confidence intervals (CI) were estimated using Poisson regression models; $p<0.05$ was considered statistically significant for differences in infection density by post-HCT time or conditioning intensity.

Results:

Figure 1. Infectious Sequelae in Patients Enrolled in OPTIMIZE

A Density of BMT CTN Grade 2-3 infections within 100 days by conditioning intensity

Sinus and/or Resp tract, Upper	1	1	0	0	0	0	0	0
Urinary tract, Upper	1	1	0	0	0	0	0	0

Median patient age was 46 (19-64) and 66 (22-78) years for MAC and RIC/NMA strata, respectively. Cytomegalovirus (CMV) serostatus was similar by conditioning intensity. By D100, 37% enrollees, 44% receiving MAC and 30% receiving NMA/RIC, experienced 101 BMT CTN Grade 2-3 infections (n=64 MAC, n=37 RIC/NMA). Infection density was

statistically higher between Days 0-30 versus Days 31-100 overall and within each conditioning intensity stratum (Figure 1A). Notably, MAC Days 0-30 infection density was significantly higher than RIC/NMA (p=0.044), but not between Days 31-100 (Figure 1A). The most common sites of BMT CTN Grades 2-3 infection were blood (n=52), lower gastrointestinal (GI) tract (n=13), and lung (n=11) (Figure 1B). Non-respiratory viruses were the most frequent pathogen type in patients receiving either MAC (n=30 infections) or RIC/NMA (n=16 infections) (Figure 1C). Gram-positive (n=16) and gram-negative (n=13) bacteria were the next most common pathogen types. CMV (MAC n=18, RIC/NMA n=8), Clostridioides difficile (MAC n=4, RIC/NMA n=3), and Escherichia coli (MAC n=4, RIC/NMA n=5) were the most frequent isolates for each of the respective pathogen types (data not shown). The most common site for the 12 acute GvHD-related BMT CTN Grades 2-3 infections was blood (n=9) (Figure 1D), and CMV (n=6) was the most common isolate (data not shown). Grades 3-4 acute GvHD-associated infections were similar by site (Figure 1D) and pathogen (data not shown).

Conclusions: Taken together, these preliminary results suggest potential difference in impact of PTCy dose reduction between MAC and RIC in the MMUD setting with respect to infection burden. Whether these preliminary observations translate into higher IFS for patients enrolled on OPTIMIZE will be addressed with data forthcoming on the study's primary endpoint.

RISK STRATIFICATION FOR EARLY EBV REACTIVATION AFTER PEDIATRIC ALLO-HSCT: DEVELOPMENT OF A CLINICAL SCORING SYSTEM

Senlin Zhang[1], Jun Lu[1], Jie Li[1], Yanhua Yao[1], Junjie Fan[1], Peifang Xiao[1], ***Shaoyan Hu***[1]
[1]*Children's Hospital of Soochow University, Suzhou, China*

Background: Epstein–Barr virus (EBV) reactivation is a clinically significant complication after pediatric allogeneic hematopoietic stem cell transplantation (allo-HSCT). Early

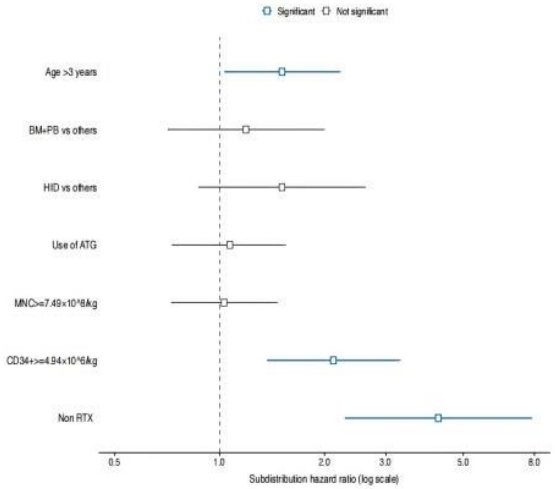
identification of high-risk patients is essential for optimizing monitoring intensity and pre-emptive therapy. This study aimed to develop and validate a simple clinical risk score to predict early EBV reactivation in children undergoing allo-HSCT.

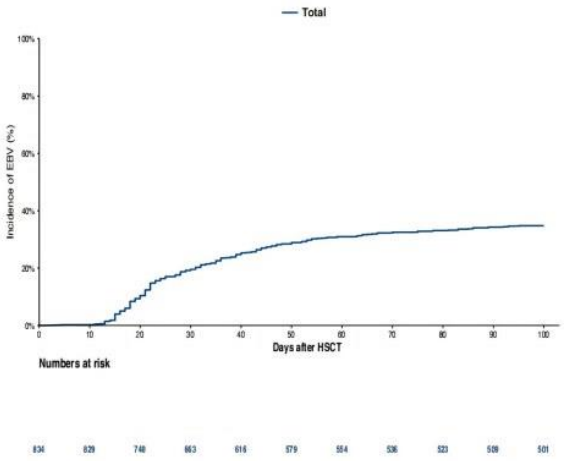
Methods: A total of 834 pediatric patients receiving allo-HSCT at Children's Hospital of Soochow University were retrospectively analyzed. Patients transplanted between 2010–2020 (n=488) served as the training cohort, and those transplanted between 2021–2024 (n=346) as the validation cohort. EBV reactivation was defined as two consecutive EBV DNAemia measurements exceeding 500 copies/mL. EBV reactivation within 100 days post-transplant was evaluated using competing-risk models. Variables with $P<0.05$ in multivariable Fine–Gray analysis were incorporated into a weighted risk-scoring system and validated temporally.

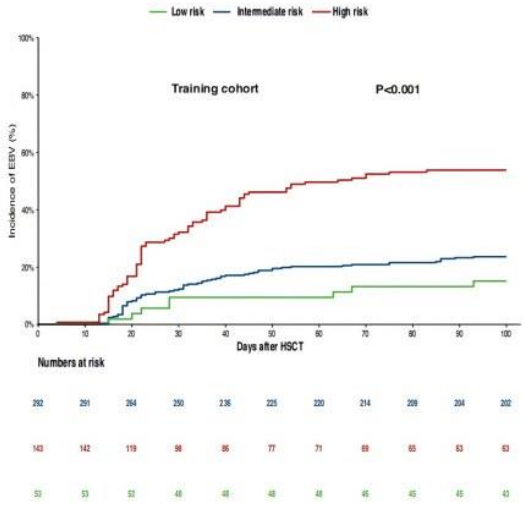
Results: Baseline characteristics differed significantly between the two cohorts, reflecting temporal evolution in transplant practices. The validation cohort exhibited higher rates of rituximab use (39.1% vs. 18.0%), ATG-containing conditioning (96.5% vs. 58.8%), haploidentical donors (75.1% vs. 50.8%), and PB grafts (44.2% vs. 22.5%), along with a greater proportion of older children (>11 years: 30.3% vs. 19.7%). Cord blood use markedly declined (2.0% vs. 26.0%). CMV and EBV serostatus were similar between cohorts. The overall cumulative incidence of EBV reactivation by day 100 in the entire cohort was 37.7%. Multivariable analysis identified three independent predictors of EBV reactivation: age >3 years, omission of rituximab in conditioning, and $CD34^+$ cell dose $>4.94\times10^7$/kg. A weighted score (2, 4, and 2 points) stratified patients into low- (0–3), intermediate- (4–6), and high-risk (7–8) groups, with corresponding 100-day EBV incidences of ~15.1%, ~23.6%, and ~53.8% ($P<0.001$). Findings were consistent in the validation cohort (5.0% vs 32.9% vs 56.8%, $P<0.001$), demonstrating temporal robustness.

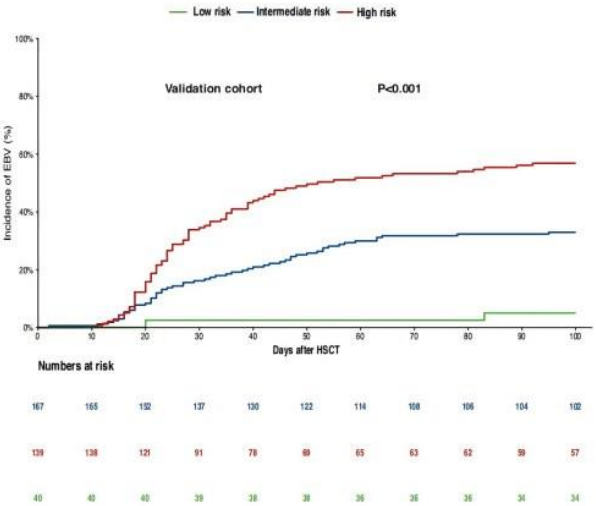
Factor	Univariable analysis
	HR (95% CI)
Male vs female	1.010 (0.731–1.400)
Age >3 year	1.700 (1.170–2.480)
Malignant vs non-malignant	0.913 (0.643–1.300)
MAC vs (RIC/NMA)	0.884 (0.610–1.280)
BM+PB vs others	2.120 (1.520–2.950)
ABO matched vs mismatched	1.160 (0.847–1.590)
HLA matched vs mismatched	1.200 (0.849–1.690)
HID vs others	2.180 (1.560–3.060)
EBV serostatus positive(R)	1.050 (0.418–2.630)

CMV serostatus positive (R)	0.573 (0.246–1.340)
ATG, yes vs no	1.460 (1.040–2.050)
Ara-c, yes vs no	0.880 (0.639–1.210)
TBI, yes vs no	1.040 (0.579–1.880)
MNC≥7.49×10^8/kg	1.390 (1.010–1.900)
CD34+≥4.94×10^6/kg	2.580 (1.840–3.620)
RTX, no vs yes	3.350 (1.830–6.120)









Conclusions: We developed and validated a practical three-factor score that reliably discriminates EBV reactivation risk after pediatric allo-HSCT and may support individualized surveillance and prophylactic strategies. The absence of external validation remains a limitation, underscoring the need for future multicenter prospective studies.

Clinical Trial Registry: None.

ADENOVIRUS IN THE ERA OF INCREASING ALTERNATE DONOR HSCT: OUTCOMES, PREDICTORS, AND THERAPEUTIC RESPONSE OVER THE LAST DECADE

Krithika Krishnakumar[1], *Nithya Sheshadri*[1], *Vijayshree Muthukumar*[1], *Minakshi Balwani*[1], *Kavitha Ganesan*[1], *Vidhya Krishna*[1], *Indira Jayakumar*[1], *Ramya Uppuluri*[1], *Revathi Raj*[1]
[1]*Apollo Specialty Hospital, Chennai, India*

Background: Adenoviral reactivation represents a serious infectious complication in children undergoing hematopoietic stem cell transplantation (HSCT), particularly with increasing reliance on alternate donor transplantation. Immunosuppression, delayed immune recovery, and intensive conditioning regimens are recognized contributors to increased susceptibility. This study aimed to determine the incidence, risk factors, management, and clinical outcomes associated with adenoviral reactivation in children undergoing alternate donor HSCT.

Methods: This retrospective observational study included patients up to 25 years of age who underwent alternate donor HSCT between July 2014 and June 2025. Indications included hemoglobinopathies, inborn errors of immunity (IEI), inborn errors of metabolism (IEM), bone marrow failure syndromes (BMFS), and malignancies. Clinical data was obtained from medical records, including transplant type, conditioning regimen, graft-versus-host disease (GVHD) prophylaxis, virological monitoring, and therapeutic interventions. All patients underwent weekly multiplex polymerase chain reaction (PCR) surveillance for cytomegalovirus (CMV), Epstein–Barr virus (EBV), and adenovirus until Day 100 post-transplant. Adenoviral reactivation prompted a 50% reduction in immunosuppression and initiation of weekly cidofovir at 5 mg/kg.

Results: A total of 1,245 HSCTs were performed during the study period, of which 700 (56.2%) were alternate donor transplants. Adenoviral reactivation occurred in 77 patients, reflecting an incidence of 11%. The median age at transplantation was 8.4 years (range: 7 months–22 years), with a male-to-female ratio of 1.2:1. Underlying diagnoses included hemoglobinopathies (n=27), IEI (n=18), malignancies (n=16), BMFS (n=11), and IEM (n=5).
Haploidentical HSCT using post-transplant cyclophosphamide (PTCY) demonstrated the highest association with adenoviral reactivation (59.7%), followed by TCR α/β–depleted

haploidentical grafts (19.5%) and matched unrelated donor transplants (13%) (p<0.001). Myeloablative conditioning was significantly associated with higher incidence compared with reduced-intensity conditioning **(67.5%, p=0.004)**. The median time to detection was 45 days post-HSCT, with viral load ranging from 135 to 7.95×10^7 copies/ml. Acute GVHD occurred in 59.7% of the cohort, and 53.2% required escalation of immunosuppression in the week preceding reactivation. Lymphopenia was common, with 57.1% demonstrating Day-30 absolute lymphocyte count below 500/µL.
One-third of patients cleared the virus following immunosuppression modification alone, while 66% received a median of 3 doses of cidofovir (range: 1–11). Co-infections were prevalent: CMV (61%), BK virus (15.6%), and EBV (13%). Overall survival was 62.3%, with a median follow-up of 27.5 months.

Conclusions: Adenoviral reactivation occurred in 11% of alternate donor HSCT recipients with a mortality rate of 31.1%. Myeloablative conditioning and PTCY-based haploidentical transplantation were significant risk factors. Early immune reconstitution, particularly achieving adequate lymphocyte recovery by Day 30, appears critical in reducing risk. Strengthened post-transplant surveillance and optimized immune-modulatory strategies may improve outcomes in this high-risk group.

IMPACT OF INTERLEUKIN-6 DYNAMICS ON INFECTION SEVERITY AND CLINICAL OUTCOMES IN PATIENTS WITH HEMATOLOGICAL MALIGNANCIES UNDERGOING INTENSIVE THERAPY AND ALLOGENEIC STEM CELL TRANSPLANTATION

Paul Gustav Thomas Meisen[1], Jonathan Bobak[1], Felicitas Schulz[1], Nora Liebers[1], ***Ben-Niklas Baermann***[1]*, Sören Twarock[1], Alexander Hölscher[1], Kathrin Nachtkamp[1], Annika Kasprzak[1], Felix Matkey[1], Titus Watrin[1], Malika El Yaouti[1], Ulrich Germing[1], Sascha Dietrich[1], Guido Kobbe[1], Paul Jäger[1]*
[1]University Hospital Düsseldorf, Düsseldorf, Germany

Background: Infectious and inflammatory complications remain a major cause of morbidity and non-relapse mortality in patients with hematological malignancies undergoing intensive chemotherapy or allogeneic stem cell transplantation (allo-SCT). Early recognition of clinically relevant inflammatory events is challenging in immunocompromised patients, as clinical signs and routinely used biomarkers such as C-reactive protein (CRP) often show delayed or nonspecific responses. Interleukin-6 (IL-6) is a rapidly responding proinflammatory cytokine and may provide earlier and prognostically relevant information during severe inflammatory events. This study evaluated the diagnostic and prognostic relevance of IL-6 dynamics in a real-world cohort of high-risk hematological patients.

Methods: We conducted a retrospective, monocentric cohort analysis including 81 patients with hematological malignancies treated between 2020 and 2024. All patients experienced

clinically significant inflammatory events graded CTCAE ≥3, defined by a documented IL-6 increase to ≥100 pg/ml. Patients were treated with intensive chemotherapy or in the peri-transplant setting after allo-SCT. Serial IL-6 measurements were analyzed in relation to inflammatory kinetics, initiation or escalation of antibiotic therapy, microbiologically documented infections, intensive care unit (ICU) admission, and overall survival (OS). IL-6 dynamics were compared with CRP and procalcitonin (PCT) where available. Predictive performance for ICU admission and mortality was assessed using receiver operating characteristic (ROC) analyses.

Results: Eighty-one patients (median age 59.8 years) were analyzed; 72/81 (88.9%) were in the allo-SCT setting. IL-6 elevation preceded conventional biomarkers, rising approximately 24–48 hours before a clinically relevant CRP increase. IL-6 kinetics were rapid, with a median of 24.0 hours from the last IL-6 value <100 pg/ml to the first rise ≥100 pg/ml and 24.9 hours from first rise to peak, illustrating distinct kinetic patterns between resolving and fatal inflammatory courses (Figure 1A).
IL-6 peak levels identified patients at risk for severe clinical deterioration: IL-6 peak predicted ICU admission with an AUC of 0.763; an optimal cut-off of 1736 pg/ml yielded 74.2% sensitivity and 71.9% specificity (negative predictive value 80.5%) (Figure 1B).
IL-6 clearance was the strongest outcome discriminator. All patients with documented IL-6 normalization below 100 pg/ml survived, whereas all patients without IL-6 decline died, and most required ICU care. IL-6 peak showed the highest prognostic accuracy for mortality (AUC 0.80), followed by later IL-6 measurements (AUC 0.78), while early single measurements were less informative. Rapid IL-6 increases (ΔIL-6 >1346 pg/ml early or >2600 pg/ml to peak) were associated with fatal outcome. Mortality increased with delayed or absent IL-6 decline (<72 h: 11.1%; >72 h: 26.9%; no decline: 100%).

Conclusions: IL-6 dynamics provide early and clinically meaningful information during severe inflammatory events in patients with hematological malignancies undergoing intensive therapy or allo-SCT. IL-6 rises earlier than CRP, defined IL-6 cut-offs identify patients at imminent risk for ICU admission, and IL-6 clearance versus non-clearance stratifies distinct survival phenotypes. To validate these findings, an ongoing analysis of approximately 500 patients after allo-SCT with longitudinal IL-6 data is underway, aiming to confirm the dissertation-derived thresholds and develop clinically applicable IL-6–guided decision algorithms in the post-transplant setting.

PRE-TRANSPLANT CLOSTRIDIOIDES DIFFICILE INFECTION: A TIMING-DEPENDENT PREDICTOR OF GI GVHD AND EARLY MORTALITY IN ALLOGENEIC HSCT RECIPIENTS

Wenyi Wang[1,2,3], *Yibo Wu*[1,2,3], *Yunbo Chen*[4], *Xiaoyu Lai*[1,2,3], *Lizhen Liu*[1,2,3], *Jimin Shi*[1,2,3], *Yanmin Zhao*[1,2,3], *Luxin Yang*[1,2,3], *Lin Li*[1,2,3], *Jian Yu*[1,2,3], *Huarui Fu*[1,2,3], *Panpan Zhu*[1,2,3], *He Huang*[1,2,3], *Yi Luo*[1,2,3]

[1]*Bone Marrow Transplantation Center of The First Affiliated Hospital & Liangzhu Laboratory, Zhejiang University School of Medicine, Hangzhou, China,* [2]*Institute of Hematology, Zhejiang University, Hangzhou, China,* [3]*Zhejiang Province Engineering Research Center for Stem Cell and Immunity Therapy, Hangzhou, China,* [4]*State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, The First Affiliated Hospital, School of Medicine, Zhejiang University, Hangzhou, China*

Background: *Clostridioides difficile* infection (CDI) is a frequent complication following allogeneic hematopoietic stem cell transplantation (allo-HSCT), yet its impact on post-transplant outcomes remains controversial. Therefore, this study aimed to evaluate the risk factors for CDI and its association with early post-transplant complications and overall clinical outcomes.

Methods: This retrospective, single-center study included patients who underwent allo-HSCT at our center between January 2021 and December 2023 and experienced diarrhea in the peri-transplant period (from conditioning to discharge from laminar flow). Stool screening for *C. difficile* was routinely performed for all patients who developed diarrhea during the peri-transplant period. CDI was defined as the occurrence of diarrhea (three or more unformed stools within a 24-hour period) accompanied by a positive stool test result for *C. difficile*.

Results: A total of 593 patients was included in the study. Among these diarrheic recipients, 64 patients developed CDI. The cumulative incidence of CDI was 12.1% (95% CI, 9.5%-15.1%), with a median onset of day -1 (range, -7 to +26) relative to HSCT. Multivariate analysis revealed that older age was independently associated with a lower risk of CDI (HR, 0.97; 95% CI, 0.96-0.99; P = 0.006). No significant association was found between overall CDI and gastrointestinal acute graft-versus-host disease (GI aGVHD), severe infection or 100-day non-relapse mortality (NRM) in both univariate analysis or multivariate analysis. However, the timing of CDI dramatically influenced prognosis. When patients were stratified by the median onset time of CDI, pre-transplant CDI was suggestive of a trend toward an increased risk of grade 1-4 GI aGVHD, grade 2-4 GI aGVHD in the univariate model (Table 1). Multivariate analysis confirmed pre-CDI as an independent risk factor for grade 1-4 (HR, 2.46; P=0.022) and grade 2-4 (HR, 2.32; P=0.048) GI aGVHD (Table 1). Moreover, pre-transplant CDI conferred a substantially elevated risk of severe fungal infection (HR, 7.65; P=0.007) and 100-day NRM (HR, 3.26; P=0.044).

Table 1

Variables	Univariate		Multivariate	
	HR (95%CI)	p	HR (95%CI)	p
Grade 1-4 GI aGVHD				
CDI before HSCT		0.033		0.022
No	Reference		Reference	
Yes	2.29 (1.07, 4.92)		2.46 (1.14, 5.30)	
CDI after HSCT		0.307		-
No	Reference		-	
Yes	0.36 (0.05, 2.58)		-	
Grade 2-4 GI aGVHD				
CDI before HSCT		0.07		
No	Reference		Reference	0.048
Yes	2.16 (0.94, 4.95)		2.32 (1.01, 5.34)	
CDI after HSCT		0.357		-
No	Reference		-	
Yes	0.39 (0.05, 2.86)		-	

Conclusions: Our study demonstrates that the timing of onset is a critical determinant of the adverse impact of CDI on severe complications and mortality in diarrheic allo-HSCT recipients. Further prospective studies are warranted to investigate targeted prevention or pre-emptive management of pre-transplant CDI to improve transplant outcomes.

HHV-6B INFECTION ADVERSELY IMPACTS OUTCOMES AFTER ALLOGENEIC STEM CELL TRANSPLANTATION: A MULTICENTER, CASE-CONTROL STUDY

*Luxiang Wang[1], Zhang Ruoxuan[2], Xueqi Xie[3], Yu Yi[4], **Jiayu Huang**[1], Chuanhe Jiang[1], Haiyang Lu[1], Zengkai Pan[1], Gaoxiang Wang[2], Yang Yang[2], Weijie Cao[3], Hua Jin[5], Shilin Gan[6], Xiaofan Li[7], Wei Shi[8], Yanmin Zhao[4], Yang Cao[2], Xiaoxia Hu[1]*
[1]Ruijin Hospital affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai,

China, [2]Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China, [3]The First Affiliated Hospital of Zhengzhou University, Zhengzhou, China, [4]The First Affiliated Hospital & Liangzhu Laboratory, Zhejiang University School of Medicine, Hangzhou, China, [5]Nanfang Hospital, Southern Medical University, Guangzhou, China, [6]Gobroad Research Center, Shanghai, China, [7]Fujian Medical University Union Hospital, Fujian, China, [8]Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China

Background: Latent human herpesvirus 6B (HHV-6B) can reactivate in patients with hematologic diseases who have undergone allogeneic hematopoietic stem cell transplantation (allo-HCT). Its impact on post-transplant outcomes, particularly in haploidentical (HID) allo-HCT–dominant cohorts, however, is unclear.

Methods: In this multi-center retrospective study, we conducted a case-control study from December 2019 to January 2025 to evaluate clinical outcomes and risk factors of adult patients receiving allo-HCT with different type of HHV-6B reactivation. 112 patients were included in the HHV-6B reactivation group, with a one-to-four ratio matched to the control group. 27 patients diagnosed with HHV-6B encephalitis were classified as HHV-6B encephalitis^{pos} group, and the rest 85 patients in the HHV-6B reactivation group were defined as HHV-6B encephalitis^{neg} group.

Results: After inverse propensity weighting, the 1-year OS was significantly lower in the HHV-6B group (74.4% [95% *CI*: 65.4–84.6%]) compared to controls (88.7% [95% CI: 85.3–92.1%], *P*<0.001), while the 1-year NRM was significantly higher in the HHV-6B group (20.3% [95% *CI*: 16.0–24.5%]) compared to controls (6.7% [95% CI: 5.0–8.3%], *P* < 0.001). The 1-year relapse rates were comparable between groups (3.4% [95% *CI*: 1.5–5.3%] *vs*. 4.8% [95% CI: 3.4–6.2%], *P*=0.27). However, the 1-year OS and NRM rates were not statistically different between the encephalitis^{pos} and encephalitis^{neg}groups (OS: 61.8% [95% *CI*: 45.7%–83.6%] *vs.* 77.2% [95% *CI*: 67.6%–88.1%], *P*=0.079; NRM: 33.9% [95% *CI*: 13.1%–49.7%] *vs*. 21.1% [95% *CI*: 10.6%–20.3%], *P*=0.12). Propensity score–weighted multivariable logistic regression identified hematopoietic cell transplantation–specific comorbidity index (OR, 2.075; 95% *CI*: 1.002–4.295; *P*=0.04), donor-specific antibody (OR, 2.336; 95% *CI*: 1.087–5.02; *P*=0.03), platelet engraftment failure (OR, 4.190; 95% *CI*: 1.147–15.306; *P*=0.03), and steroid-refractory acute graft-versus-host disease (OR, 3.024; 95% *CI*: 1.548–5.904; *P*=0.001) as risk factors for HHV-6B infection. Landmark Cox regression analyses using a 180-day cut-off showed that HHV-6B infection (HR, 1.825; 95% *CI*: 0.879–3.788; *P*=0.016), platelet engraftment (HR, 3.812; 95% *CI*: 1.625–8.945; *P*=0.002) and grade II–IV aGvHD (HR, 2.632; 95% *CI*: 1.243–5.574; *P*=0.011) were associated with reduced OS within the first 180 days post-transplant, but not thereafter. Based on a nomogram for HHV-6B infection prediction, 107 patients were categorized as high risk (HR; ≥80th percentile), and 453 as low risk (LR). This stratification correctly identified 87% of patients without HHV-6B infection and 49.5% with infection. Patients in the HR group had a significantly higher likelihood of HHV-6B infection compared to the LR group (odds ratio, 6.55; 95% *CI*: 4.1–10.4; *P*<0.001).

	HR (95%CI)	***p*-value**

Group		
non-HHV-6B infectio	Reference	
HHV-6B infection	1.825 (0.879–3.788)	0.016
Grades II–IV aGvHD		
No	Reference	
Yes	2.632 (1.243–5.574)	0.011
Platelet engraftment

VIROLOGIC OUTCOMES BY BASELINE CMV VIRAL LOAD IN HCT RECIPIENTS TREATED WITH MARIBAVIR: POST HOC ANALYSIS OF PHASE 2 AND 3 TRIALS

Genovefa A. Papanicolaou[1,2], *Robin K. Avery*[3], *Michael Boeckh*[4], *Wendy Chao*[5], *Joan Gu*[5], *Tien Bo*[5]
[1]*Memorial Sloan Kettering Cancer Center, New York, United States of America (the),* [2]*Weill Cornell Medicine, New York, United States of America (the),* [3]*Johns Hopkins University, Baltimore, United States of America (the),* [4]*Fred Hutchinson Cancer Center, Seattle, United States of America (the),* [5]*Takeda Development Center Americas, Inc., Cambridge, United States of America (the)*

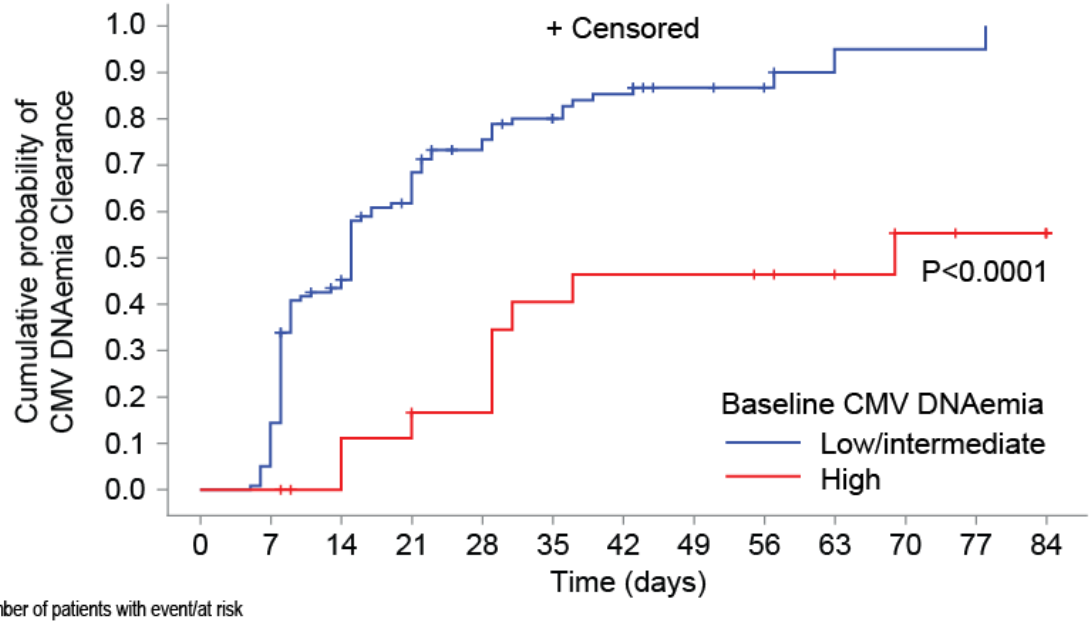
Background: In hematopoietic cell transplant (HCT) recipients, cytomegalovirus (CMV) viral load is a predictor of CMV disease and mortality in the context of severe immunosuppression. Higher baseline CMV DNAemia (viral load) has been associated with delayed DNAemia clearance in addition to host factors. Maribavir is an oral benzimidazole riboside antiviral approved for refractory CMV infection post transplant. This analysis examined virologic and safety outcomes by baseline DNAemia in HCT recipients with refractory CMV infection treated with maribavir in clinical trials.

Methods: We conducted an exploratory, post hoc analysis of two maribavir trials in HCT recipients with refractory CMV infection: a phase 2, dose-ranging study (1263-202; SHP620-202; NCT01611974) and a phase 3 study versus investigator-assigned therapy (SOLSTICE; NCT 02931539). Patients received maribavir for up to 24 weeks in study 202 and 8 weeks in SOLSTICE. Analyses were restricted to maribavir-treated patients. Baseline plasma CMV DNAemia was categorized as low/intermediate (study 202: <10,000 copies/mL; SOLSTICE: <91,000 IU/mL) or high (study 202: ≥10,000 copies/mL; SOLSTICE: ≥91,000 IU/mL). Efficacy endpoints included DNAemia clearance by week 8 and at any time on study. Safety endpoints included the incidence of adverse events (AEs), treatment-emergent AEs (TEAEs), and AEs leading to treatment interruption or discontinuation, or death. Outcomes were summarized descriptively by DNAemia category. Time to CMV DNAemia clearance at any time during the study was assessed by DNAemia category using Kaplan-Meier analysis with log-rank testing.

Results: A total of 138 maribavir-treated HCT patients were included, of whom 118 (85.5%) had low/intermediate and 20 (14.5%) had high baseline plasma CMV DNAemia. Median (range) age was 55.0 (19-77) and 60.5 (26-69) years in the low/intermediate and high DNAemia groups, respectively; 52.5% and 55.0% were male. By week 8, a higher proportion of patients with low/intermediate versus high baseline DNAemia achieved DNAemia clearance (64.4% vs 40.0%, respectively). DNAemia clearance was observed beyond week 8 (Figure). At any time during the study, DNAemia clearance was achieved in 82.2% of the low/intermediate DNAemia group and 45.0% of the high DNAemia group. Time to first DNAemia clearance was significantly shorter for patients with low/intermediate versus high

baseline DNAemia (P<0.0001; Figure). Overall, AE incidence was similar between DNAemia groups; however, AEs leading to treatment interruption or discontinuation, or death, occurred more frequently among patients with high versus low/intermediate baseline DNAemia (Table).

Figure. Inverse Kaplan-Meier curve for time to first confirmed undetectable CMV DNAemia at any time during the study up to Week 12 (Day 84) by baseline DNAemia category



Number of patients with event/at risk

Low/intermediate (n=118)	0/118	17/112	36/63	25/40	7/24	4/17	4/11	1/6	0/5	2/2	0/1	0/1	1/0
High (n=20)	0/20	0/20	2/18	1/16	0/14	4/10	1/9	0/9	0/8	0/7	1/4	0/3	0/3

DNAemia categories were determined using the definition from the respective studies: low/intermediate: study 202: <10,000 copies/mL; SOLSTICE: <91,000 IU/mL; high: study 202: ≥10,000 copies/mL; SOLSTICE: ≥91,000 IU/mL.

Table. Safety data for HCT recipients with refractory CMV by baseline DNAemia category

	Low/intermediate DNAemia (n=118)	High DNAemia (n=20)
Patients with AEs, n (%)	118 (100)	20 (100)
Number of AEs, n	1859	277

Patients with TEAEs, n (%)	117 (99.2)	20 (100)
Number of TEAEs, n	1224	261
Mild, n (%)[a]	699 (57.1)	116 (44.4)
Moderate, n (%)[a]	395 (32.3)	102 (39.1)
Severe, n (%)[a]	115 (9.4)	34 (13.0)
Maximal, n (%)[a]	15 (1.2)	9 (3.4)
Patients with AEs resulting in death, n (%)	28 (23.7)	9 (45.0)
Patients with serious TEAEs, n (%)	57 (48.3)	16 (80.0)
Patients with discontinuations of study drug due to AEs, n (%)	27 (22.9)	10 (50.0)
Patients with study drug interruptions due to AEs, n (%)	11 (9.3)	6 (30.0)

[a]Percentages calculated from the total number of TEAEs.
AE, adverse event; TEAE, treatment emergent adverse event

Conclusions: In this post hoc analysis of maribavir-treated HCT recipients with refractory CMV infection, a higher proportion of patients with low/intermediate baseline CMV DNAemia achieved DNAemia clearance, and more rapidly, than those with high baseline DNAemia, without an increase in overall AE frequency. These data reflect a population with complex treatment needs, especially in those with high DNAemia, and further research is warranted to determine if early identification and initiation/switch to maribavir could improve clinical outcomes in patients with refractory post-HCT CMV infection.

PROGNOSTIC IMPLICATIONS OF CMV INFECTION/DISEASE AND HHV-6 ENCEPHALITIS IN CORD BLOOD TRANSPLANT RECIPIENTS RECEIVING FOSCARNET

Shogo Matsui[1], *Hisashi Yamamoto*[1], *Mika Kuno*[1], *Otoya Watanabe*[1], *Kyosuke Yamaguchi*[2], *Kosei Kageyama*[2], *Daisuke Kaji*[1], *Yuki Taya*[2], *Aya Nishida*[1], *Shinsuke Takagi*[1], *Yuki Mori*[1], *Go Yamamoto*[1], *Atsushi Wake*[2], *Shuichi Taniguchi*[1], *Naoyuki Uchida*[1]
[1]*Toranomon Hospital, Tokyo, Japan,* [2]*Toranomon Hospital Kajigaya, Kanagawa, Japan*

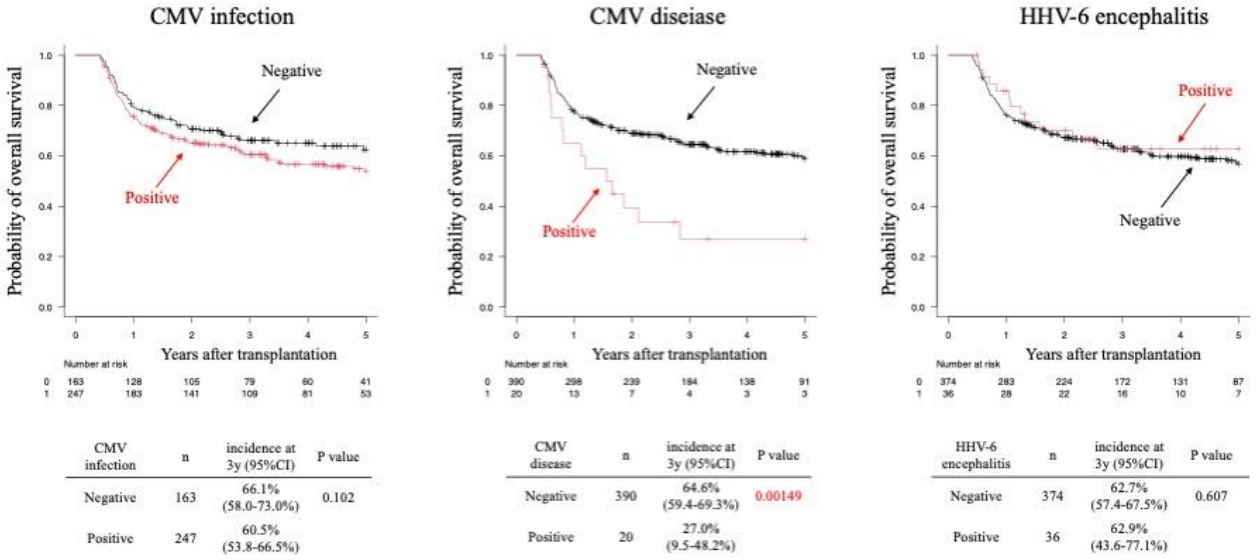
Background: Cytomegalovirus (CMV) infection remains an important post-transplant complication despite improved management. Human herpesvirus 6 (HHV-6) encephalitis is another severe infectious disease with high incidence in cord blood transplantation (CBT). Foscarnet (FOS) is an effective therapeutic agent against CMV infection and HHV-6 encephalitis; however, large-scale studies evaluating prophylactic FOS use in CBT are limited.

Methods: We retrospectively analyzed patients who underwent first single-unit CBT between 2016 and 2022 and received prophylactic FOS (120 mg/kg/day). FOS was planned from day 7 to day 50 post-transplant, with modification at physician discretion. Prophylactic administration of letermovir was not performed. Tacrolimus and mycophenolate mofetil were used for GVHD prophylaxis.
Primary endpoints were the cumulative incidence of CMV infection and its impact on relapse, non-relapse mortality (NRM), and overall survival (OS). Secondary endpoints included the incidence of CMV disease and HHV-6 encephalitis, as well as their impact on clinical outcomes. Multivariate analyses included age, disease, year of transplant, conditioning regimen, remission status, performance status, HCT-CI, HLA mismatch, total body irradiation use, and development of grade II-IV acute graft-versus-host disease (aGVHD).
Landmark analyses using events by day 150 were performed to assess the impact of CMV infection, CMV disease, HHV-6 encephalitis, and aGVHD.
The log-rank test was used to compare OS. Cumulative incidence was compared using Gray tests. Death was considered as a competing event. Fine-Gray or Cox proportional hazards models were used for multivariate analysis.
Reasons for early discontinuation of FOS (<30 days) were also assessed.

Results: A total of 491 patients were included. The cumulative incidence of CMV infection by day 150 was 53.5%. CMV infection was more common in patients aged ≥60 years (51.0% vs. 37.1%, p<0.01) and those who received reduced-intensity conditioning (20.4% vs. 11.3%, p<0.01).
In univariate analysis, CMV infection was not significantly associated with 3-year cumulative incidence of relapse (15.7% vs. 16.2%, p=0.77) or OS (60.5% vs. 66.1%, p=0.102), but was associated with higher NRM (23.9% vs. 15.5%, p=0.023). However, multivariate analysis showed no independent association between CMV infection and relapse, NRM, or OS. The cumulative incidence of CMV disease by day 150 was 4.1%. Among the 20 cases that developed CMV disease within 150 days, the disease types were gastrointestinal disease (15 cases), pneumonia (3 cases), and encephalitis (2 cases). Although CMV disease did not significantly affect relapse, it was associated with markedly higher NRM (57.9% vs. 18.5%, p<0.01) and inferior OS (27.0% vs. 64.6%, p<0.01). The cumulative incidence of HHV-6 encephalitis by day 150 was 9.2%. HHV-6 encephalitis had no significant impact on NRM (23.4% vs. 20.4%, p=0.965) or OS (62.9% vs. 62.7%, p=0.607). FOS was discontinued within 30 days in 204 patients (41.5%), mainly due to renal dysfunction (155; 75.5%), which improved in 122 patients (79.2%) after cessation.

		CMV reactivation		
Characteristic	**Group**	**Negative n = 186 (%)**	**Positive n = 304 (%)**	***P***
Age	<60	117 (62.9)	149 (49.0)	0.003
	60≦	69 (37.1)	155 (51.0)	
Disiase	AML	127 (68.3)	212 (69.7)	0.403
	ALL	34 (18.3)	43 (14.1)	
	MDS	25 (13.4)	49 (16.1)	
Conditioning regimen	Myeloablative	165 (88.7)	242 (79.6)	0.009
	Reduced intensity	21 (11.3)	62 (20.4)	
Remission status	CR	56 (30.1)	87 (28.6)	0.759
	non-CR	130 (69.9)	217 (71.4)	
Performance status	0,1	170 (91.4)	275 (90.5)	0.872
	2	16 (8.6)	29 (9.5)	

Characteristic	Group	CMV reactivation Negative n = 186 (%)	Positive n = 304 (%)	*P*
HCT-CI	0	66 (35.5)	113 (37.2)	0.928
	1,2	77 (41.4)	121 (39.8)	
	≧3	43 (23.1)	70 (23.0)	
HLA mismatch	≦2	64 (34.4)	116 (38.2)	0.44
	3≦	122 (65.6)	188 (61.8)	
TBI	Absent	133 (71.5)	204 (67.1)	0.317
	Present	53 (28.5)	100 (32.9)	



Conclusions: In CBT with prophylactic FOS, CMV infection was associated with higher NRM, with CMV disease showing a more pronounced impact and adversely affecting OS. Although prophylactic FOS did not sufficiently prevent HHV-6 encephalitis, its occurrence did not affect outcomes.

Background: Bronchoscopy (BS) with bronchoalveolar lavage (BAL) is widely used for diagnosing lower respiratory tract infections (LRTI). Lack of standardisation in BAL procedures makes it difficult to compare the diagnostic performance of BAL across studies.

Methods: We conducted a survey to identify BS/BAL practices in allogeneic hematopoietic cell transplantation (allo-HCT) recipients with LRTI in EBMT transplant centres.

Results: The response rate was 113/653 (17%) from adult centres (n=57), paediatric centres (n=26), and mixed centres (n=30).
In 111/113 (98%) centres, BAL is performed in patients with clinical symptoms of LRTI and CT findings, especially when undetermined aetiology after non-invasive tests (92/113; 81%). Specific contraindications are a risk for patients being/remaining intubated after BAL (45/111; 41%) and thrombocytopenia <20 x10^9/l, refractory to platelet transfusion (21/111; 19%).
Less than 100 ml of fluid is instilled in 27/82 adult centres (33%), while 100-200 ml is instilled in 52/82 (63%). 34/97 (35%) centres systematically analyse bronchial aspirate in addition to BAL fluid (BALf).
A microbiologist/infectious diseases expert is involved in the decision on which tests to perform in 65/111 (59%) centres, while a routine set of microbiological tests is applied in 46/111 (41%).
Standard tests performed in BALf either routinely or on demand include: PCR multiplex pneumonia panels covering respiratory viruses either alone or together with bacteria (101/109; 93%), PCR assays in single-plex or oligoplex formats (89/106 centres; 84%), and detection of genotypic resistance markers when appropriate (41/106 centres; 39%).
Standard bacterial culture is performed routinely in 99/104 (95%) centres. Legionella, Mycoplasma, Mycobacterium tuberculosis, and other mycobacteria are routinely tested in 61/104 (59%), 76/105 (72%), 60/102 (59%), and 38/101 (38%) centres, respectively, and only on clinical suspicion in 41/104 (39%), 25/105 (24%), 41/102 (41%), and 56/101 (55%), respectively.
Fungal tests (excluding Pneumocystis) in BAL are performed routinely in 95/103 (92%) centres and include galactomannan (94/102, 92%), culture (79/102; 77%), Aspergillus PCR-qualitative (57/102; 56%), Mucorales PCR-qualitative (39/102; 38%), panfungal PCR-

qualitative (32/102; 31%), Aspergillus PCR-quantitative (25/102; 24%). Pneumocystis jirovecii pneumonia (PJP)-directed tests are performed routinely in BALf in 80/101 (79%) centres, mainly PCR (66/99; 67%). A significant number of centres also apply PJP PCR on bronchial aspirate (66/98; 67%), endotracheal aspirate (51/98; 52%), and sputum (39/98; 40%).
Genotypic and phenotypic antifungal susceptibility testing is performed in 35/101 (35%) and 67/101 (66%) centres either in the centre or sent to a reference centre.
CMV PCR is routinely tested in 80/101 (79%) centres. In 53/99 (53%) centres, the treatment for CMV is based on a PCR flexible threshold in BALf, depending on a clinical situation, whereas in 34/99 (34%) centres, it is based on any positive result without a threshold. The practices concerning tests for EBV, HHV6, and Toxoplasma are summarized in the table.
Respiratory viruses, including Adenovirus, Human metapneumovirus, Influenza, Parainfluenza, Respiratory syncytial virus, and SARS-CoV-2, are routinely tested in 85-96% of centres, regardless of season, in 76/97 centres (78%).

Table 1.
Criteria for testing and treatment of specific pathogens in allo-HCT patients

Pathogens	EBV	HHV6	Toxoplasma
Criteria for testing in BALf in patients with LRTI			
Routinely	43/100 (43%)	34/100 (34%)	24/99 (24%)
Only in patients with interstitial pneumonitis	12/100 (12%)	14/100 (14%)	10/99 (10%)
Only in patients with interstitial pneumonitis and other negative tests	22/100 (22%)	31/100 (31%)	29/99 (29%)
Never	23/100 (23%)	21/100 (21%)	36/99 (36%)
Treatment approach in a specific scenario*			
Always treated	19/78 (24%)	17/77 (22%)	35/65 (54%)
Treated if other plausible co-pathogens were not detected in BAL	18/49 (37%)	22/52 (42%)	8/29 (28%)
Treated if PCR is positive both in BALf and in plasma	10/49 (20%)	12/52 (23%)	5/29 (17%)

Treated based on viral load in BALf - any positive result without the threshold	4/49 (8%)	4/52 (8%)	5/29 (17%)
Treated based on viral load in BALf - we use a specific fixed threshold	2/49 (4%)	2/52 (4%)	2/29 (7%)
Treated based on viral load in BALf - we use a flexible threshold depending on the clinical situation	30/49 (61%)	36/52 (69%)	20/29 (69%)
*Specific clinical scenario: treatment of allo-HCT patient on immunosuppressive therapy with interstitial pneumonitis based on pathogen detection in BALf			

Conclusions: The results of this study reveal differences in practices and highlight the need to harmonize them to enable comparison and optimization of BS/BAL performance.

MOST PATIENTS DON'T NEED COMPLETE REVACCINATION AFTER AUTOLOGOUS PERIPHERAL BLOOD STEM CELL TRANSPLANTATION

Kerstin Schäfer-Eckart[1], Knut Wendelin[1], Johannes Gärtner[1], ***Sabine Dressler***[1]
[1]Klinikum Nürnberg, Paracelsus Medizinische Privatuniversität, Nürnberg, Germany

Background: Autologous peripheral blood stem cell transplantation (ASCT) is a well established treatment modality esp. in patients (pts.) with Multiple Myeloma and Malignant Lymphoma. The preceding conditioning therapy induces profound immunosuppression, which is assumed to result in the loss of acquired immunity, included vaccine-induced protection. Consequently, complete revaccination is currently recommended for patients similar to pts. undergoing allogeneic transplantation, although the supporting evidence is considerably weaker. To our knowledge, no published data are available regarding the actual loss of immunization after autologous transplantation. Given that the duration and degree of immunosuppression are markedly shorter and less pronounced compared to allogeneic transplantation, we hypothesized that immunization titers might be preserved. To test this, we prospectively assessed antibody titers before and after ASCT.

Methods: Serological testing before and after autologous transplant was performed for tetanus-antitoxin, poliovirus-antibodies (type 1 and 3) and antipneumococcal-IgG. Tetanus-antitoxin (IgG) was measured by EIA with a detection limit of 0.03 IE/ml and a protection threshold of 0,1 IE/ml. Poliovirus-antibodies were assessed by neutralisation assay (WHO),

with a protective titer defined as ≥ 1:8. Anti-pneumococcal-IgG was determined by EIA, with a positive threshold of > 3,3 mg/l.

Results: Forty-five patients (pts) were included in the analysis. The median age was 59 years (range, 19–74). Underlying diagnoses included multiple myeloma in 27 pts, non-Hodgkin lymphoma in 13 pts, Hodgkin lymphoma in 4 pts, and germ cell tumor in 1 pt.

In 26 pts, antibody titers against tetanus, poliomyelitis and pneumococci were assessed both before and at a median of 8 months (range, 4–19) after autologous stem cell transplantation (ASCT). Before ASCT, most pts had protective antibody titers against tetanus (24/26 pts.) and pneumococci (22/26pts.). These titers were preserved after ASCT in all but one pt. In contrast, only 13/26 pts had protective antibody titers against poliomyelitis before ASCT, and 3 of these 13 pts lost the protective titers after ASCT.

In 19 pts, only post-ASCT antibody titers were available. Protective titers were observed in 14/19 pts against tetanus and in 12/19 pts against pneumococci, but in only 7/19 pts against poliomyelitis.

Conclusions: Our findings showed a high percentage of patients with protective antibody titers against tetanus and pneumococci, but not against poliomyelitis, both before and after ASCT. Therefore, we conclude that routine complete revaccination of all patients after ASCT is not necessary. A more tailored approach—assessing post-transplant antibody titers and vaccinating only when indicated—may be more appropriate.

Disclosure: No disclosure.

OUTCOME OF CMV PNEUMONIA AFTER HEMATOPOIETIC CELL TRANSPLANTATION IN THE ERA OF MODERN TRANSPLANTATION AND CMV PREVENTION PRACTICES

Alicja Sadowska-Klasa[1,2], *Hu Xie*[1], *Guang-Shing Cheng*[1], *Danniel Zamora*[3,1], *Paul Carpenter*[1], *Wendy Leisenring*[1], *Michael Boeckh*[1]
[1]*Fred Hutchinson Cancer Center, Seattle, United States of America (the),* [2]*Medical University of Gdansk, Gdansk, Poland,* [3]*City of Hope, Duarte, United States of America (the)*

Background: The incidence of early cytomegalovirus (CMV) pneumonia has decreased significantly with the introduction of routine PCR surveillance and next letermovir prophylaxis in allogeneic hematopoietic cell transplantation (HCT) recipients; however, late episodes of the CMV disease still occur and contribute to transplant-related mortality. The aim of this study was to assess CMV pneumonia-related mortality in the modern era of changing transplantation and CMV prevention and diagnostic practices and to evaluate the impact of antiviral therapies and immunoglobulin administration on patient outcomes.

Methods: We retrospectively analyzed the incidence of proven or probable CMV pneumonia (defined according to published criteria) among patients who underwent transplantation between 1986 and 2022 at Fred Hutchinson Cancer Center. In the subset of patients transplanted after 2000, we evaluated recipient, donor, transplant, viral, and treatment-related factors associated with overall and CMV-attributable mortality using Cox regression models. Attributable mortality was defined as death that occurred within 6 months after the day of CMV disease onset with active CMV disease at autopsy and/or respiratory failure, with no other cause directly contributing to the death (Clin Inf Dis 61:31, 2015).

Results: A total of 448 patients were identified, with decreasing numbers over the last 20 years: 133 cases between 2000–2011 and 26 cases between 2012–2022 (Figure 1A). Of these, 141 patients received antiviral treatment, and were included to the detailed analysis. None of the patients with early disease received letermovir prophylaxis. Co-pathogens were detected in bronchoalveolar lavage in 58 cases (41%), and 45 patients (32%) required mechanical ventilation at the time of diagnosis. Furthermore, 28 (20%) were diagnosed with an additional lung condition, such as organizing pneumonia (11%), idiopathic pneumonia syndrome (IPS; 7%), or diffuse alveolar hemorrhage (DAH; 1%).
Outcomes improved significantly after 2000, with the lowest incidence of CMV-related mortality observed in the most recent era at 11% (95% CI, 2.8–27.1%) (Figure 1B). In univariable analysis, female sex, lymphopenia, elevated bilirubin prior to CMV onset, mechanical ventilation, high-dose steroids (>2 mg/kg), and a diagnosis of DAH/IPS were associated with increased overall and CMV-attributable death risk. However, only mechanical ventilation, elevated bilirubin, and female sex remained significant in multivariable models adjusted for year of transplantation (Figure 1C). Over the past two decades, mechanical ventilation rates at the time of diagnosis remained high (2000-2011: 26.3%; 2012-2022: 50%), while there were no patients with elevated bilirubin in the more recent period (62.4%; 0%). The addition of IVIG or CMV-specific immunoglobulin was not associated with benefit in overall survival compared to antiviral therapy alone (Figure 1C, 1D).

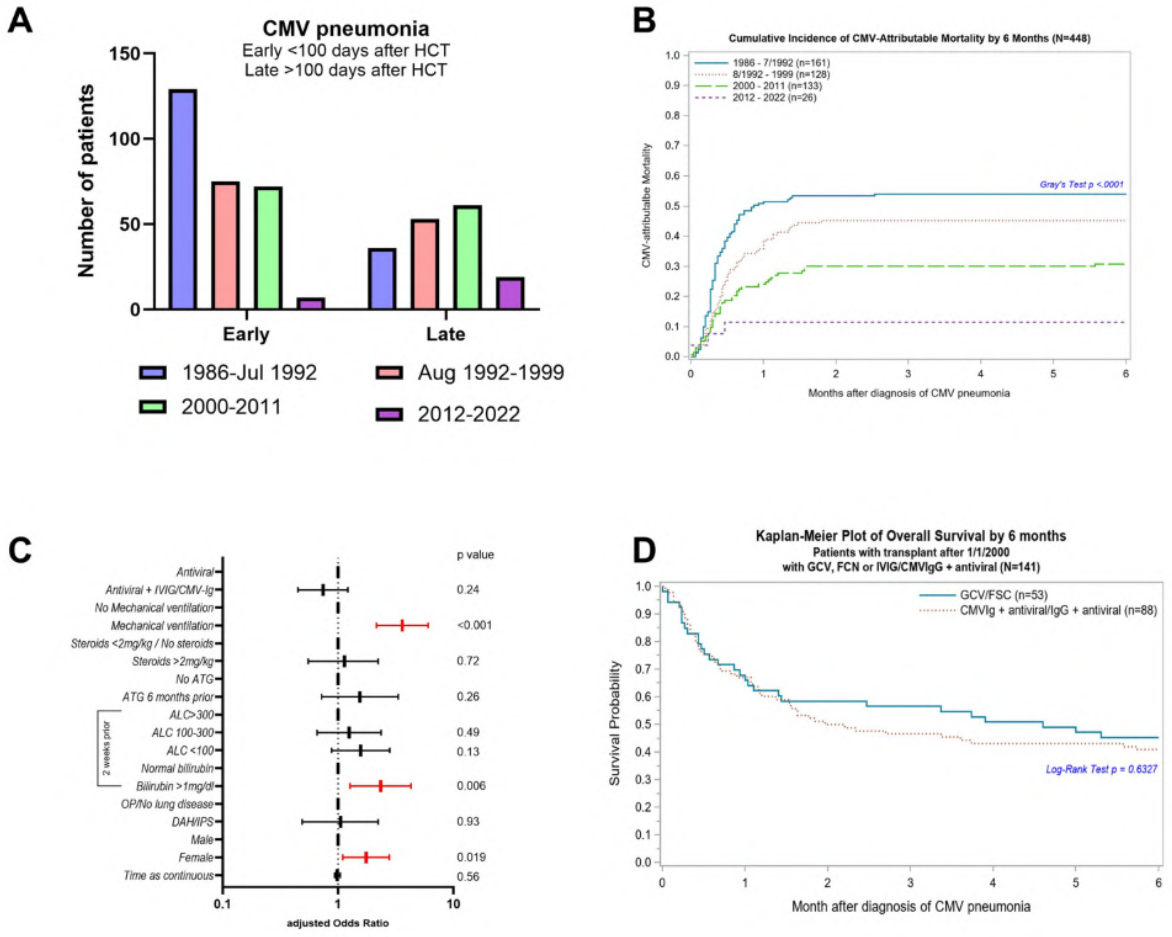

Figure 1. A) Distribution of early and late cases of CMV disease across four time periods; (B) cumulative incidence curves for CMV-attributable mortality in these periods; (C) multivariable model for overall mortality among patients transplanted after 2000 and treated with antiviral therapy; and (D) 6-month overall survival in this subset of patients.

Conclusions: CMV pneumonia incidence and mortality have continued to decline in the modern era, although late cases remain clinically relevant. The prognosis for patients requiring mechanical ventilation at the time of diagnosis remains poor, despite the improvement of transplant and supportive care techniques. The addition of IVIG or CMV-specific immunoglobulin to antiviral therapy did not show a clear survival benefit in this cohort, suggesting limited evidence to support their routine use.

EBV REACTIVATION AND PTLD IN THE LETERMOVIR ERA: BEYOND ANTIVIRAL PROPHYLAXIS

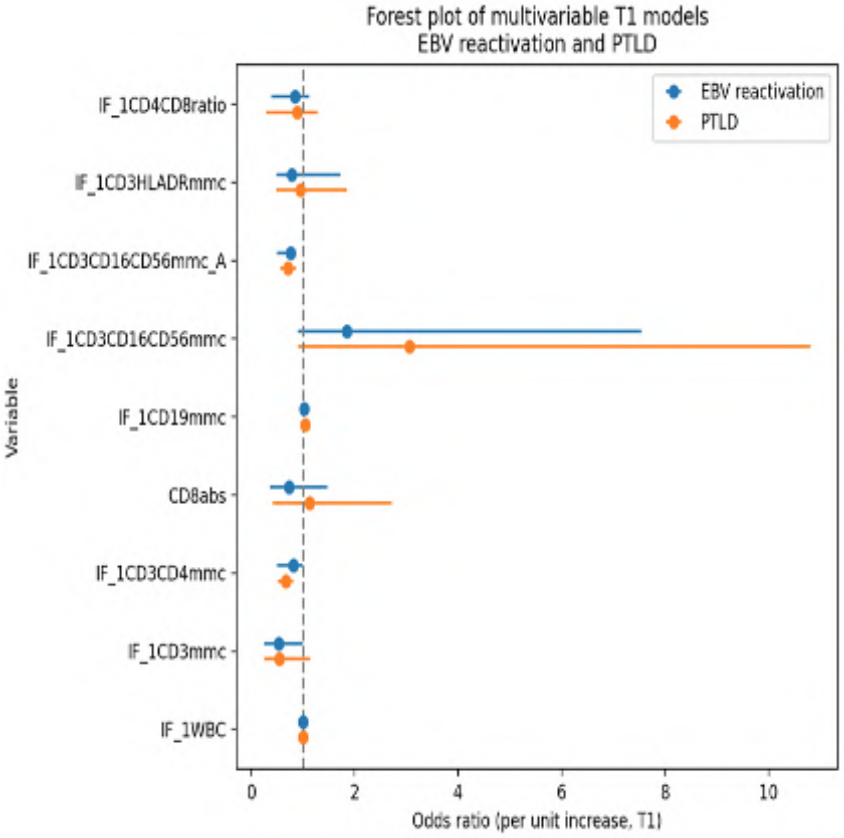
Ilaria Cutini[1], *Chiara Camerini*[1], *Giacomo Coltro*[1], *Antonella Gozzini*[1], *Edoardo Simonetti*[1], *Mirella Giordano*[1], *Gaia Mirabella*[1], *Alessio Mazzoni*[1], *Francesca Matani*[1], *Francesco Annunziato*[1], *Alessandro Maria Vannucchi*[1], *Chiara Nozzoli*[1]
[1]*Careggi University Hospital, Florence, Italy*

Background: Epstein–Barr virus reactivation (EBV-R) and post-transplant lymphoproliferative disorders (PTLD) remain major complications after allo-HSCT. Although EBV-PTLD occurs in 1–3% of unselected recipients, incidence increases to 8–10% in high-risk settings, including in vivo T-cell depletion, specific donor types, and severe aplastic anaemia. Emerging evidence suggests a possible rise in EBV-R and PTLD in the letermovir era, especially after haploidentical transplantation, potentially related to impaired early immune reconstitution. Consistently, our centre has observed a progressive increase in both EBV-R and PTLD over time.

Methods: We retrospectively analyzed 196 allo-HSCT from June 2019 to May 2025, with ≥6 months' follow-up, to assess EBV-R and PTLD incidence. Clinical and transplant variables were compared annually, including EBV/CMV serostatus, conditioning intensity, GVHD prophylaxis, letermovir use, GVHD, corticosteroid exposure, infections, relapse, and immune reconstitution at day +30. EBV-R was defined as EBV-DNA>10,000 copies/mL, and suspected PTLD per ECIL-6 criteria. Statistical analyses included χ^2, Spearman's test, Mann–Whitney U tests, ROC-guided logistic regression, and Kaplan–Meier analyses to identify risk factors and cumulative risks.

Results: EBV-R occurred in 30/196 patients (15.3%) and PTLD in 14/196 (7.1%). EBV-R and PTLD rates increased over time, peaking in 2023 at 22.7% and 18.2%, respectively, although year-to-year differences were not statistically significant. Baseline transplant characteristics and transplant-related complications did not differ between EBV-R and PTLD groups, except for immune reconstitution parameters, including NK-cells (p=0.0019), activated NK/T-cells (p=0.0266), and the CD4/CD8 ratio (p=0.0266).
In univariate analyses, EBV-R was associated with ATG exposure (p<0.001), PTCy use (p<0.001), and higher Fujimoto risk score (p=0.0056), with a trend for letermovir exposure (p=0.085), and differed by transplant type (p<0.001). PTLD was significantly associated with EBV reactivation (r=0.65,p<0.001), ATG use (r=0.24,p=0.0006), PTCy (r=−0.21,p=0.0028), transplant type (r=−0.16,p=0.023), and Fujimoto risk (r=0.14,p=0.047), but not with CMV reactivation.
Given the median onset of EBV-R/PTLD at 42 days (IQR 38.3–54.5), analyses focused on day 30. At this timepoint, EBV-positive patients showed higher WBC counts and lower CD3+,

CD4+, CD8+, and activated NK/T-cells, with increased counts of NK- and B-cells (all p≤0.002). ROC analysis identified NK-cells (AUC 0.72), WBC (AUC 0.69), and B-cells (AUC 0.68) as predictors of EBV-R.
Similarly, PTLD patients showed higher WBC counts (p=0.019), lower CD3+ (p<0.001), CD4+ (p<0.001), and CD8+ (p=0.007), and increased NK- (p<0.001) and B-cells (p<0.001). ROC analysis identified NK-cells (AUC 0.80,p<0.001), B-cells (AUC 0.70,p=0.001), and WBC (AUC 0.70,p=0.0017) as the strongest predictors of PTLD.
In multivariable models, higher early CD4+ (OR 0.82, p=0.05) and activated NK/T-cells (OR 0.71,p<0.01) were independently protective against both EBV-R and PTLD, whereas higher B-cell counts (p=0.05) increased the risk of both outcomes (Fig.1).



Conclusions: IIn this real-world allo-HSCT cohort, EBV-R and PTLD increased over time and were associated with ATG, PTCy, and donor type. Day-30 immune reconstitution was a key risk factor. EBV-R/PTLD were marked by poor T-cell recovery, increased NK- and B-cells, and a protective effect from higher early $CD4^{+}$ and activated NK/T-cells. Early immune monitoring may enable risk stratification and identify patients at risk for EBV-R and PTLD.

IMPACT OF EBMT 2025 DEFINITIONS ON THE IDENTIFICATION OF CATHETER-RELATED BLOODSTREAM INFECTIONS AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Juan Manuel Cerezo-Martín[1], *Lucrecia Yañez San Segundo*[1,2], *Irene Fernández-Bardón*[1], *Elba Vélez-Blanco*[1], *Irene Gorostidi-Álvarez*[1], *Jose Antonio Flores-García*[1], *Maria Terán-Diaz*[1], *Olga Zamanillo-Algorri*[1], *Esther López-Ramos*[1], *Patricia M. Retuerta-Agudo*[1], *Enrique Ocio*[1,2], *María Aránzazu Bermúdez*[1,2]
[1]*Hospital Universitario Marqués de Valdecilla, Santander, Spain,* [2]*Universidad de Cantabria, Santander, Spain*

Background: Central venous catheters (CVC) play a central role in the care of patients undergoing allogeneic hematopoietic stem cell transplantation (Allo-HSCT). Catheter-related bloodstream infections (CRBSI) are a significant complication, sometimes underestimated. Recently, the EBMT Infectious Working Party has published refined definitions of bloodstream infections (BSI) in the presence of CVC addressing their variability across the literature (*Clin Microbiol Infect 2025*). While IDSA guidelines require rigorous laboratory proof, like paired cultures, to definitively diagnose catheter-related infections (CRBSI) in general populations. In contrast, EBMT guidelines adopt these standards for transplant patients, allowing "presumed" diagnoses when strict testing isn't feasible and prioritize the distinction between gut-origin infections (MBI-BSI) and catheter infections.
The aim of this study is to compare previously described definitions of CRBSI (IDSA, Infectious Diseases Society of America, 2009) with the new EBMT definitions.

Methods: We retrospectively analyzed all patients undergoing Allo-HSCT consecutively at our center, between 2015 and 2024. All positive blood cultures were evaluated. Only first episodes of bacteremia were considered; subsequent episodes in the same patient were excluded.

Results: The study analyzed 432 patients (median age 56 years; 62.3% male) undergoing Allo-HSCT, with acute myeloid leukemia (37%) being the most frequent underlying disease. A total of 265 probable BSI episodes were evaluated, of which 224 were classified as definite BSI, occurring at a median of 7 days post-transplant. While Gram-negative bacilli accounted for 51% of definite BSIs, with *Escherichia coli* (27%) being the most frequent pathogen, the comparison of CRBSI definitions revealed significant differences. Only 28 episodes met the strict criteria for both IDSA and EBMT definite CRBSI, predominantly driven by CoNS (68%). In contrast, the EBMT probable CRBSI criteria identified an additional 46 episodes, capturing clinically relevant pathogens such as *Staphylococcus aureus* (11%) and *Candida parapsilosis* (4%) that were absent in the definite group. In the probable EBMT CRBSI category, a total of 27 CVC was removal to infectious issues: persistent bacteremia (n=5), persistent fever (n=8), signs of local infection (n=12) and sepsis/septic shock (n=2). The frequency of pathogen groups according to IDSA and EBMT definitions is shown in Table 1.
The cumulative incidence from Allo-HSCT at day +15, day +30, and day +90 for definite BSI

was 36%, 41%, and 46%, respectively. The cumulative incidence for probable EBMT CRBSI was 9%, 10%, and 12%, respectively; for definite IDSA/EBMT CRBSI, 5%, 5%, and 7%, respectively; and for probable/definite EBMT CRBSI, 14%, 15%, and 19%, respectively. Consequently, applying the combined probable and definite EBMT definitions increased the cumulative incidence of CRBSI at day +90 to 19%, compared to only 7% using the strict definite criteria.

	PROBABLE CRBS EBMT 2025 n=46	DEFINITE CRBSI IDSA 2009 n=28	PROB/DEFINITE CRBSI EMBT 2025 n=74
Microorganism group			
Gram-positive coccus	44 (96)	21 (75)	65 (88)
Gram-negative bacilli	0	6 (21)	6 (8)
Other	2 (4)	1 (4)	3 (4)
Most common identified species			
CoNS	39 (85)	19 (68)	59 (80)
Intes. GNB	0	6 (20)	6 (8)
Other GNB	0	1 (4)	1 (1)
S. aureus	5 (11)	0	5 (7)
Candida parapsilosis	2 (4)	0	2 (2)
Other	0	1 (4)	1 (1)

Table 1. Representation of pathogens identified according to EBMT and IDSA criteria.
CoNS: coagulase-negative staphylococcus; Intes: intestinal; GNB: Gram-negative bacilli.

Conclusions: BSI remains a significant complication after Allo-HSCT. The implementation of the EBMT 2025 definitions leads to an increased identification of CRBSI. Their use allows the

identification of frequent and clinically important pathogen groups that were not captured by previous definitions.

Disclosure: No disclosure.

B089

INCREASED INCIDENCE OF INFECTIONS WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE AS GVHD PROPHYLAXIS IN MATCHED SIBLING AND UNRELATED DONOR STEM CELL TRANSPLANTATION

Athanasios Gakopoulos[1], *Michael Panousieris*[1], *Kyriaki Kontitsi*[1], *Eleni Porfyriou*[1], *Antonios Patrinos*[1], *Alexandra Kontoula*[1], *Maria Katsareli*[1], *Vasiliki Delistrati*[1], *Vasiliki Varsama*[1], *Maria-Eleni Karatza*[1], *Marina Papageorgiou*[1], *Soultana Tryfonidou*[1], *Evgenia Gourgouveli*[1], *Tatiana Tzenou*[1], *Georgia Kourti*[1], *Ifigeneia Tzannou*[1], *Stavros Gigantes*[1], *Ioannis Tsonis*[1], *Ioannis Baltadakis*[1]
[1]*Evaggelismos Hospital, Athens, Greece*

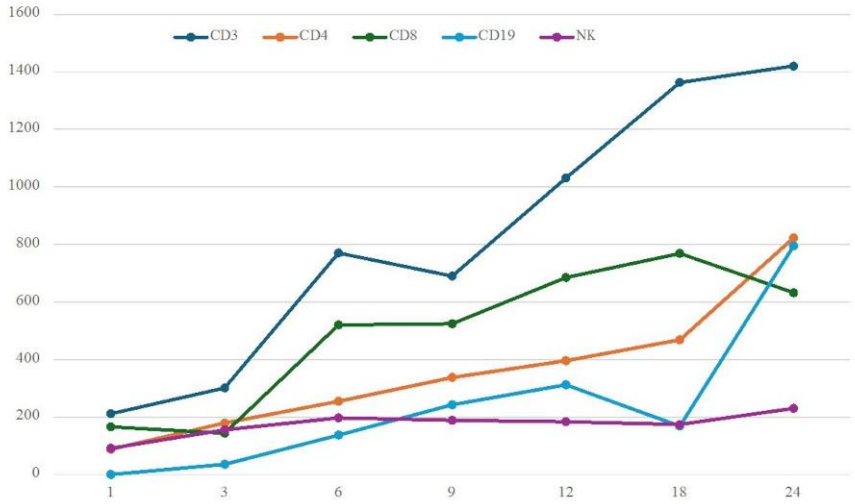
Background: Besides haploidentical procedures, post-transplant cyclophosphamide (PTCy) has become the standard-of-care GvHD prophylaxis in stem cell transplantation (SCT) from matched sibling (MSD) and matched during post-transplant period. The aim of this study was to assess immune reconstitution and infectious complications in a cohort of patients who received PTCy for matched sibling or unrelated donor SCT.

Methods: Between 02/2021 and 05/2025, 133 consecutive patients, aged 17-79 years (median; 56), underwent SCT from MSD (n=33), MUD (n=100) or MMUD (n=20), with PTCy (40 mg/kg/day for MSD and 50 mg/kg/day for MUD/MMUD, on days +3 and +4) in combination with calcineurin inhibitor/mycophenolate mofetil as GvHD prophylaxis. Underlying diseases included AML (n=79), MDS (n=23), other myeloid neoplasms (n=8), ALL (n=18), and lymphomas (n=5). Conditioning was myeloablative (n=92) or reduced-intensity (n=41), based on chemotherapy (n=113) or TBI (n=20). Immune reconstitution was monitored by flow cytometry at 3-monthly intervals. Infections were categorized according to site and type of pathogen.

Results: Engraftment (ANC >500/uL) was observed in 127/133 (95.5%) patients at a median of 15 (12-44) days. With a median follow-up of 23 (6-58) months, overall survival at 2 years was 72.9% (95% CI; 65.2-81.6). Non-relapse mortality (NRM) and cumulative incidence or relapse (CIR) at 2 years were 18.5% (95% CI; 12.6-27.1) and 13.3% (95% CI; 8.3-21.4), respectively. The rates of grade II-IV or III-IV acute GvHD at 180 days, and of moderate/severe chronic GVHD at 24 months were 44.6% (95% CI; 36.8-54.0), 5.3% (95% CI; 2.6-10.9), and 26.8% (95% CI; 19.8-36.2), respectively. T cell reconstitution (median absolute CD4+ count >200 and >400/uL) was encountered at 6 and 18 months, respectively. Overall, 251 infections were observed in 104/133 (78.2%) patients. Infections were classified as bacteremias (n=84, 33.5%), bacterial site-specific other than C. difficile (n=71, 28.3%), C. difficile (n=10, 4%), viral (n=73, 29%), and fungal (n=12, 4.8%), and protozoan (n=1, 0.4%). Viral infections were CMV reactivation (n=19), CMV enteritis (n =6),

BKV cystitis (n=24), and COVID-19 or other respiratory (n=13 and 11, respectively). Fungal pathogens were yeasts (n=7), molds (n=4), and mucor (n=1). Infections were identified as contributing factors in 19/21 recorded fatalities.

Image 1: Immune reconstitution in month 1, 3, 6, 9, 12, 18 and 24 after transplantation.



Months from alloSCT	1	3	6	9	12	18	24
CD3	212	301	770	690	1030.5	1363	1420
CD4	88	179	255	337.5	396	468.5	823
CD8	166	144	520	524	685	768.5	632
CD19	0	36	137	243	312	168.5	795
NK	92	156	197	188.5	183.5	174	230

Conclusions: Although PTCy significantly reduced the incidence of both severe acute and chronic GvHD, infections remain prevalent among patients and represent a major cause for morbidity and mortality. Optimization of the PTCy immunosuppression regimen may facilitate hematopoietic and immune reconstitution, thereby reducing the incidence of infections.

Disclosure: Nothing to disclose.

B090

EFFICACY AND SAFETY OF MARIBAVIR IN HEMATOPOIETIC CELL TRANSPLANT RECIPIENTS BY BASELINE NEUTROPENIA STATUS: A POST HOC ANALYSIS OF PHASE 2 AND 3 CLINICAL TRIALS

Alicja Sadowska-Klasa[1], *Robin K. Avery*[2], *Michael Boeckh*[3], *Wendy Chao*[4], *Joan Gu*[4], *Tien Bo*[4], *Genovefa A. Papanicolaou*[5,6]
[1]*Medical University of Gdańsk, Gdańsk, Poland,* [2]*Johns Hopkins University, Baltimore, United States of America (the),* [3]*Fred Hutchinson Cancer Center, Seattle, United States of America (the),* [4]*Takeda Development Center Americas, Inc., Cambridge, United States of America (the),* [5]*Memorial Sloan Kettering Cancer Center, New York, United States of America (the),* [6]*Weill Cornell Medicine, New York, United States of America (the)*

Background: Recipients of hematopoietic cell transplantation (HCT) are susceptible to myelotoxicity associated with anti-cytomegalovirus (CMV) agents such as ganciclovir or valganciclovir. In the phase 3 SOLSTICE trial (NCT02931539), lower rates of myelosuppression were observed with maribavir compared with ganciclovir/valganciclovir in HCT recipients with refractory CMV infections. This exploratory post hoc analysis of clinical trial data assessed the efficacy and safety of maribavir in patients with post-HCT refractory CMV infection, according to baseline neutropenia status.

Methods: Data from maribavir-treated HCT recipients in SOLSTICE and a phase 2, dose-ranging study (1263-202; SHP620-202; NCT01611974) were stratified by baseline neutrophil count: ≤1000/mm^3 (moderate-to-severe neutropenia); >1000/mm^3 to 1500/mm^3 (mild neutropenia); >1500/mm^3 (no neutropenia). Patients enrolled in the SOLSTICE study were required to have a baseline absolute neutrophil count of ≥1000/mm^3, and thus only participants from study 202 were included in the moderate-to-severe neutropenia cohort. Participants with confirmed CMV DNAemia clearance at the end of study week 8 were considered responders regardless of whether maribavir was discontinued before the end of the stipulated 8 weeks of therapy. Responder rates and incidence of adverse events (AEs) were summarized descriptively, and time to CMV clearance at any time during the studies was assessed by neutropenia category using Kaplan-Meier (KM) analysis with log-rank test.

Results: In total, 139 maribavir-treated HCT recipients with baseline moderate-to-severe (n=12), mild (n=11), or no neutropenia (n=116) were included in this analysis. Baseline demographics for this population are summarized in the Table. At the end of week 8, 10/12 (83.3%) and 7/11 (63.6%) participants with moderate-to-severe or mild neutropenia versus 68/116 (58.6%) with no neutropenia were considered responders to maribavir. Responder rates at any time during the study were 11/12 (91.7%), 9/11 (81.8%), and 87/116 (75.0%) in patients with moderate-to-severe, mild or no neutropenia, respectively. Time to CMV DNAemia clearance, as assessed by KM analysis, was similar across the three neutropenia categories (P=0.1644), as well as between those with and without neutropenia (P=0.0979; Figure). Treatment-emergent AEs were observed in 100% of participants with moderate-to-severe or mild neutropenia, and in 99.1% of participants without neutropenia. Adverse events led to discontinuations in 25.0%, 9.1%, and 28.4% of participants with moderate-to-severe, mild or no neutropenia, respectively.

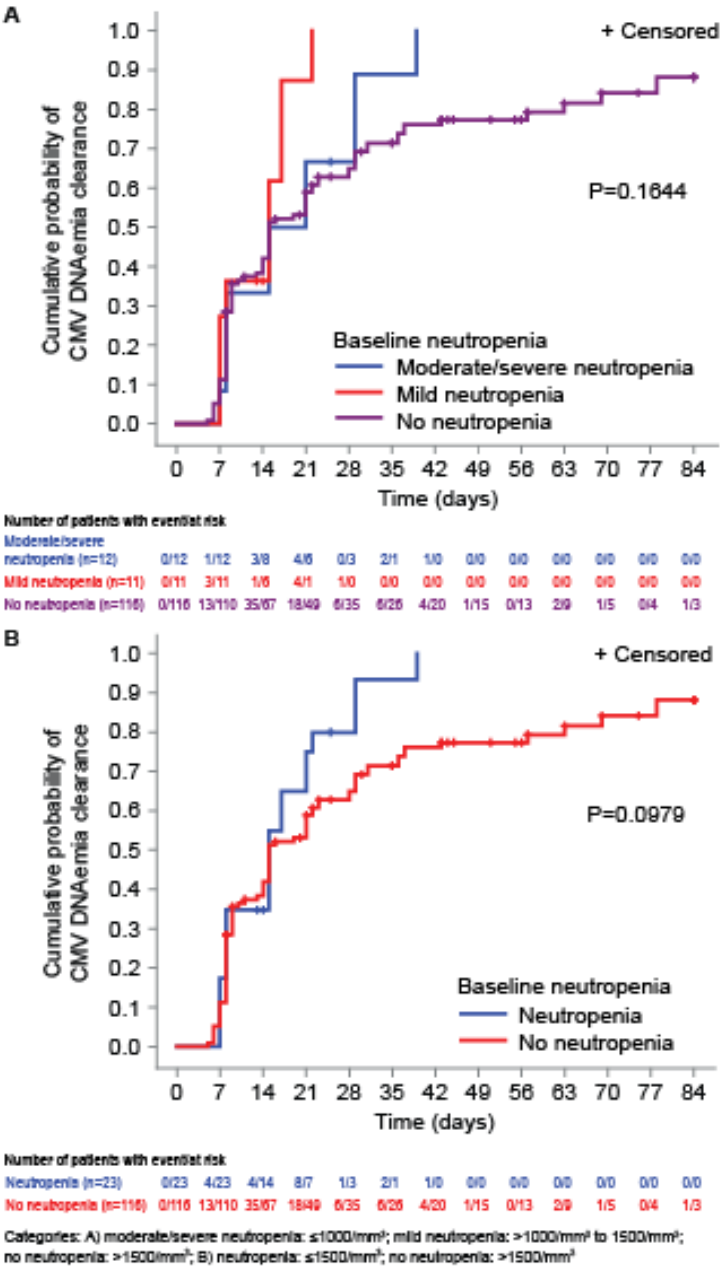
Table. Baseline demographics and safety data for HCT recipients with refractory CMV by baseline neutropenia category

	Neutrophil count ≤1000/mm^3 (n=12)	Neutrophil count >1000/mm^3 to 1500/mm^3 (n=11)	Neutrophil count >1500/mm^3 (n=116)
Age, years (median [range])	45.5 (24–65)	60.0 (19–73)	58.0 (19–77)
Male, n (%)	7 (58.3)	3 (27.3)	64 (55.2)
Race, n (%) Asian Black or African American White Other Missing	 1 (8.3) 4 (33.3) 6 (50.0) 1 (8.3) 0	 2 (18.2) 1 (9.1) 8 (72.7) 0 0	 8 (6.9) 8 (6.9) 85 (73.3) 13 (11.2) 2 (1.7)
Patients with AEs, n (%)	12 (100)	11 (100)	116 (100)
Number of AEs, n	148	110	1891
Number of TEAEs, n (%)[a]	123 (83.1)	82 (74.5)	1293 (68.4)
Mild, n (%)[b]	50 (40.7)	47 (57.3)	727 (56.2)
Moderate, n (%)[b]	55 (44.7)	26 (31.7)	420 (32.5)
Severe, n (%)[b]	14 (11.4)	9 (11.0)	126 (9.7)
Maximal, n (%)[b]	4 (3.3)	0	20 (1.5)

Patients with AEs resulting in death, n (%)	3 (25.0)	2 (18.2)	32 (27.6)
Patients with serious TEAEs, n (%)	5 (41.7)	6 (54.5)	62 (53.4)
Patients with study drug discontinuations due to AEs, n (%)	3 (25.0)	1 (9.1)	33 (28.4)
Patients with study drug interruptions due to AEs, n (%)	2 (16.7)	1 (9.1)	14 (12.1)

[a]Percentages calculated from the total number of AEs.
[b]Percentages calculated from the total number of TEAEs.
AE, adverse event; TEAE, treatment-emergent adverse event

Figure. Inverse Kaplan-Meier Curves of time to first confirmed undetectable plasma CMV DNAemia at any time during the study up to Week 12 (Day 84) by baseline neutropenia category



Categories: A) moderate/severe neutropenia: ≤1000/mm³; mild neutropenia: >1000/mm³ to 1500/mm³; no neutropenia: >1500/mm³; B) neutropenia: ≤1500/mm³; no neutropenia: >1500/mm³

Conclusions: This post hoc analysis of phase 2 and 3 clinical data in HCT recipients with refractory CMV infection showed no statistically significant differences in time to CMV DNAemia clearance and broadly similar overall AE profiles in maribavir-treated patients with and without baseline neutropenia. Although these findings are based on small sample sizes, especially in the neutropenia groups, they support the use of maribavir as a therapeutic

option in HCT recipients with refractory CMV infection, regardless of neutropenia, and warrant further research.

THE ORAL MICROBIOME IN PEDIATRIC HEMATOPOIETIC CELL TRANSPLANT RECIPIENTS

Kyu Lee[1], Cliff Beall[2], Hashimi Shahr[2], Eugene Leys[2], Janice Townsend[1], Ashok Kumar[1], Ann Griffen[2], ***Rajinder Bajwa***[1]
[1]Nationwide Childrens Hospital, Columbus, United States of America (the), [2]The Ohio State University, Columbus, United States of America (the)

Background: Oral mucositis (OM) is a frequent and debilitating complication during hematopoietic stem cell transplantation (HSCT), contributing significantly to pain, impaired nutrition, prolonged hospitalization, and increased infection risk. OM is also a well-recognized risk factor for bloodstream infections (BSI) due to mucosal barrier injury that facilitates microbial translocation. Although oral microbial dysbiosis has been proposed as a contributing factor in OM development and oral bacteria have been implicated as sources of BSI, most prior work has focused on adults, leaving a critical gap in pediatric populations. This prospective study was designed to characterize the pediatric oral microbiome during HSCT, explore whether specific microbial signatures are associated with the incidence and severity of OM, and determine whether oral organisms could be linked to BSI episodes occurring during transplant.

Methods: Ten pediatric subjects undergoing HSCT were followed longitudinally throughout their transplant course. Oral health assessments—including gingivitis scores, plaque index, tongue coating, and OM grading—were recorded at serial time points. Site-specific oral samples from plaque, buccal mucosa, and tongue, as well as microbial DNA from BSI-positive blood cultures, were collected for 16S rRNA gene sequencing. Microbial beta-diversity was assessed using Bray–Curtis dissimilarity, and PERMANOVA was applied to evaluate whether community composition varied by oral site or OM severity. Amplicon sequence variants generated through the DADA2 pipeline provided high-resolution, strain-level microbial fingerprints, allowing us to precisely track specific microbial species across different oral niches and determine whether the same organisms appeared in the bloodstream during BSI events.

Results: All subjects demonstrated progression of OM and dynamic changes in oral health indices as they moved through conditioning, the neutropenic phase, and subsequently engraftment. Distinct microbial communities were observed across oral sites (P = 0.001), reflecting the unique ecological environments of plaque, mucosa, and tongue. As OM severity increased, significant shifts in community composition occurred within each niche (plaque P = 0.023; buccal mucosa P = 0.006; tongue P = 0.041), suggesting that mucosal injury is associated with measurable restructuring of the oral microbiome.
Six of the ten subjects experienced BSI events (including two events in one subject). Sequencing revealed polymicrobial bloodstream profiles containing microbial species typically residing in the oral cavity. High-resolution ASV matching demonstrated overlap between oral microbial species and those detected in blood culture samples, supporting an oral source for BSI in multiple cases. These findings suggest that OM-associated microbial disruption may facilitate translocation of oral microbes into the bloodstream during HSCT.

Conclusions: Distinct, site-specific microbial signatures were identified in pediatric HSCT recipients, and these communities shifted significantly with the development and progression of OM. High-resolution microbial tracking provided molecular evidence linking bloodstream pathogens to the oral cavity, emphasizing the oral microbiome as an important—and potentially modifiable—source of infectious risk during HSCT. These data lay the groundwork for future mechanistic microbiome studies and support the development of targeted oral health or microbiome-directed interventions to reduce OM severity and prevent BSI in children undergoing HSCT.

SURVEY BY THE INFECTIOUS DISEASES WORKING PARTY OF EBMT ON THE USE OF RECOMBINANT HERPES ZOSTER VACCINE AFTER AUTOLOGOUS AND ALLOGENEIC HAEMOPOIETIC STEM CELL TRANSPLANTATION

Maria Stamouli[1], *Lotus Wendel*[2], *Juana Schwartz-Mota*[2], *Catherine Cordonnier*[3], *Per Ljungman*[4], *Rafael de la Camara*[5], *Gloria Tridello*[2], *Jan Styczynski*[6], *Dina Averbuch*[7]
[1]*Attikon University General Hospital, Athens, Greece,* [2]*Leiden Study Unit, EBMT, Leiden, Netherlands (the),* [3]*Hopital Henri Mondor, Creteil, France,* [4]*Dept of Cellular Therapy and Allogeneic Stem Cell Transplantation, Karolinska University Hospital Huddinge, Div. of Hematology, Dept. of Medicine Huddinge, Karolinska Institutet, Stockholm, Sweden,* [5]*Hematology Department, Hospital de la Princesa, Madrid, Spain,* [6]*Department of Pediatric Hematology and Oncology, Collegium Medicum, Bydgoszcz, Poland,* [7]*Faculty of Medicine, Hebrew University of Jerusalem; Pediatric Infectious Diseases, Hadassah Medical Center, Jerusalem, Israel*

Background: For many years, the only existing vaccine for Herpes Zoster (HZ) was a live-attenuated vaccine that wasn’t recommended in immunocompromised patients. The

recombinant HZ vaccine (RZV, Shingrix®) was shown to be safe and effective in a randomized observer-blind, phase-III trial in adults after autologous HSCT (auto-HSCT)(Bastidas et al, JAMA 2019). In that study, the first dose of vaccine was administered between 50-70 days after transplant, and the second dose 1-2 months thereafter. Patients with antiviral prophylaxis for HZ of more than 6 months were excluded. However, there are few data about the use of this vaccine after auto-HSCT in the real world. Moreover, information about Shingrix® after allogeneic HSCT (allo-HSCT) is limited.
This survey shows a current picture of the use of RZV in transplant centres of the EBMT network, its reimbursement, and the management of prophylaxis.

Methods: A 20-item questionnaire regarding RZV, approved by the scientific board of IDWP-EBMT, was sent to all centres performing HSCT on February 10th, 2025.

Results: 187 adult HSCT centres responded to this survey. Results are shown in Table 1. Most European centres get reimbursed for the vaccine.
Allo-HSCT: 107/157 centres have RZV in their routine schedule. 98/105 centres (93.3%) started RZV based on time after transplant either alone (54/105;51.4%) or in combination with other factors (44/105;41.9%). Other factors more commonly mentioned are corticosteroids, other immunosuppression and chronic Graft vs Host Disease (GvHD).
10/17 centres (58.8%) that started vaccination 3-6 months after transplant provided prophylaxis regardless of RZV, while 20/44 centres (45.4%) that started 6-12 months and 11/36 centres (30.5%) that started >1 year after transplant provided prophylaxis regardless of RZV
Auto-HSCT:103/170 centres have RZV in their routine schedule. Only 25/103 centres (35.4%) use the 2-dose interval (30-59 days) as recommended in the phase III study.
9/12 centres (75%) that started the vaccine <3 months and 29/42 centres (69%) that started 3-6 months after transplant provided prophylaxis regardless of RZV. 18/37 centres (48.6%) that gave RZV 6-12 months after transplant, and 5/8 centres (62.5%) that gave RZV >1 year after transplant provided antiviral prophylaxis regardless of RZV.

Table 1

	Allo-HSCT	**Auto-HSCT**
Number of centres	157	179
Reimbursement	107/157 (68.2%)	115/172 (66.9%)
RZV used in the routine vaccination schedule	107/157 (68.2%)	103/170 (60.6 %)
RZV start based on time after transplant	98/105 (93.3%)	99/103 (96.1%)
< 3 months	0	12/99(12.1%)
3-6 months after transplantation	18/98 (18.4%)	42/99(42.4%)

6-12 months after transplantation	44/98 (44.9%)	37/99 (37.4%)
>1 year after transplantation	36/98 (36.7%)	8/99 (8.1%)
RZV start based on other factors	51/105 (48.6%)	NA
Posology of RZV 1 dose 2 doses >2 doses	 3/101 (3.0%) 95/101 (94.1%) 3/101 (3.0%)	 2/100 (2.0%) 96/100 (96%) 2/100 (2.0%)
Interval between doses		
<30 days 30-59 days 60-90 days >90 days	2 (2.1%) 38 (39.6%) 54 (56.3%) 2 (2.1%)	4 (4%) 35 (35.4%) 57 (57.6%) 3 (3%)
Antiviral drug prophylaxis		
Stopped prophylaxis after RZV administration	60/104 (57.7%)	39/101 (38.6%)
based on time after last dose	45/60 (75%)	33/39 (84.6%)
<14 d 15-30 d >30 d	12 /45(26.7%) 18/45 (40.0%) 15/45 (33.3%)	9/33 (27.3%) 12/33 (36.4%) 12/33 (36.4%)
Based on other factors alone	15/60 (25%)	6/39 (15.4%)
RZV does not influence decision on prophylaxis	44/104 (42.3%)	62/101 (61.4%)

Conclusions: This survey shows that most transplant centres that responded have incorporated RZV into their vaccination schedules after HSCT. Despite the paucity of data, more responding centres use RZV after allo-HSCT (68.2%) than after auto-HSCT (60.6%).
In auto-HSCT, most centres started the vaccination either 3-6 months or 6-12 months post-transplant, while in the phase III study RZV was administered 50-70 days post-transplant. Interestingly, most centres continue prophylaxis regardless of vaccination
In allo-HSCT, most centres started RZV based on time after HSCT, alone or together with other factors, mostly the absence of chronic GvHD and/or immunosuppressive treatment. Most centres started vaccination at 6 months or later. Although 58% of centres stopped prophylaxis after vaccination, in 42% of centres, vaccination with RZV didn't influence the decision on prophylaxis.
Centres that gave RZV earlier after allo-HSCT were more likely to report that vaccination didn't affect decision on prophylaxis, although this trend was not as pronounced in auto-HSCT.

ANAKINRA TO REDUCE FEVER DURING NEUTROPENIA AND MUCOSITIS IN MULTIPLE MYELOMA PATIENTS RECEIVING AUTOLOGOUS STEM CELL TRANSPLANTATION AFTER HIGH-DOSE MELPHALAN – A RANDOMIZED CONTROLLED TRIAL

Eva Molendijk[1], *Charlotte de Mooij*[2], *Martijn Bakker*[3], *Steven Teerenstra*[1], *Suzanne van Dorp*[1], *Roger Brüggemann*[1], *Walter van der Velden*[1], *Gerwin Huls*[3], *Nicole Blijlevens*[1]
[1]*Radboudumc, Nijmegen, Netherlands (the)*, [2]*Elizabeth TweeSteden Ziekenhuis, Tilburg, Netherlands (the)*, [3]*University of Groningen, Groningen, Netherlands (the)*

Background: The recombinant human IL-1 receptor antagonist anakinra is effective in ameliorating murine chemotherapy-induced mucositis and fever during neutropenia. In this phase 2b AFFECT-2 trial, multiple myeloma (MM) patients receiving high-dose melphalan (HDM) followed by autologous stem cell transplantation (ASCT) were randomized between placebo or anakinra to reduce the incidence of fever during neutropenia and mucositis severity.

Methods: MM patients admitted for ASCT after single dose HDM 200mg/m2 were 1:1 randomized between once daily anakinra 300 mg iv or placebo for 15 days starting at day of HDM infusion. Patients with uncontrolled infections, bowel disease or impaired renal function with eGFR <40 ml/min were excluded. Ninety patients were required to detect a reduction from 80% to 50% in our primary outcome incidence of fever during neutropenia, with a two-sided test, α of 0.05 and power of 80%. Fever during neutropenia was defined as a tympanic temperature ≥38.5°C and ANC < 0.5 × 10^9 /l or expected to fall below 0.5 × 10^9 /l in the next 48 hours.
During hospital admission vital functions, clinical oral and intestinal mucositis scores, antibiotic use and feeding method were registered daily. Plasma for citrulline concentration (biomarker for intestinal mucositis), C-reactive protein (CRP) and exploratory cytokine analysis was collected thrice-weekly. Blood cultures were collected daily between 4 and 12 days after ASCT and in case of fever. Positive blood cultures were classified into laboratory confirmed blood stream infections (LCBI) and mucosal barrier injury related LCBI (MBI-LCBI) according to the American Center of Disease Control. Patients received oral ciprofloxacin prophylaxis and ceftazidime iv in case of neutropenic fever.
Primary outcome was analyzed with Chi square test. Continuous outcomes were tested with independent samples T-tests or zero count inflated model if appropriate. Repeated measurements were analyzed with linear mixed models.

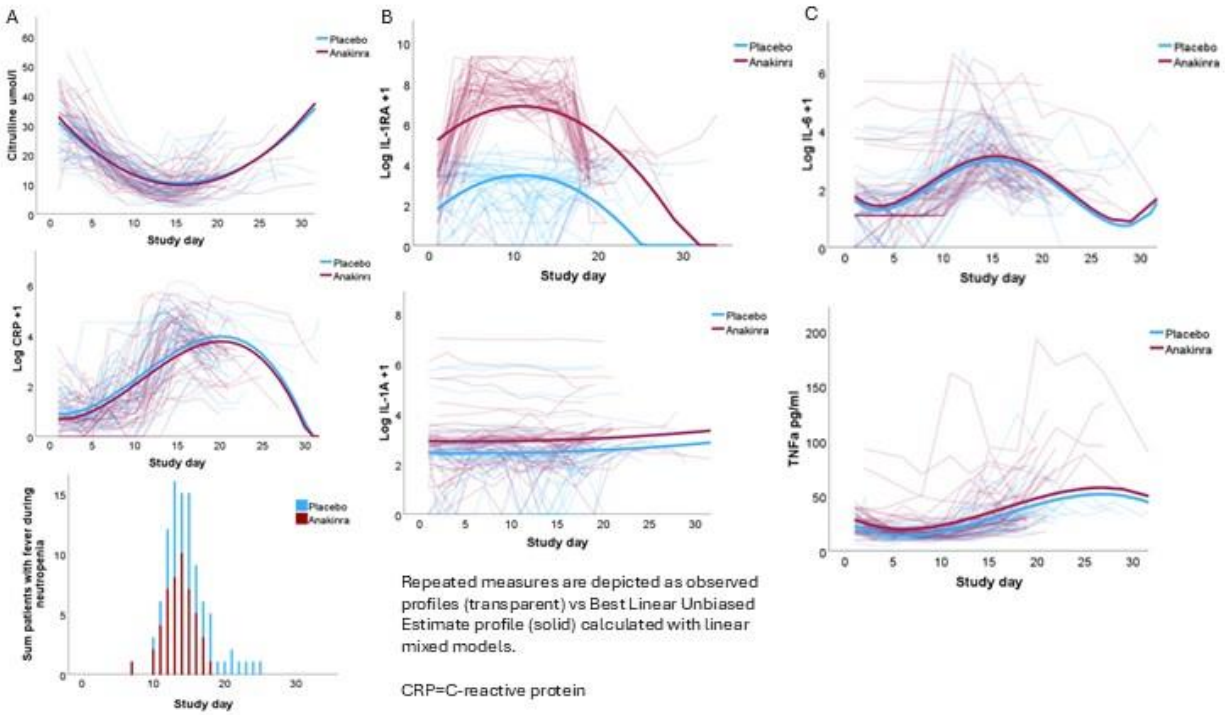
Results: 87 patients were enrolled were enrolled between October 2019 and March 2023. The intention-to-treat population consisted of 82 patients who received ≥1 dose of study medication. Basic characteristics were comparable between groups.
Fever during neutropenia occurred in 18 patients in the anakinra group (40.9%) and 21

patients in placebo group (55.3%), *P*= 0.194, OR 0.56 (CI 0.23-1.35).
Daily clinical mucositis scores, feeding method, hospital stay and empirical antibiotic therapy use were not significantly different between groups.
Incidence of LCBI was low, table 1.
Citrulline concentration declined throughout hospitalization in both groups to <10 umol/l around 10 days after ASCT reflecting severe gut mucositis. At the same time, CRP peaked and fever during neutropenia occurred, figure 1A.
Anakinra administration resulted in higher IL-1 receptor antagonist (IL-1RA) concentrations than in the placebo group. IL-1a concentrations were consistent and tended to be higher in the anakinra group, figure 1B. IL-6 peaked together with CRP and fever, TNFa peaked around repopulation, figure 1C.

Nr of patients with BSI per type	**Anakinra**	**Pathogens**	**Placebo**	**Pathogens**
LCBI type 1, n	5	*Pseudomonas aeruginosa, Acinetobacter radioresistens, Enterococcus faecalis, Granulicatella adiacens, Streptococcus pneumoniae*	2	*Sphingomonas species, Staphylococcus aureus*
LCBI type 2, n	2	*Micrococcus luteus, Staphylococcus epidermidis*	2	*Staphylococcus epidermidis*
MBI-LCBI type 1, n	0		0	
MBI-LCBI type 2, n	2	*Streptococcus mitis*	2	*Streptococcus mitis, Streptococcus gallolyticus*
Total, n	9		6	

In both groups 1 patient had a LCBI 1 and MBI-LCBI 2 during hospitalization.

Figure 1. Citrulline, CRP and cytokine profiles next to incidence of fever during neutropenia during hospitalization.



Conclusions: Anakinra did not prevent development of fever during neutropenia nor severe mucositis, also reflected by rise of IL-6 and TNFa despite high IL-1RA. Severe intestinal mucositis coincided with fever during neutropenia whilst incidence of LCBI was low.

Clinical Trial Registry: Clinicaltrials.gov NCT04099901

Disclosure: This trial was funded by KWF Dutch Cancer Society.

B094

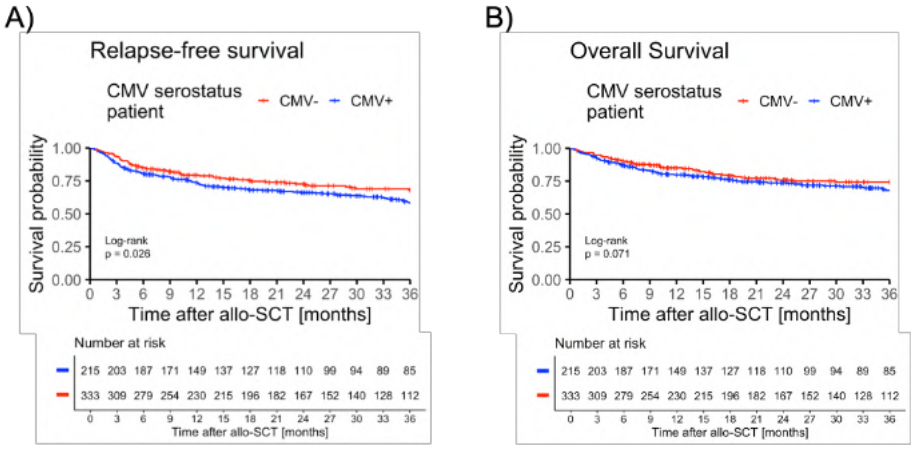
THE IMPACT OF CMV-SEROPOSITIVITY ON OUTCOMES AFTER ALLOGENEIC STEM CELL TRANSPLANTATION IN THE ERA OF LETERMOVIR IN AML AND MDS PATIENTS

Lina Kolloch[1], *Judith Boschke*[2], *Christian Reicherts*[1], *Julian Ronnacker*[1], *Hanna Schneider*[1], *Jörn Albring*[1], *Julia Marx*[1], *Eva Eßeling*[1], *Georg Lenz*[1], *Matthias Stelljes*[1]
[1]*University Hospital Münster, Muenster, Germany,* [2]*University Hospital Cologne, Cologne, Germany*

Background: Until the approval of letermovir for the prophylactic treatment of cytomegalovirus (CMV) positive patients after allogeneic stem cell transplantation (allo-SCT), CMV infections were frequent and relevant problems after allo-SCT. Furthermore, the CMV serostatus has been linked to survival outcomes and relapse incidence. However, the introduction of letermovir has changed the field and the current impact of CMV positivity on outcomes after allo-SCT remains unclear.

Methods: A total of 548 patients with acute myeloid leukemia (AML) and myelodysplastic neoplasia (MDS) who underwent allo-SCT between 2018 and 2024 at our center were divided in 2 groups according to their CMV serostatus. We retrospectively analyzed associations between patient and donor CMV status and clinical outcomes, including overall survival (OS), relapse-free survival (RFS), incidence of relapse, non-relapse mortality (NRM), and graft-versus-host-disease (GvHD).

Results: 333 patients (61%) were CMV seropositive (CMV+) and 215 patients (39%) were CMV seronegative (CMV-). Both groups were well balanced regarding diagnosis and associated risk factors like prevalence of a complex karyotype, age at allo-SCT, gender, Hematopoietic Cell Transplantation-specific Comorbidity Index (HCT-CI) score, remission before allo-SCT, and immunosuppressive regimens. 66% in the CMV+ group versus 20% in the CMV- group had a CMV+ donor. 97% of the CMV+ patients received primary prophylaxis with letermovir.
With a median follow-up of two years for the whole cohort, CMV+ patients trended towards lower two-year overall survival (OS) rate (74% vs. 76%, p=0.071) higher relapse incidence (20% vs. 13%, p=0.075) and a significantly lower RFS rate (66% vs. 73%, p=0.026). A subgroup analysis of CMV+ patients showed a trend towards higher relapse incidences for those transplanted from CMV+ donors (incidence of relapse at 2 years for CMV+ donors: 23% vs. 12% for CMV- donors, p=0.056). In multivariate analysis for RFS including variables found to be significant in univariate analyses (age >60 years, HCT-CI score, Eastern Cooperative Oncology Group performance score and complex karyotype), the patients' CMV serostatus trended towards significance (HR: 1.33, p=0.062), while the CMV serostatus of the donor did not affect RFS (univariate: HR: 1.1, p=0.45).
During the entire follow-up, 94 patients had a CMV infection with subsequent preemptive therapy, 31 of those occurred during prophylaxis with letermovir. A preemptive therapy against CMV did not influence survival outcomes (yes vs. no, two-year OS rate: 72% vs. 75%, p=0.48; two-year RFS rate: 68% vs. 71%, p=0.82). Incidence of acute or chronic GvHD and duration of immunosuppression did not significantly differ between CMV+ and CMV- patients.
Cellular immune reconstitution measured by CD4+ and CD8+ T-cells on day +100 revealed a faster reconstitution in CMV+ patients (median CD4+/µl: 137 vs. 108 for CMV-, p=0.028, median CD8+/µl: 230 vs. 201 for CMV-, p=0.016).



Conclusions: Our findings suggest that, even in the letermovir era, the CMV serostatus may still affect RFS. Furthermore, we found no evidence that prophylaxis with letermovir or CMV infection are relevant risk factors for relapse in our large cohort of AML and MDS patients. However, further studies are needed to confirm these findings and to evaluate the possible impact of donor CMV serostatus and the underlying mechanisms.

MARIBAVIR FOR TREATMENT OF REFRACTORY/RECURRENT CYTOMEGALOVIRUS INFECTION IN ALLOGENEIC HSCT RECIPIENTS

Aleksandr Siniaev[1], *Olesya Yudinceva*[1], *Ivan Moiseev*[1], *Marina Popova*[1], *Yuliya Rogacheva*[1], *Sergey Bondarenko*[1], *Alexander Kulagin*[1]
[1]*RM Gorbacheva Research Institute, Pavlov University, Saint-Petersburg, Russian Federation (the)*

Background: There is a lack of real-world data on maribavir therapy in recipients of allogeneic hematopoietic stem cell transplantation (allo-HCT). The study aimed to assess the outcomes of maribavir therapy in allo-HSCT recipients with refractory or recurrent cytomegalovirus (CMV) infection in a real-world clinical setting.

Methods: A single-center study included 51 patients, both adults (42/51, 82.4%) and children (9/51, 17.6%), following allo-HCT with refractory (42/51, 82.4%) or recurrent (9/51, 17.6%) CMV infection. Patient characteristics are presented in Table 1.

	Study group (n=51)
Age, median (range)	40 (0.2 – 66)
Sex Male Female	 29 (56.8%) 22 (43.2%)
Indications for allo-HCT Standard Salvage	 39 (76.5%) 12 (23.5%)
Donor type Haploidentical MMUD MUD MRD	 21 (41.2%) 15 (29.4%) 8 (15.7%) 7 (13.7%)
Stem cell source PBSC BM	 43 (84.3%) 8 (15.7%)
Conditioning regimen RIC MAC	 26 (51.0%) 25 (49.0%)
Post-transplant cyclophosphamide GVHD prophylaxis	49 (96.0%)
Second allo-HCT BOOST	7 (15.7%) 2 (3.9%)
CMV DNA levels at the start of 1st line treatment, median (range) IU/ml Copies/ml	 3520 (100 - 4656000) 5780 (500 - 7760000)

Duration of 1st line treatment, median (range), days	13.5 (2 - 60)

No analysis for CMV drug resistance mutations was performed. The median time from the first allo-HSCT to CMV infection onset was 36 days (range: 9–342). First-line therapy was ganciclovir in 44 cases (86.3%). Therapy was administered preemptively in 46 cases (90.2%), while 3 patients (5.8%) were treated for CMV pneumonia and 2 (4%) for CMV gastrointestinal disease. Maribavir was used as second-line therapy in 38 patients (74.5%) and as a subsequent line in 13 (25.5%). The median follow-up time from the start of maribavir therapy was 147 days (range: 2–1165).

Results: The median time from CMV infection onset to the initiation of maribavir was 18 days (range: 9–486). The median CMV DNA level at the start of therapy was 5370 IU/mL (300–4,156,259) or 1760 copies/mL (72–559,000). A response to maribavir therapy was achieved in 39 patients (76.5%). The median time to CMV clearance after starting maribavir was 15 days (range: 1–84). The achieved response was maintained at the 8-week mark in 30 patients (58.8%). CMV clearance was maintained at the 16-week mark in 13 patients (25.5%). The six-month cumulative incidence of recurred CMV infection from the start of maribavir was 33.4% (95% CI: 20 – 47.5). At the 4-week mark, the following Grade 3-4 adverse events were recorded: thrombocytopenia in 28 patients (54.9%); neutropenia, leukopenia, and anemia in 16 patients each (31.4%); and acute kidney injury with hyperkalemia in 1 patient (1.9%). However, their association with maribavir was not documented. The six-month overall survival from the start of maribavir therapy was 72.5% (95% CI: 57.2–83.2), and the six-month failure-free survival was 44.5% (95% CI: 29.5–58.4). During maribavir therapy, reactivation of other herpesviruses was also noted: Human Herpesvirus 6 in 32 patients (62.7%), Epstein-Barr Virus in 12 (23.5%), Herpes Simplex Virus types 1 and 2 in 10 (19.6%), as well as 2 cases of herpes zoster (3.9%).

Conclusions: Maribavir therapy demonstrated efficacy in achieving CMV clearance, comparable to the results of clinical trials. However, maintaining this response and preventing CMV recurrence remain challenging. Careful monitoring and management of other herpesvirus infections are essential during maribavir therapy.

Disclosure: COI: Maribavir was obtained through extended access program.

B096

EFFECTIVENESS OF A STRUCTURED PREVENTION STRATEGY FOR HBV REACTIVATION IN ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION USING HBSAG-POSITIVE DONORS

Hematology, Zhejiang University, Hangzhou, China, [4]Department of Hematology, Zhejiang Cancer Hospital, Hangzhou Institute of Medicine (HIM), Chinese Academy of Sciences, Hangzhou, China

Background: Donor scarcity frequently necessitates the use of HBsAg-positive donors, yet no unified guidelines exist for managing allogeneic hematopoietic stem cell transplantation (allo-HSCT) from such donors. Building on our retrospective evidence supporting a structured HBV management protocol, we conducted a prospective single-center evaluation of this strategy.

Methods: Between May 2020 and February 2025, 47 patients undergoing allo-HSCT from HBsAg-positive donors at our center were prospectively enrolled. Donors with detectable HBV DNA received entecavir 0.5 mg/day until completion of stem cell collection. HBsAg-positive recipients received long-term antiviral prophylaxis. HBsAg-negative recipients received HBIG at months 0, 1, and 2, followed by HBV vaccination at 1 year. Antiviral therapy was initiated immediately upon HBV reactivation (HBVr). The primary endpoint was the cumulative incidence of HBVr; secondary endpoints included HBV-related hepatitis, non-relapse mortality (NRM), and liver-related mortality. The study was approved by the Ethics Committee of the First Affiliated Hospital of Zhejiang University School of Medicine (ChiCTR2000032614).

Results: After a median follow-up of 1309 days (95% CI, 1043–1540), 12 patients developed HBVr, including 4 with HBV-related hepatitis. HBVr occurred at a median of 464 days post-HSCT (IQR, 307–623). The 3-year cumulative incidences of HBVr and HBV-related hepatitis were 30% (95% CI, 16–44) and 10% (95% CI, 3.1–22), respectively. The 3-year NRM was 9.4% (95% CI, 2.9–21), and no liver-related deaths occurred.
Among 10 HBsAg-positive and 37 HBsAg-negative recipients, HBVr occurred in 3 and 9 patients, respectively. The 3-year cumulative incidences of HBVr, HBV-related hepatitis, and NRM were 37%, 23%, and 0% in HBsAg-positive patients, and 28%, 6.1%, and 12% in HBsAg-negative patients, respectively, with no significant differences (all $p>0.05$) (Fig.1A-C). Following HBVr, antiviral therapy was modified in HBsAg-positive recipients, whereas HBsAg-negative recipients initiated antiviral treatment with entecavir or tenofovir.
HBsAg-negative recipients were further stratified into $HBcAb^+/HBsAb^+$ (n=17), $HBcAb^+/HBsAb^-$ (n=4), and $HBcAb^-$ (n=16) groups. Within this cohort, 21 recipients received hepatitis B vaccination at 1 year after allo-HSCT. $HBcAb^+/HBsAb^-$ patients had a significantly higher 3-year HBVr incidence (100%, 95% CI, 100–100) compared with $HBcAb^-$ (6.7%, 95% CI, 0.37–27; $p<0.001$) and $HBcAb^+/HBsAb^+$ patients (27%, 95% CI, 7.5–52; $p=0.007$) (Fig.1D).
Among the 9 HBsAg-negative recipients who developed HBVr, HBsAb titers declined consistently prior to reactivation, with a median titer of 0.45 mIU/mL (IQR, 0–1) at the time of HBVr (Fig.1E). In the overall HBsAg-negative cohort, serial monitoring demonstrated a marked decline in HBsAb levels after HSCT, reaching persistently low levels by 6 months post-transplantation (Fig.1F).

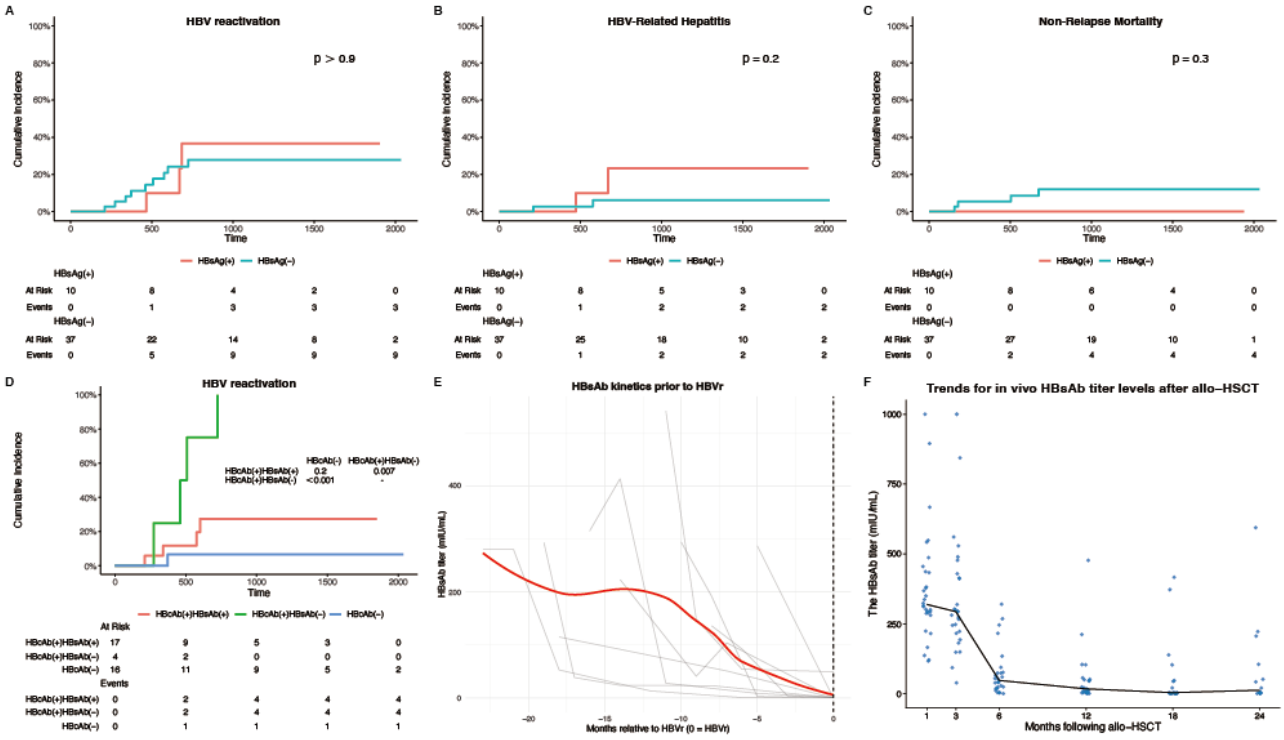

Figure 1. HBV-related outcomes and HBsAb dynamics following allo-HSCT from HBsAg-positive donors

Conclusions: This prospective study demonstrates that a novel HBV management strategy is feasible and associated with excellent hepatic safety, with no liver-related mortality observed. Although HBVr occurred, it was clinically manageable. Substantial heterogeneity in HBVr risk was observed among HBsAg-negative recipients with different baseline serologic profiles, providing important insights for the future refinement of risk-stratified preventive strategies. Dynamic declines in HBsAb levels may serve as an early biomarker of HBVr risk. Collectively, these findings support broader implementation and further refinement of structured HBV management when using HBsAg-positive donors in allo-HSCT.

Clinical Trial Registry: The study was registered in the Chinese clinical trial registry (ChiCTR2000032614).

LETERMOVIR PRIMARY PROPHYLAXIS IS A PROTECTIVE FACTOR FOR SURVIVAL IN HEMATOPOIETIC CELL TRANSPLANT RECIPIENTS. DATA

FROM THE FIRST PROSPECTIVE MULTICENTER STUDY IN LATIN AMERICA

Fabian Herrera[1], *Diego Torres*[1], *Lucas Tula*[2], *Noelia Mañez*[3], *Florencia Otermin*[4], *Ana Laborde*[5], *María Laura Pereyra*[6], *Manuel Alderete*[7], *Hugo Peretti*[8], *María José Eusebio*[9], *Silvina García Rojas*[9], *Nicolás Lasserre*[1], *Julieta Dalmaroni*[2], *Facundo Arguello*[3], *María Elena Silva*[4], *María Luz González Ibañez*[5], *Rocío Gago*[6], *Santiago Adriani*[8], *Rosana Jordán*[9]
[1]*Centro de Educación Médica e Investigaciones Clínicas (CEMIC), Buenos Aires, Argentina,* [2]*Hospital de Alta Complejidad El Cruce, Buenos Aires, Argentina,* [3]*Hospital Italiano de Buenos Aires, Buenos Aires, Argentina,* [4]*Hospital Italiano de La Plata, Buenos Aires, Argentina,* [5]*Fundación de Lucha contra la Leucemia (FUNDALEU), Buenos Aires, Argentina,* [6]*Hospital Universitario Austral, Buenos Aires, Argentina,* [7]*Instituto Alexander Fleming, Buenos Aires, Argentina,* [8]*Sanatorio Británico de Rosario, Rosario, Argentina,* [9]*Hospital Británico de Buenos Aires, Buenos Aires, Argentina*

Background: Letermovir (LET) primary cytomegalovirus (CMV) prophylaxis in Allogeneic Hematopoietic Cell Transplant Recipients (aHCT) is not available in many Latin American countries and has limited access. Therefore, data on its use are currently scarce.
The aim of the study was to describe and compare the incidence of clinically significant infection (cs-CMVi), CMV disease (CMV-d), CMV-related rehospitalization, and mortality between patients who received LET primary prophylaxis or were managed with preemptive therapy (PET). We further aimed to identify risk factors for overall mortality at day +200 post-HCT.

Methods: A prospective observational multicenter cohort study was conducted in 9 referral centers in Argentina between January 2020 and September 2025. Adult CMV-seropositive aHCT recipients who received LET until day 100 post-HCT or were managed with PET were included. Weekly CMV plasma viral load was monitored from pre-engraftment and follow-up to day +200 post-HCT. Baselines and clinical characteristics, risk factors for cs-CMVi and CMVd, and outcome variables were evaluated. A propensity score (PS) to balance baseline covariates was used. Adjusted conditional multivariate logistic regression analysis to PS was used to identify independent risk factors for 200-day mortality.

Results: Five hundred and fifty-one patients were included (PET: 346 and LET: 205), with median ages of 41 years (IQR: 28-53) in the PET group and 46 years (IQR: 33-60) in the LET group ($p < 0.001$). The most frequent underlying diseases were acute myelogenous leukemia (33.2%) and acute lymphoblastic leukemia (28.49%), with no differences between groups. CMV seronegative donors, alternative donors, post-transplant Cyclophosphamide administration and T-cell depletion were compared in PET vs. LET groups: 12.43% vs. 30.73% ($p<0.001$), 56.94% vs. 87.32% ($p<0.001$), 51.73% vs. 80.98% ($p<0.001$), and 12.14% vs. 15.61% ($p=0.24$), respectively. High risk stratification for the development of CMV-d was 88.15% in the PET group compared to 97.07% in the LET group ($p=0.003$). cs-CMVi, CMV-d, and CMV-related rehospitalization at day 100 post-HCT were compared between the PET and LET groups: 54.34% vs. 7.32% ($p<0.001$), 7.51% vs. 0% ($p=0.001$), and 37.86% vs. 10.24% ($p<0.001$), respectively. Mortality at day 200 post-HCT was 21.68% in the PET group vs. 16.10% in the LET group (0.11). Multivariate analysis adjusted for PS identified the following risk factors for mortality: graft failure, OR 16.57, CI 95%, 5.23-55.52

(p<0.001), GvHD with high dose of corticosteroids, OR 1.90, CI 95%, 1.19-3.04 (p=0.007), and lymphopenia < 300/ mm^3, OR 1.78, CI 95%, 1.10-2.89 (p=0.019). LET primary prophylaxis was a protective factor for survival, OR 0.51, CI 95%, 0.29-0.89 (p=0.018).

Conclusions: Our cohort largely comprised patients at high risk of developing cs-CMVi and CMV-d. Notwithstanding that, LET primary prophylaxis effectively prevented CMV-related complications, reduced rehospitalizations and was a protective factor for survival. These data support the use of this antiviral for primary prophylaxis in seropositive aHCT patients in Latin American countries.

SAFETY OF OMITTING ANTIBACTERIAL PROPHYLAXIS IN ADULT ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANT RECIPIENTS: EXPERIENCE FROM A SINGLE CANADIAN CENTER

Omar Eduard0 Fernández Vargas[1], *Laetitia Yahiatene*[2], *Annie Brisebois-Boyer*[3], *Maude Bachand-Fournier*[3], *Imran Ahmad*[1], *Léa Bernard*[1], *Sandra Cohen*[1], *Jean-Sébastien Delisle*[1], *Thomas Kiss*[1], *Daiana Rodriguez*[1], *Denis-Claude Roy*[1], *Jean Roy*[1], *Guy Sauvageau*[4], *Olivier Veilleux*[1], *Antoine Couture-Cossette*[3], *Sylvie Lachance*[1]
[1]*Institut d'Hématologie, Greffe et Thérapie Cellulaire, Université de Montréal, Montréal, Canada,* [2]*Université de Montréal, Montréal, Canada,* [3]*CIUSS de l'Est de l'Ile de Montréal, Université de Montréal, Montréal, Canada,* [4]*IRIC, Université de Montréal, Montréal, Canada*

Background: Graft-versus-host disease (GVHD) and infectious complications remain major contributors to non-relapse mortality (NRM) following allogeneic hematopoietic cell transplantation (alloHCT). Guidelines from major societies (IDSA, NCCN) recommend antibacterial prophylaxis (pATB) for patients at increased infectious risk however, although pATB reduces fever and bacteremia, it has not shown improved survival, and emerging evidence suggests fluoroquinolone (FQ) exposure may disrupt the intestinal microbiome and increase acute GVHD. Rising antimicrobial resistance and higher rates of *Clostridioides difficile* infections have led many centers to reconsider routine prophylaxis. After demonstrating that pATB increase GI GVHD and impaired survival, our center ceased pATB and evaluated infectious complications and early transplant outcomes.

Methods: We conducted a retrospective single-center study of consecutive adults undergoing alloHCT from November 2022 to March 2025 without routine pATB. Patients

receiving experimental graft manipulation or a second alloHCT were excluded. Collected variables included demographics, donor type, graft source, and conditioning intensity. All patients had central venous access. First-line therapy for febrile neutropenia (FN) in stable, non–high-risk patients was cefepime. Outcomes included FN rates, bacteremia, bacterial distribution, infection-related mortality (IRM), acute GVHD (including GI involvement), use of carbapenems or vancomycin, and *C. difficile* infection. Descriptive statistics summarized safety outcomes.

Results: We analyzed 204 consecutive alloHCT recipients (median age 56.5 years). Acute leukemias (49.0%), MDS/MPN (27.9%), and lymphomas (13.2%) were most common indications. Matched unrelated donors accounted for 62.7%, and peripheral blood stem cells for 85.8% (Table 1).
FN occurred in 185 (90.7%) patients, and 86 (46,5%) of these had documented bacteremia. Isolated gram-positive and gram-negative bacteria were present in 37.2% and 36% of these FN episodes, respectively, and 26.7% had polymicrobial infections. Fluoroquinolone resistance among gram-negative isolates occurred in 14/54 (25.9%) evaluable cases, whereas cefepime resistance was identified in only two patients. Carbapenems were required in 64 (34.6%) FN episodes, and vancomycin in 93 (50.3%). Among 31 cases of *Clostridioides difficile* infection, 13 were detected prior to any antibiotic exposure, and one patient had a recent pre-transplant episode (Table 2).
aGVHD developed in 96 patients (47.1%), with upper GI involvement in 21.6% and lower GI in 11.3%; eight patients (3.9%) had grade III–IV lower-GI disease. There were 35 relapses and 39 deaths, including 17 NRM events attributed to GVHD (n=3), organ toxicity (n=3), COVID-19 (n=2), PTLD (n=2), hepatic failure (n=1), endothelial injury (n=1), bleeding (n=1), and bacterial infections (n=4). Infection-related deaths predominantly occurred in patients with FQ resistant isolate or identifiable high-risk features. Median follow-up was 12.6 months, with 12-month NRM of 7.8% and IRM of 2.2%.

Conclusions: In this alloHCT cohort managed without pATB, FN rates, and bacteremia were within expected ranges and effectively managed with cefepime. Fluoroquinolone resistance was found in 25,9% of gram-negative bacteriemia. Many *C. difficile* infections occurred independently of antibiotic exposure. Severe acute GI-GvHD and NRM rates were low. Severe infection-attributable mortality was uncommon and non preventable by pATB. Overall, these results suggest that omission of antibacterial prophylaxis is safe in well-monitored alloHCT recipients and supports ongoing antimicrobial stewardship. Further comparative studies are needed to refine patient selection.

Figure 1. alloHCT characteristics

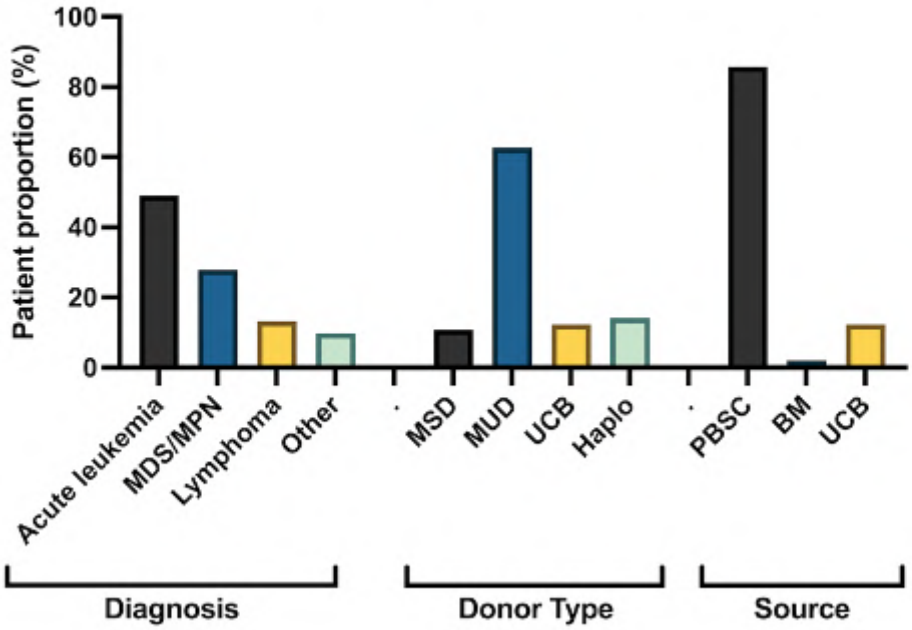

Table 2. Infectious outcomes, antimicrobial use and GvHD rates

Domain	Variable	Results
Febrile Neutropenia (FN)	FN episodes, n (%)	185/204 (90.7)
Bacteremia among FN	Bacteremia, n (%)	86/185 (46.5)
	Gram-positive isolate, n (%)	32/86 (37.2)
	Gram-negative isolate, n (%)	31/86 (36.0)
	Mixed (both), n (%)	23/86 (26.7)
Antimicrobial resistance	Gram-negative fluoroquinolone resistance, n (%)	14/54 (25.9)
Therapy for FN	Cefepime as first-line, n (%)	163/185 (88.1)
	Carbapenem use, n (%)	64/185 (34.6)
	Vancomycin use, n (%)	93/185 (50.3)
Other infectious outcomes	*C. difficile* infection, n (%)	31/204 (15.2%)
Acute Graft-versus-Host Disease (aGvHD)	Any grade aGvHD, n (%)	96/204 (47.1)
	Upper aGvHD, n (%)	44/204 (21.6)
	Lower aGvHD, n (%)	23/204 (11.3)

Variables with denominator 185 refer to patients with febrile neutropenia; variables with denominator 204 refer to the full allo-HCT cohort.

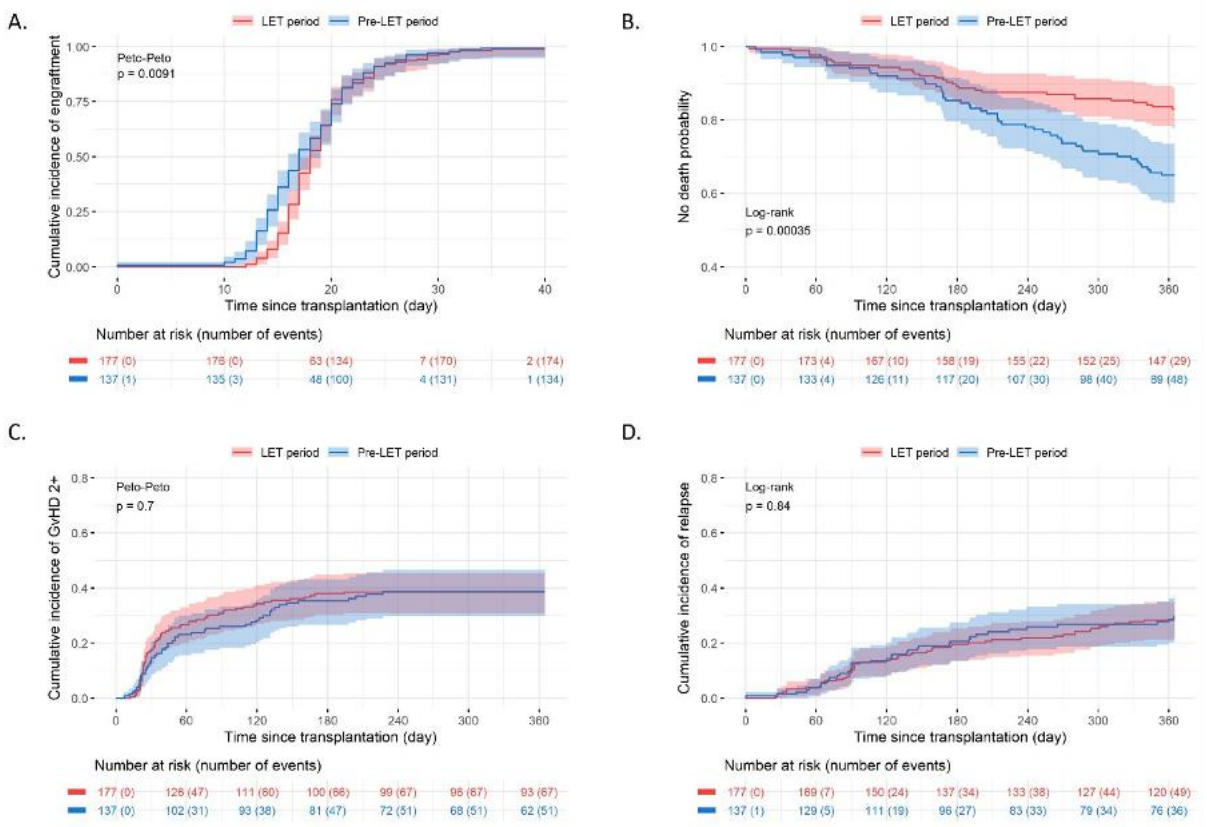
EARLY ADMINISTRATION OF LETERMOVIR PROPHYLAXIS POST-ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION IS ASSOCIATED WITH DELAYED ENGRAFTMENT

Léna Royston[1], Catia Vieira Gomes[1], Ming Zou[2], Yves Chalandon[1], Stavroula Masouridi-Levrat[1], Laurent Kaiser[1], Christian Van Delden[1], ***Dionysios Neofytos***[1]
[1]University Hospital of Geneva, Geneva, Switzerland, [2]University Hospital Basel, Basel, Switzerland

Background: Since its introduction as primary prophylaxis in allogeneic hematopoietic cell transplant recipients (allo-HCTR), multiple studies have confirmed the broad beneficial influence of letermovir on both virological and hematological outcomes. However, its impact on hematologic reconstitution and especially engraftment remains poorly described.

Methods: We conducted a retrospective cohort study including all consecutive adult allo-HCTR (16.11.2015-31.12.2023) in our center. Letermovir prophylaxis was administered after 01.05.2019 from day (d) 1 to d100 posttransplant in CMV-seropositive patients (R+). We assessed the differences in cumulative incidences (Log-rank or Peto-Peto tests, as appropriate) in the time-to-engraftment, all-cause mortality, hematological relapse and grade≥2 acute GvHD by 1-year posttransplant, in CMVR+ allo-HCTR in the pre- and post-letermovir periods.

Results: Overall, 137 (65%) and 177 (60%) allo-HCTR were considered as CMV R+ during the pre- and post-letermovir periods, respectively. Patient characteristics were similar between the 2 periods except for higher rates in the post-letermovir period of peripheral blood versus bone marrow stem cells for HCT sources, and of cyclophosphamide-based regimens for GvHD prophylaxis. In CMV R+, engraftment was significantly delayed in the letermovir period (median 17d versus 18d post-HCT in the pre- and post-letermovir periods, respectively, p = 0.009, Figure 1A). As already reported, 1-year all-cause mortality was significantly decreased during the letermovir period ($p < 0.001$, Figure 1B), whereas cumulative incidences at 1-year of acute GvHD and hematologic relapse were similar (Figure 1C-1D). In multivariate Cox regression analysis, letermovir prophylaxis was negatively associated with engraftment (hazard ratio 0.71, $p = 0.008$).



Conclusions: In our cohort, engraftment is slightly but significantly delayed in allo-HCTR+ receiving letermovir compared to the pre-letermovir period, despite the reduction in post-HCT CMV reactivation incidence and improved survival. In the literature, few studies report on engraftment but 5/9 studies also find delayed engraftment in letermovir-receiving patients. This effect is independent of other tested covariables and could be due to the drug itself or virus-mediated. Additional studies are needed to confirm this association and explore its clinical significance.

Disclosure: No conflict of interest related to this work.

EXHALED-BREATH VOLATILE MARKERS OF INVASIVE PULMONARY ASPERGILLOSIS IN PEDIATRIC CANCER AND STEM CELL TRANSPLANT PATIENTS: A PILOT STUDY

Laura Rotte[1], *Shahriyar Shahbazi Khamas*[2], *Janine Nijhuis*[1], *Anne Neerincx*[2], *Anke-Hilse Maitland*[3], *Tom Wolfs*[4], *Paul Brinkman*[2], *Caroline Lindemans*[1]

[1]Princess Maxima Center for Pediatric Oncology, Utrecht, Netherlands (the), [2]Amsterdam University Medical Center, University of Amsterdam, Amsterdam, Netherlands (the), [3]University Medical Center Groningen, Groningen, Netherlands (the), [4]Wilhelmina Children's Hospital, University Medical Center Utrecht, Utrecht, Netherlands (the)

Background: Invasive pulmonary aspergillosis (IPA) remains a major clinical challenge in pediatric cancer and stem cell transplant patients and has a high mortality. Early and accurate diagnosis is complicated by a lack of specificity of CT chest imaging, limited sensitivity of bronchoalveolar lavage (BAL) diagnostics and the invasiveness of lung sampling procedures. Exhaled breath analysis might offer a non-invasive alternative by detection of volatile organic compounds (VOCs). In this pilot we aimed to identify mold-associated VOCs in the exhaled breath of pediatric cancer and stem cell transplant patients with IPA.

Methods: Between March 2022 and December 2024, a prospective case–control study was conducted at the Princess Máxima Center for Pediatric Oncology. Exhaled breath samples were collected from immunocompromised children with probable or proven IPA, taken at initial diagnosis and after completion of antifungal treatment. They were compared to exhaled breath samples collected from immunocompromised children without IPA. Sparse partial least square discriminant analysis was used to develop a VOC model consisting of the most relevant VOCs discriminating between groups. The performance of the model was tested by calculation of the area under the receiver operating characteristic curve (AUROCC). VOCs were explored and annotated for metabolic origin using Kyoto Encyclopedia of Genes and Genomes, FungiDB, and the Human Metabolome Database.

Results: Thirty-three children were enrolled (21 pulmonary IPA cases, 12 controls), yielding 45 breath samples. Discriminative VOCs between cases and controls were, 3-methyl-1-butanol, α-pinene, and ethyl acetate, achieving an AUROC of 0.93 (95% CI: 0.82–1.00) in the training set and 1.00 (95% CI: 1.00–1.00) in the test set. Longitudinal analysis showed declining levels of these VOCs following antifungal therapy. Pathway annotation linked these compounds to fungal amino acid degradation (3-methyl-1-butanol), central carbon metabolism (ethyl acetate), and terpenoid biosynthesis (α-pinene), consistent with known *Aspergillus* metabolic pathways.

Conclusions: This study identified three candidate VOCs as potential biomarkers associated with pulmonary aspergillosis in pediatric cancer and stem cell transplant patients. Their strong diagnostic performance and decrease following antifungal treatment suggest potential roles in both non-invasive diagnosis and therapeutic monitoring. Validation in larger, independent cohorts is needed to confirm these results and support the development of breath-based diagnostic tools for IPA.

Disclosure: Nothing to declare.

CMV INFECTION AFTER ALLOGENEIC HSCT IN SERONEGATIVE RECIPIENTS TRANSPLANTED FROM A SEROPOSITIVE DONOR: A MONOCENTRIC RETROSPECTIVE STUDY

Constance Fournier[1], Mathilde Ruggiu-Goirand[1], Marie Robin[1], Flore Sicre de Fontbrune[1], David Michonneau[1], Clara Caillon[1], Matthieu Jestin[1], Florian Chevillon[1], Nathalie Dhedin[1], Regis Peffault de Latour[1], Jerome Le Goff[1], ***Alienor Xhaard***[1]
[1]*Hopital Saint-Louis, Paris, France*

Background: CMV infection is a significant cause of morbidity and mortality after allogeneic hematopoietic stem cell transplantation (alloHSCT). The incidence of CMV infection has been reported as high as 30% in seronegative recipients transplanted from a seropositive donor (D+/R-). Since 2017, letermovir (LMV) prophylaxis is recommended after alloHSCT in R+ to decrease the incidence of clinically significant CMV infection (CS-CMVi). However, its use in D+/R- has not been studied.

Methods: In this monocentric retrospective cohort, we compared among D+/R-, patients receiving or not LMV prophylaxis after alloHSCT (based on the physician in charge's personal decision). CMV PCR was prospectively collected in blood twice weekly from transplantation until D+100. CS-CMVi was defined as CMV infection requiring pre-emptive treatment (according to locally defined threshold) or CMV disease. Transplant characteristics were extracted from the EBMT Promise registry. Clinical data were collected from electronic medical records. The primary outcome was the cumulative incidence of CS-CMVi at D+100 in both groups. Survival curves were generated using Kaplan–Meier and multivariable analysis was conducted using a time-dependent Cox proportional hazards model. All statistics were performed in R.

Results: We included 163 D+/R- patients transplanted from January 2012 to March 2025 in Saint-Louis hospital, Paris, France: 18 patients received LMV while 145 did not. Patient characteristics are presented in the table.
Between alloHSCT and D+100, CMV PCR was positive at least once in 34/145 patients (23.4%) in the no-LMV group vs 0/18 in the LMV group ($p<0.01$). However, the incidence of CS-CMVi was not statistically different (24/145 (16.5%) in the no-LMV group vs 0/18 in the LMV group, $p= 0.07$). First line pre-emptive treatment was given for a median of 23 days (min: 15, max: 68) and was ganciclovir in 23/24 patients (96%). Eight patients (33.3%) needed second-line foscarnet treatment due to cytopenia (n= 7) or virological failure (n= 1). CMV contributed to death in one patient. There was no significant difference in the D+100-overall survival (88%, 95%CI [88-96] in the no-LMV group vs 93%, 95%CI [62-97] in the LMV group, $p= 0.45$).
Excluding patients from the LMV group, we aimed to identify risk factors for CMV PCR positivity. In univariate analysis, only TBI significantly increased the risk of positive CMV PCR, while the underlying hematological disease, intensity of conditioning, anti-thymocyte globulin (ATG), donor type, stem cell source, sex matching and graft-versus-host disease

(GVHD) as a time-dependent covariate, did not. In multivariate analysis including GVHD as a time-dependent covariate, ATG and TBI, only TBI remained significant (HR 2.4, 95%CI [1.1-5.4], p= 0.03).

	Overall population n = 163	Letermovir n=18 (%)	No Letermovir n=145 (%)	p

Conditioning intensity				0.88
Reduced-intensity	114 (69.9)	13 (72.2)	101 (69.6)	
Myelo-ablative	49 (30.1)	5 (27.8)	44 (30.3)	
ATG	97 (55.8)	7 (38.8)	90 (62)	0.07
Alemtuzumab	11 (6.7)	4 (22.2)	7 (4.8)	0.02
TBI (all doses)	38 (23.3)	2 (11.1)	36 (24.8)	0.24
TBI ≤ 8 Gy	17 (10.4)	2 (11.1)	15 (10.3)	0.92
GvHD prophylaxis				
CNI alone	10 (6.1)	3 (16.6)	7 (4.8)	0.08

CNI + MMF	99 (60.7)	11 (61.1)	88 (60.7)	0.97
CNI + MTX	54 (33.1)	4 (22.2)	50 (34.5)	0.42
PTCy + CNI + MMF	19 (11.7)	5 (27.8)	14 (9.6)	0.04

Conclusions: In our cohort, the incidence of positive CMV PCR in D+/R- alloHSCT patients was lower than historically reported. LMV significantly reduced the incidence of CMV PCR positivity, and was associated with a trend towards a significant reduction in the incidence of CS-CMVi, maybe due to the small size of the cohort. TBI was the only factor significantly associated with a CMV PCR positivity.

CYTOMEGALOVIRUS REACTIVATION IN A SINGLE CENTER PAEDIATRIC COHORT UNDERGOING HAEMATOPOIETIC STEM CELL TRANSPLANTATION AND USE OF LETERMOVIR

*Marina García-Morin[1], María Salvador-Rodríguez[1], **Teresa Martín Aláez**[1], Paula Gallardo Ortiz[1], Pablo González Navarro[2], Eduardo J. Bardón-Cancho[1], Elena Cela[1], Alba Gonzalez Guerrero[1], Jose Manuel Marco-Sanchez[1], Cristina Belendez[1]*
[1]Pediatricas Haematology Unit. Hospital General Universitario Gregorio Marañon, Madrid, Spain, [2]Unidad de Metodología y Bioestadistica - Instituto de Investigacion Sanitaria Gregorio Marañon, Madrd, Spain

Background: Viral reactivations, especially cytomegalovirus (CMV), are a common complication in paediatric patients undergoing hematopoietic stem cell transplantation (HSCT). In recent years, letermovir has been authorized for the prophylaxis in seropositive HSCT recipients and has shown to reduce CMV reactivations.
Objective: To evaluate, under real-world conditions, the effectiveness of letermovir use in paediatric patients.

Methods: Retrospective observational study of pediatric patients undergoing HSCT from May 2010 to July 2025 at a tertiary hospital. The collected variables included: age, donor/recipient CMV serology, prophylaxis with letermovir, myeloablative or reduced-intensity conditioning, administration of serotherapy and donor type (HLA- identical sibling [MSD], haploidentical with post-transplant cyclophosphamide, other related donors [MMFD] and matched unrelated donor [MUD]. The efficacy variables studied were CMV reactivation, CMV disease, treatment with foscarnet or ganciclovir, and other viral reactivations.

Results: A total of 134 patients were included; the median age at transplant was 7.5 years old (range 3.5 months – 18 years). Underlying diseases included: haemoglobinopathies 78, malignant diseases 41, bone marrow failures 9, immunodeficiencies 6. Donor type were as follows: MSD 84, Haploidentical 33, MMFD 6, MUD 11. Conditioning was myeloablative in 125

patients (93%) and reduced intensity in 9. Serotherapy was administered in 93 patients (69%).
Eighty-four % of recipients and 78% of donors were CMV-seropositive; 7% of recipients were CMV-negative while donors were positive. Twelve patients (9%) with negative serology (donor and recipient) were excluded, leaving 122 patients for further analysis.
A total of 79/122 patients (65%) experienced CMV reactivation. Among those without prophylaxis, the reactivation and treatment rates were 33% in MSD recipients without serotherapy, 73% with serotherapy, 63 % in haploidentical donors, 83% in MMFD (all but 1 with serotherapy) and 56 % in MUD.
Sixteen (13%) patients received letermovir: 11 had a haploidentical transplant, 2 a MUD and 3 a MSD. Among these patients, only 2/16 (13%) required foscarnet/ganciclovir due to progressive increase in viral load, 2 developed HHV-6 encephalitis and one macrophage activation syndrome caused by HHV-6. All patients stopped letermovir before day 200 post-transplant. 2 patients suffered CMV- reactivation, one of them with enteritis involvement. Regarding the safety profile, no significant toxicities were reported. One patient experienced grade 1 vomiting related to administration. No treatments were discontinued due to toxicity. Only one patient in the cohort without letermovir developed possible HHV-6 encephalitis (versus metothrexate toxicity).

Conclusions: CMV reactivation is a common complication following HSCT. Letermovir could be effective for prophylaxis in seropositive paediatric patients without significant toxicity. In our series, patients who received serotherapy reactivated CMV more frequently. However, further studies with larger sample sizes and longer follow-up are needed to assess its effectiveness, as well as its impact on CMV reactivation after discontinuing prophylaxis and other viral reactivations, such as HHV-6, which could potentially be covered by preemptive treatment with foscarnet and/or ganciclovir.

B104

PRESERVATION OF ADAPTIVE IMMUNITY AFTER NONMYELOABLATIVE HEMATOPOIETIC CELL TRANSPLANTATION IN ADULTS WITH SICKLE CELL DISEASE (PROTECT STUDY)

*Elisabeth Dovern[1,2], Maud Zwolsman[1,2,3], Abraham Goorhuis[1,2], Bart Biemond[1,2,4], Katja Wolthers[1], **Erfan Nur**[1,3,4]*
[1]Amsterdam UMC, Amsterdam, Netherlands (the), [2]Amsterdam Institute for Infection and Immunity, Amsterdam, Netherlands (the), [3]Sanquin Research and Landsteiner Laboratory, Amsterdam, Netherlands (the), [4]Cancer Center Amsterdam, Amsterdam, Netherlands (the)

Background: Recipients of allogeneic hematopoietic cell transplantations (HCT) generally lose vaccination-derived immunity, necessitating revaccination. Patients with sickle cell disease (SCD) undergoing matched sibling donor (MSD) transplantation with nonmyeloablative alemtuzumab/total body irradiation (TBI) conditioning develop mixed lymphoid chimerism, potentially preserving their own immunity. We hypothesized that mixed

chimerism after nonmyeloablative MSD transplantation results in preservation of immunity, rendering revaccination potentially unnecessary.

Methods: Preservation of previously developed immunity against measles, rubella, and *Streptococcus pneumoniae* vaccinations was prospectively evaluated in SCD patients undergoing nonmyeloablative transplantation (mixed chimerism; n=24) as compared to patients undergoing haploidentical HCT with a more intensive conditioning regimen (full donor chimerism; n=14). To confirm that the preservation of pre-transplant immunity was recipient-derived, we evaluated immunity against HBV vaccination in subgroup of patients undergoing MSD (n=6) or haploidentical (n=6) transplantation and in non-transplant control SCD patients (n=6). None of the donors had been infected by or vaccinated against HBV. All patients received HBV vaccinations in an accelerated schedule in the months before transplantation. Additionally, immune reconstitution was assessed by measuring lymphocyte subsets (CD3+, CD4+, CD8+, CD19+, and natural killer cells), and total IgG levels at baseline and multiple timepoints after transplantation.

Results: After a follow-up of 24 months, immunity preservation was higher in MSD recipients than in haploidentical recipients for measles (86% vs 70%, p=0.36) and rubella (95% vs 67%, p=0.053), as shown in Figure 1A/B. Pneumococcal immunity remained intact in 95% of MSD recipients compared to only 17% of haploidentical recipients (p=0.005; Figure 1C). Of the patients vaccinated with HBV prior to HCT, three patients (50%) in the MSD cohort and two patients (33%) in the haploidentical cohort lost protective anti-HBs titers, with results in the MSD cohort likely confounded by rituximab treatment shortly after transplantation. In the non-transplant control cohort, one patient remained seronegative and another patient with initial response lost protection against HBV. Immune reconstitution after HCT followed similar trajectories in both groups, with CD3+, CD4+, CD8+, and CD19+ counts falling below reference values after 3 months and recovering to normal levels between 12 and 24 months. However, throughout follow-up, MSD recipients maintained significantly higher total IgG levels, most pronounced at +3 months (16.1 vs 8.1 g/L, p<0.001).

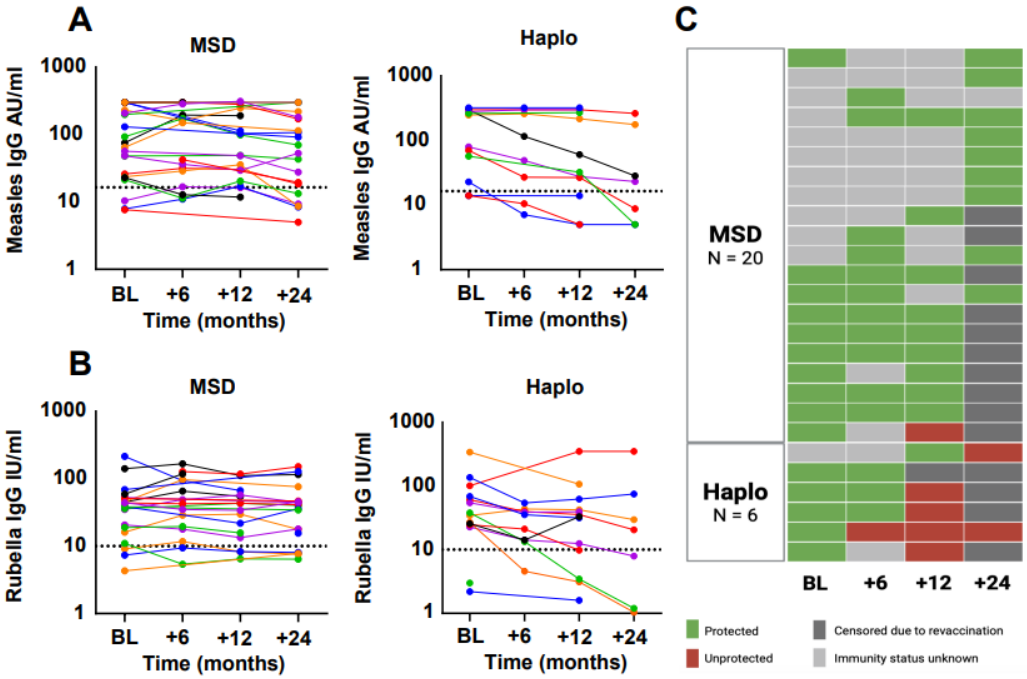

Figure 1. Course of measles (A) and rubella (B) specific IgG titers in the months following hematopoietic cell transplantation (HCT) for MSD (left) and haploidentical (right) groups. Protective threshold is indicated by the dotted line. Measles seropositivity cutoff value > 16.5 AU/mL. Rubella cutoff value > 10 IU/mL. Each line represents an individual subject. (C) Course of immunity against Streptococcus pneumoniae infection at baseline, +6, +12 and +24 months after HCT for MSD and haploidentical transplant recipients. Each row represents an individual subject. Subjects without any data regarding pneumococcal immunity and subjects with only baseline available are not shown. For the single value ELISA, subjects with a titer above 37 mg/L are considered immune. For the multiple subvariant test, subjects with antibody titers above 1.0 µg/mL for 6 or more pneumococcal serotypes are considered immune. Abbreviations: BL = baseline, MSD = matched sibling donor.

Conclusions:
Our results suggest that nonmyeloablative MSD transplantation leading to mixed chimerism results in better preservation of pre-transplant immunity compared to haploidentical transplantations with full donor chimerism. MSD recipients demonstrated high preservation of immunity across important pathogens, whereas haploidentical recipients showed considerable variability in immune preservation, both across pathogens and between patients. The comparable preservation of anti-HBV response between the transplant groups and the non-transplant controls indicates that the preservation of pre-transplant immunity is recipient-derived rather than donor-derived, as all the donors were not exposed to HBV (vaccination). These findings suggest that standard early revaccination programs may be omitted or delayed in adults with SCD undergoing nonmyeloablative MSD transplantation. Whether revaccination in this specific group can fully be abandoned should be subject of future research.

CAN RECTAL SWABS PREDICT POST-HCT *PSEUDOMONAS AERUGINOSA* INFECTIONS? – A PRELIMINARY SINGLE-CENTER ANALYSIS

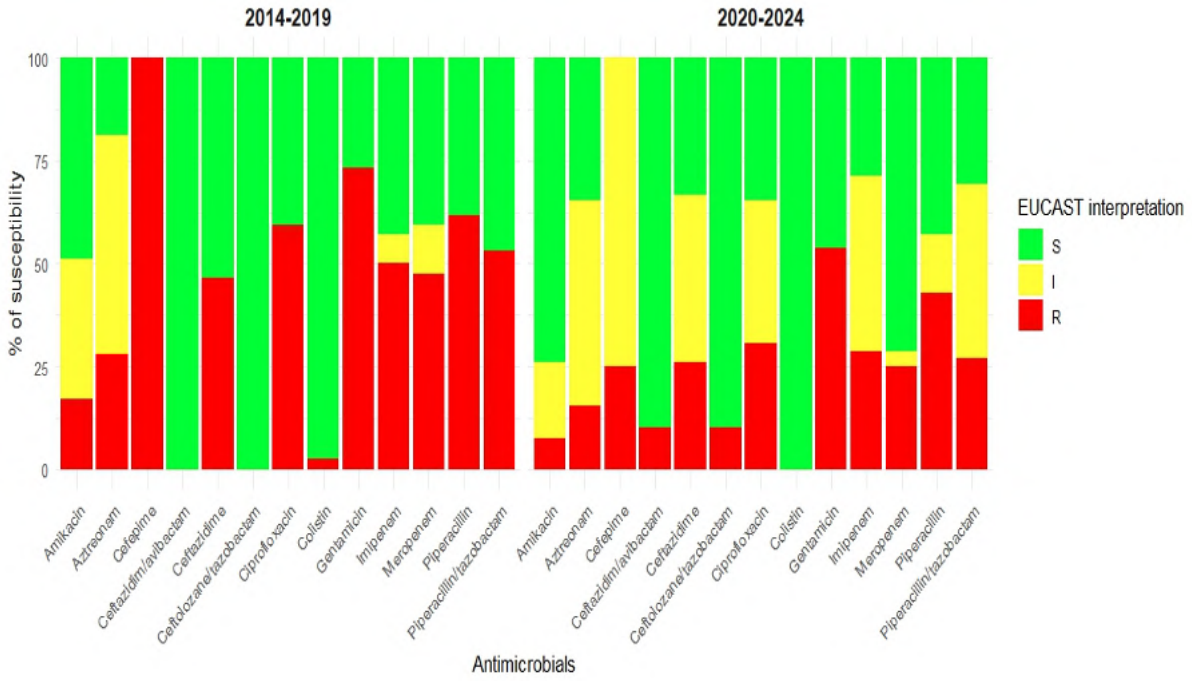
Daniele Vanni[1], Giovanna Travi[1], Francesco Peracchi[1,2,3], Martina Soldarini[1], Leonardo Luzi[1,2], Matilde Ferrario[2,1], Lorenzo Romeo[1], Chiara Vismara[1], Massimo Puoti[1,2], Roberto Cairoli[1,2], ***Giovanni Grillo***[1]
[1]*Grande Ospedale Metropolitano Niguarda, Milan, Italy,* [2]*University of Milano-Bicocca, Milan, Italy,* [3]*University of Milano, Milan, Italy*

Background: Patients undergoing hematopoietic cell transplantation (HCT) are at high risk for severe infections due to immunosuppression. Colonization with multidrug-resistant organisms increases the risk of invasive infections, particularly early post-transplant. Data on Pseudomonas aeruginosa (PSAE) colonization in HCT recipients remain limited.

Methods: We retrospectively included all adult patients who underwent autologous or allogeneic HCT at ASST GOM Niguarda, Milan, between January 1, 2014, and December 31, 2024. Clinical and microbiological data were obtained through comprehensive chart review. As part of routine clinical practice, rectal surveillance cultures were performed in all patients before transplantation and subsequently on a weekly basis post-transplant. Patients with documented PSAE colonization during the transplantation hospitalization were selected for further analysis. All invasive PSAE infections diagnosed during the study period were identified. The cumulative incidence of PSAE infection was calculated at 30 days post-transplant for non-colonized patients and at 30 days post-colonization for colonized patients, with death considered a competing event.

Results: A total of 980 patients were analyzed. Sixty-three patients had at least one PSAE-positive rectal swab, and among these, 9 developed a PSAE infection within 30 days of colonization (cumulative incidence 14.3%, 95% confidence interval [CI] 5.19–22.50%). In contrast, among 917 non-colonized patients, 9 developed PSAE infection within 30 days post-transplant (cumulative incidence 0.98%, 95% CI 0.34–1.62%). Characteristics of colonized patients are in Table 1. Reduced intensity conditioning with Thiotepa-Fludarabine-Melphalan was more frequent among colonized patients who developed infection (66.7% vs. 27.8%, p=0.017). Overall mortality was low and comparable between groups (11.1% vs. 9.3%). Multiple-site colonization was more common in infected patients compared with non-infected patients (66.7% vs. 31.5%, p=0.046). Antimicrobial susceptibility patterns of rectal isolates are shown in Figure 1: susceptibility to carbapenems increased over time, likely reflecting antimicrobial stewardship interventions, whereas resistance to ceftazidime/avibactam and ceftolozane/tazobactam increased.

Variable	Not infected n=54	PSAE infection n=9
Male	30 (55.6%)	4 (44.4%)
Charlson Comorbidity Index, Median (IQR)	3 (2-4)	2 (2-3)
Disease		
Acute Leukemia	28 (51.9%)	3 (33.3%)
Chronic Leukemia	2 (3.7%)	2 (22.2%)
Myelodispastic Syndrome/Myelofibrosis	6 (11.2%)	0 (0%)
Lymphoma	12 (22.2%)	2 (22.2%)
Multiple Myeloma	6 (11.1%)	2 (22.2%)
Type of Transplant		
Allogenic	38 (70.4%)	8 (88.9%)
Autologous	16 (29.6%)	1 (11.1%)
Absolute Neutrophil Count at the Colonization date, Median (IQR)	0.69 (0.045-2.05)	0.61 (0.11-2.91)
Site of P. Aeruginosa Colonization		
Rectal	41 (73.2%)	9 (100%)
Pharyngeal	12 (26.8%)	0 (0%)
Multiple site of colonization	17 (31.5%)	6 (66.7%)
90 day pre-transplant antimicrobial exposure	28 (51.9%)	3 (33.3%)
Mucositis	37 (68.5%)	5 (55.6%)



Conclusions: Patients colonized with PSAE exhibited a markedly higher 30-day cumulative incidence of invasive infection compared with non-colonized patients (14.3% vs 0.98%). Rectal colonization with PSAE is strongly predict subsequent invasive infection in HCT recipients, underscoring the importance of systematic surveillance and targeted preventive strategies.

B106

INTRODUCING MIPI-RADS, MOLD-ASSOCIATED INVASIVE PULMONARY INFECTION - REPORTING AND DATA SYSTEM, FOR UNIFORM ASSESSMENT AND REPORTING OF CHEST CT-IMAGING OF PULMONARY INVASIVE MOULD INFECTIONS

Elizabeth De Kort[1], *Steven Schalekamp*[1], *Anet Veringa*[2], *Cornelia Schaefer-Prokop*[3], *Nicole Blijlevens*[1]
[1]*Radboud University Medical Center, Nijmegen, Netherlands (the),* [2]*Onze Lieve Vrouwe Gasthuis, Amsterdam, Netherlands (the),* [3]*Meander Medisch Centrum, Amersfoort, Netherlands (the)*

Background: In haemato-oncology patients, ambiguous radiological reports are a common reason for starting antifungal therapy inappropriately. Current EORTC/MSGERC2020 imaging features have low sensitivity in the detection of pulmonary invasive mould infections (pIMI). These features are time-dependent and can be missed or misinterpreted by radiologists and clinicians in the presence of coinciding pulmonary pathology. In this study we developed a standardised reporting system for pIMI: MIPI-RADS, to be used in the assessment of unenhanced chest CT imaging in the haemato-oncology population at risk. We describe its performance and interobserver agreement.

Methods: MIPI-RADS was developed using current EORTC/MSGERC 2020 imaging features for pIMI and appraisal of 53 chest CT scans of haemato-oncology patients with EORTC/MSGERC probable or proven pIMI.
The MIPI-RADS was subsequently retrospectively evaluated on 110 chest CT scans (38 probable/proven pIMI) performed for suspicion of pIMI in two multicentre randomised controlled trials. A total of 8 observers were included with varying experience (range 1-24 years). In the reference standard, positives were defined as those with probable or proven pIMI only. Fleiss kappa value was calculated, and performance of the median scores of the observers were compared with the reference standard.

Results: MIPI-RADS is structured similar to other imaging reporting and data systems and grades the suspicion for pIMI in haemato-oncology patients with neutropenia on a scale from 1 (low) to 4 (high). The sensitivity, specificity, positive and negative predictive value for the median score of observers compared to the reference standard was 82%, 46%, 44% and 83%, respectively. The Fleiss kappa agreement between observers was 0.61 (p-value <0.001), indicating substantial agreement.

Table 1 MIPI-RADS

Mold associated Invasive Pulmonary Infection-Reporting And Data System

Grade	Summary	Imaging findings	Level of suspicion for pIMI
0	Not readable	Not readable	Not readable
1	no abnormalities	Normal CT imaging	No suspicion
2	aspecific findings or features not compatible with pIMI	• tree-in-bud • consolidation with or without air-bronchogram (and no other associated findings) • clustered bronchocentric solid or nonsolid nodules • diffuse ground glass or diffuse groundglass and (geographic) consolidations • Nodules <5 mm • Typical PFNs**	Low suspicion
3	Features not entirely compatible with pIMI and/or compatible with other etiologies	• Single solid nodule 5-10 mm • Single solid nodule >10 mm without halo • Multiple solid nodules in 1 lobe without halo • Multiple solid nodules in multiple lobes <10 mm without halo • tree-in-bud / airway thickening with surrounding groundglass	Indeterminate suspicion
4	Features compatible with pIMI	• Single solid nodule >10 mm with halo • Multiple solid nodules in 1 lobe at least one with halo • Multiple solid nodules in more than 1 lobe • Cavitating nodules • One or multiple consolidations + associated finding (bronchus cut-off or perifocal thickened interlobular septa or rim of ground glass) • Reversed halo	High suspicion

* pIMI =pulmonary invasive mold infection.**PFN=perifissural nodule

Radboudumc

	Value by indicated test	95% Confidence interval
Sensitivity	0,82	0,64-0,92
Specificity	0,46	0,35-0,57
Positive predictive value	0,44	0,33-0,56
Negative predictive value	0,83	0,69-0,92
Fleiss kappa	0,61	0,58-0,64

Table 2

Diagnostic performance of MIPI-RADS* and interobserver agreement
*MIPI-RADS was divided in low versus high suspicion for pulmonary invasive mold infection.

Conclusions: MIPI-RADS performs moderately well in categorizing pIMI in hemato-oncology patients. Adopting MIPI-RADS will enable concise and discrete communication of imaging results between radiologists and clinicians. Importantly, it will facilitate consistent data collection and outcome monitoring in research and daily practice.

Disclosure: E. de Kort has received a research grant from Gilead sciences which was paid to institution.

[3]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Spain, [4]ICO Bellvitge, Barcelona, Spain, [5]Hospital Pablo Tobon Uribe, Medellín, Colombia

Background: HHV-6 viremia is frequent after allogeneic hematopoietic cell transplantation (allo-HCT), but there is great difficulty in knowing its pathogenic capacity. The HHV-6B subtype is the main pathogen that causes sudden exanthema in childhood and remains latent in T lymphocytes and monocytes. Among allo-HCT recipients, encephalitis represents the most recognized clinical manifestation of HHV6 infection (incidence 1%), and has also been associated with delayed hematopoietic engraftment. In contrast, involvement of other organs is rarely reported, such as hepatitis, or underrecognized, particularly in the gastrointestinal tract, partly due to the inherent difficulties in establishing a definitive diagnosis.
Considering that changes in transplant strategies, including the widespread use of post-transplant cyclophosphamide (PTCy) and the introduction of letermovir for CMV prophylaxis, may have contributed to an increased incidence of HHV-6 infection, this study describes the incidence and clinical spectrum of HHV-6 infection in allo-HCT recipients at our institution.

Methods: All patients undergoing allo-HCT from 2015 to 2025 (June) at our institution were included. According to major modifications in transplant strategies, patients were classified into three sequential periods: Period 1: 2015-2019, when PTCy was used only in haploidentical and mismatched unrelated donor transplantation (MMUD); Period 2: 2020 and Sept-2021, when PTCy use was progressively extended to matched related and unrelated donors; Period 3: Oct-2021 and June-2025, when PTCy use was universalized, and letermovir was implemented for CMV prophylaxis.
Cases of HHV-6 infection were retrospectively analyzed. HHV-6 PCR in blood was performed in the presence of fever, rash and cytopenias; in blood and cerebrospinal fluid in cases with neurological symptoms; and HHV-6 PCR in tissue, in presence of symptoms in other organs (hepatitis or gastrointestinal), after having ruled out other causes (CMV, GvHD).

Results: A total of 514 adult patients were included, and their baseline characteristics are reported in Table 1.
A total of 80 patients had HHV6 reactivation or infection, in a median of 28,5 days (range 4-340 days) after allo-HCT, with a cumulative incidence function (CIF) of 16%. Cumulative incidence for HHV6 infection was 5% in first period (PTCy in Haplo and MMUD); 28% in the second period (PTCy for all types of allo-HCT) and 26% in the third period (PTCy for all types of transplants and Letermovir for CMV prophlylaxis). Viremia was detected in 14% of cases; Encephalitis was diagnosed in 2% of patients and Gastrointestinal (GI) infection was detected in 84% of patients. GI infection was diagnosed in symptomatic patients and confirmed in endoscopic biopsy by PCR-RT detection. Median viral load in tissue was 17,100 copies/ml (range 2,580-71,731,500) or 140 copies/100.000 cel (range 25-7,032).
Approximately, 60% of patients with HHV6 infection received and responded to antiviral treatment, the median duration of antiviral treatment was 7 days for viremia and 21 days for GI infection.

IMPACT OF DONOR CMV-SPECIFIC HUMORAL AND CELL-MEDIATED IMMUNITY ON CMV-IMMUNE RECONSTITUTION AND INFECTION AFTER ALLOGENEIC HEMATOPOIETIC STEM-CELL TRANSPLANTATION

Guillermo Ramos Moreno[1], *Isabel Rodríguez Goncer*[1,2], *Jose María Sánchez Pina*[1], *Pilar Martínez*[1], *Magdalena Corona de Lapuerta*[1], *Adolfo Jesús Sáez Marín*[1], *Daniel Gil Alós*[1], *María Nieves López Muñoz*[1], *María Luisa Palacios Berraquero*[1], *Alberto Blanco Sánchez*[1], *Mario Fernández Ruiz*[1,2], *Asunción Pérez Jacoíste*[1], *Jose María Aguado*[1,2], *Joaquín Martínez López*[1,2], *María Calbacho Robles*[1]
[1]*Hospital Universitario 12 de Octubre, Madrid, Spain,* [2]*Universidad Complutense de Madrid, Madrid, Spain*

Background: Cytomegalovirus (CMV) infection is a common complication after allogeneic hematopoietic stem-cell transplantation (allo-HSCT) whose risk largely depends on donor/recipient serostatus. We investigated the combined effect of donor CMV serology and CMV-specific cell-mediated immunity (CMV-CMI) on the kinetics of post-transplant immune reconstitution and the incidence of clinically significant CMV (csCMV) infection.

Methods: We conducted a prospective observational cohort study including 127 consecutive allo-HSCT recipients (94 [74.0%] CMV IgG+) at our center between January 2022 and July 2025. CMV-IgG serology was determined in all donors and recipients prior to transplantation. CMV-CMI was evaluated by means of an interferon (IFN)-γ release assay (QuantiFERON® [QTF-CMV]) in related donors before transplantation, as well as at monthly intervals in recipients through month +6. csCMV infection was defined as CMV DNAemia requiring pre-emptive therapy and/or CMV disease.

Results: Patient characteristics were summarized in table 1. Most patients received PTCy-based GVHD prophylaxis (94%) and 53% received primary CMV-prophylaxis with letermovir (Recipients who were CMV IgG + and who deemed at high risk of CMV reactivation as per Spanish reimbursement policy). Global incidence of CMV reactivation was 63%. Letermovir prophylaxis significantly reduced the incidence of csCMV infection. (18% vs 25%, p< 0,05), although it did not have a significant impact in NRM or OS in our population.
The cumulative incidence of reactive QTF-CMV (QTF-CMV_R) increased over time: 19.6% (20/102) at month +1, 42.8% (30/70) at month +3 and 52.5% (21/40) at month +6. Recipients from CMV IgG+ donors had significantly higher median IFN-γ levels in the QTF-CMV assay at months +3 (0.17 vs. 0.00 IU/mL; *P* = 0.025) and +6 (0.54 vs. 0.01 IU/mL; *P* = 0.003) compared to CMV IgG- donors. QTF-CMV was determined prior to transplantation in 84 related donors (70 [83.0%] CMV IgG+ and 16 [17.0%] CMV IgG-). Among the CMV IgG+ donors, 84.3% (59/70) had a reactive QTF-CMV assay (QTF-CMV_R). There were no significant differences in letermovir use between groups (55,7% in IgG+ QTF-CMV_R, 54% in IgG+ QTF-CMV_{NR} and 64% in IgG- donors). All recipients of IgG+ QTF-CMV $_{NR}$ donors were CMV IgG +, while 91.4% of recipients of IgG+ QTF-CMV_R donors were IgG+ (p= 0.5).
Recipients from QTF-CMV_R donors exhibited higher IFN-γ production at months +1 (0.01 vs. 0.00 IU/mL; *P* = 0.057), +3 (0.15 vs. 0.00 IU/mL; *P* = 0.086) and +6 (1.48 vs. 0.02 IU/mL; *P* = 0.038) as compared to non-reactive (QTF-CMV_{NR}) donors. The incidence of csCMV at

months +3 (37.7% vs. 63.3%; *P* = 0.107) and +6 (41.5% vs. 72.7%; *P* = 0.059) was lower in recipients from CMV IgG+ QTF-CMV_R donors as compared with QTF-CMV_{NR} donors. We also noted a higher proportion of reactive QTF during follow-up in the IgG +/QTF-CMV_R than in the IgG + / QTF-CMV_{NR} group (78% vs 45%). There were no significant differences in overall mortality or GVHD between QTF-CMV_{NR} and QTF-CMV_R donors.

Table 1: Patient Characteristics

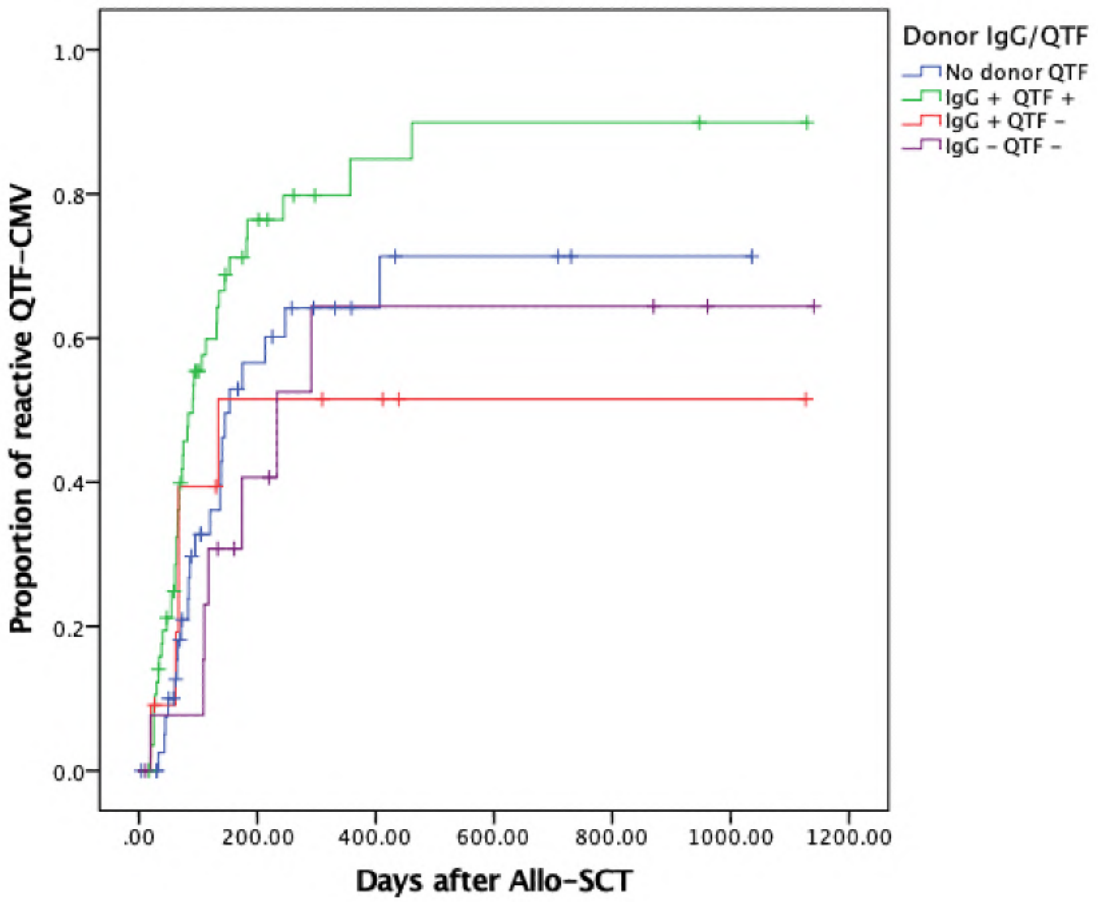
IgG + QTF -	11 (8,7)	CMV disease	7 (3,7)
GVHD prophylaxis		**CMV prophylaxis**	**n (%)**
PTCY + CNI + MMF	119 (93,7)	Recieves Letermovir	68 (53,5)
MTX + CNI	3 (2,4)	Median duration of letermovir treatment: 175 days.	
Other (ATG based)	5 (3,9)		

Figure 1: Evolution of CMV QTF reactivity by donor CMV inmune status



Conclusions: Donor CMV-specific humoral and cellular immunity contribute to earlier CMV-CMI reconstitution after allo-HSCT, consequently reducing the risk of csCMV infection. This could have implications in graft viability and donor selection.

Disclosure: Nothing to declare.

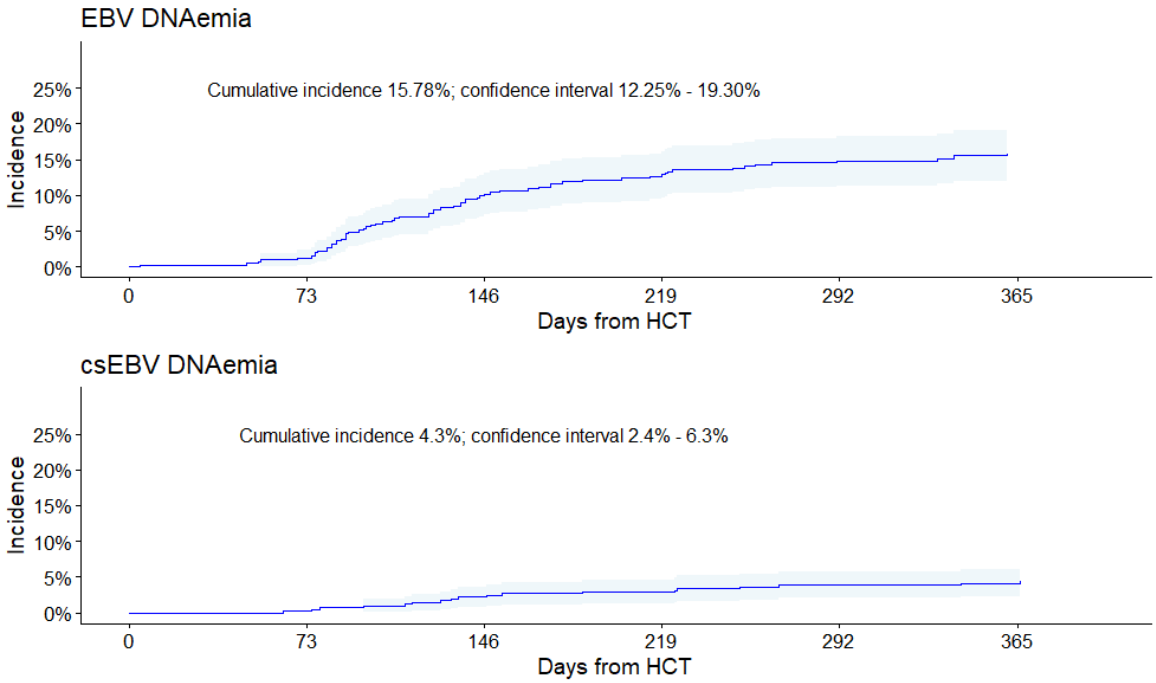
Background: The incidence of EBV-DNAemia and posttransplant lymphoproliferative disorder (PTLD) post HCT ranges from 0.1–63% (median 30%) and 1-11% (median 3%) respectively depending on transplant type and EBV monitoring. We examined the incidence of EBV-DNAemia and PTLD at Day 365 (D +365) post HCT in PTCy recipients routinely monitored by EBV qPCR in plasma at a single center.

Methods: Retrospective, observational study of adult PTCy recipients transplanted between January 2017 to June 2024 at MSK and followed through D +365. Patients received bone marrow or peripheral blood stem cell (PBSC) graft on Day (D) 0; PTCy (50 mg/kg/day) was given on D +3 and +4, and tacrolimus (or sirolimus) plus mycophenolate mofetil (or investigational itacitinib) starting on D +5. ECIL-2 definitions were used: 1) EBV DNAemia was defined as detection of EBV DNA in plasma >500 IU/mL; 2) Clinically significant EBV DNAemia (cs-EBV DNAemia) was asymptomatic EBV DNAemia treated with Rituximab. 3) EBV-PTLD was EBV DNAemia and clinical symptoms and compatible PET scan findings (Probable) and/or biopsy confirmed (Definite) respectively. Univariate logistic regression analysis was used to identify predictors of EBV DNAemia.

Results: Of 412 patients analyzed (median age 64.5 years), 69% had mismatched or haploidentical donors, 2.9% received anti-Thymocyte Globulin (ATG) and 27.4% received myeloablative conditioning. Sixty-five (15.8%) and 18 (4.3%) patients developed EBV DNAemia and cs-EBV DNAemia respectively (**Figure**). Probable and definite PTLD occurred in 10 (2.4%) and 0 (0%) patients respectively. Of 18 patients treated with Rituximab, 17 (94.4%) cleared EBV DNAemia and 1 patient died with EBV DNAemia from GVHD. By D +365, 86 patients had died, including 79 of 394 (20%) without cs-EBV DNAemia and 7 of 18 (38.9%) with cs EBV DNAemia. Death occurred at a median of 79 days (IQR 43-112) from diagnosis of cs-EBV DNAemia.
HCT from mismatched/haploidentical donor was associated with EBV-DNAemia; [odds ratio (95% confidence interval): 4.44 (2.09-10.9); $p < 0.01$]. ATG was associated with cs-EBV DNAemia and PTLD with an odds ratio of 8.56 (1.77, 32.2) and 18.7 (3.61, 80.7) respectively ($p < 0.01$) **(Table)**.

Figure: Incidence of EBV DNAemia and cs-EBVDNAemia in PTCy recipients.



Footnote: The cumulative incidence function was used. Death was a competing risk.

Table: Univariate analyses of risk factors for EBV DNAemia and cs-EBVDNAemia

	ATG	4.05	(1.17, 13.1)	0.02	8.56	(1.77,32.2)	0.003

Footnote: MDS: myelodysplastic syndrome; MPN: myeloproliferative disorder; NM-HD non-malignant hematologic disorder, CI: confidence interval: ATG: anti-thymocyte globulin

Conclusions: 1) The cumulative incidence of EBV viremia and cs-EBV DNAemia at D +365 among PTCy recipients was 15.8% and 4.3% respectively. 2) Probable PTLD developed in 10 (2.4%) patients. 3) ATG was associated with cs-EBV DNAemia and probable PTLD. 4) No death was directly attributed to EBV. Further studies are needed to define high risk PTCy groups for targeted routine EBV monitoring post HCT.

MONITORING MATTERS - SUPRATHERAPEUTIC LEVEL OF TACROLIMUS IS A PREDICTOR OF BK VIRUS REACTIVATION IN CHILDREN UNDERGOING HEMATOPOIETIC STEM CELL TRANSPLANTATION

Vijayshree Muthukumar[1], Krithika Krishnakumar[1], Minakshi Balwani[1], Nithya Sheshadri[1], Vidya Krishna[1], Indira Jayakumar[1], Kavitha Ganesan[1], Ramya Uppuluri[1], ***Revathi Raj***[1]
[1]*Apollo Speciality Hospital, Chennai, India*

Background: BK virus (BKV)–associated hemorrhagic cystitis (HC) causes significant morbidity following allogeneic hematopoietic stem cell transplantation (HSCT) in children. The reported incidence varies between 8% and 25%, depending upon conditioning regimens and graft characteristics. Calcineurin inhibitor (CNI) exposure, particularly tacrolimus, is implicated in BKV nephropathy. There is emerging evidence that fluctuating or elevated levels of CNI may predispose to BKV reactivation post-HSCT.

Methods: The objective was to characterize the clinical and virologic profile of BKV infection in pediatric HSCT recipients and to evaluate the association between tacrolimus trough concentrations and BKV reactivation.
We performed a retrospective cross-sectional analysis that included pediatric patients (≤18 years) who underwent HSCT at a tertiary care centre between January 2014 and December 2023 with documented BKV viruria, confirmed via quantitative polymerase chain reaction in urine. We reviewed patient records for demographic variables, transplant-related parameters, timing and symptomatology of BKV reactivation, and immunosuppressive drug monitoring data. We specifically collected data on tacrolimus levels within the two-week window preceding or immediately following BKV detection and labelled trough levels of over 15 ng/ml as supratherapeutic range. Statistical significance was determined using chi-square testing, with a p-value <0.05 considered significant.

Results: Among 1062 pediatric HSCT recipients over the 10-year study period, 62 patients (5.8%) developed BKV viruria. Of these, 41 patients (66.1%) exhibited tacrolimus trough levels above the institutional upper limit of therapeutic range during the critical window surrounding viral detection. This association reached statistical significance (p = 0.04), supporting a role for supratherapeutic tacrolimus exposure in BKV reactivation.
We documented urogenital symptoms like fever 8/62 (13%), hematuria 40/62 (64%), dysuria 52/62 (83%) and flank pain 14/62 (22%). A majority of the children 37/62 (59%) exhibited external genital discomfort with peculiar pain and swelling of the clitoris in female patients and balanitis in male children. The ultrasound findings include bladder wall thickening, blood clots in the bladder and hydroureteronephrosis in two cases due to obstructive uropathy. The treatment varied from symptomatic relief and hydration to severe cases needing bladder irrigation with a Foley catheter and intravenous cidofovir for up to four doses. Three children developed acute kidney injury requiring dialysis, and two needed percutaneous nephrostomy to relieve the obstructive uropathy caused by blood clots in the bladder. This varied spectrum of clinical manifestations and severity reinforces the importance of prompt evaluation of urinary symptoms.

Conclusions: Our study highlights the clinical relevance of stringent pharmacokinetic monitoring of CNIs, particularly tacrolimus, in children undergoing HSCT as elevated trough levels strongly predict subsequent BKV viruria. Vigilance for genitourinary symptoms should prompt early diagnostic screening mitigates progression to hemorrhagic cystitis and renal dysfunction. Monitoring CNI level is a simple and effective modifiable risk factor to prevent BK virus reactivation available to all transplant centres.

Disclosure: No disclosures.

ERAVACYCLINE IN ALLOGENEIC STEM CELL TRANSPLANT RECIPIENTS: A REAL-WORLD STUDY OF DRUG-DRUG INTERACTIONS WITH CYCLOSPORINE/TACROLIMUS AND ANTI-INFECTIVE EFFICACY

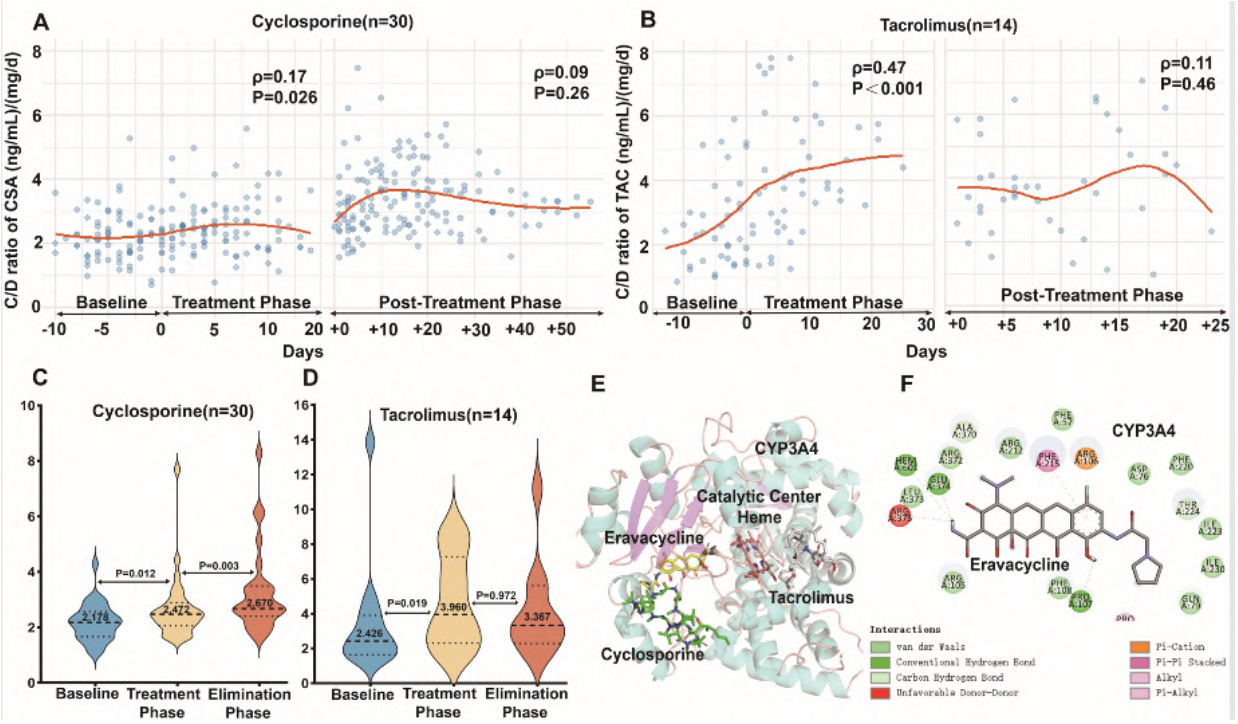
Jieya Luo[1], *Jingqi Li*[1], *Xinhui Zheng*[1], *Xin Chen*[1], *Erlie Jang*[1]
[1]*Institute of Hematology and Blood Diseases Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Tianjin, China*

Background: Calcineurin inhibitors (CNIs) are standard prophylaxis for aGVHD after allo-HSCT. Given their narrow therapeutic window, rigorous therapeutic drug monitoring is mandatory. Eravacycline, a novel synthetic tetracycline, shares the CYP3A4 metabolic pathway with CNIs, yet comprehensive data on their potential pharmacokinetic interactions are scarce. This study aimed to evaluate the drug-drug interactions between eravacycline and CNIs.

Methods: This single-center, retrospective study was conducted at the Hematology & Blood Diseases Hospital from August 2023 to July 2025, enrolling allo-HSCT recipients who received CNIs and eravacycline (50 mg q12h). CNI concentration-to-dose (C/D) ratios were monitored at a median interval of every 3 days before, during, and after eravacycline administration, with mean C/D ratios calculated for each phase.

Results: A total of 44 patients were included, with 30 receiving cyclosporine and 14 receiving tacrolimus. 72.7% (32/44) received eravacycline prior to neutrophil engraftment, while 6.8% (3/44) were treated during aGVHD. 36.4% (16/44) once experienced infections during the conditioning phase, with a median treatment duration of 11 days (IQR: 7-15). Primary infection sites were pulmonary (36.4%, 16/44) and bloodstream (27.3%, 12/44), with *Stenotrophomonas maltophilia* (38.6%, 17/44) as predominant pathogens.
In the cyclosporine group (n=30), C/D ratios increased gradually by 13.5% during eravacycline co-administration (P=0.012), necessitating a mean dose reduction of 11.1% to maintain therapeutic levels. Correlation analysis and Lowess regression demonstrated a weak but statistically significant association between eravacycline exposure and C/D ratio elevation (ρ=0.17, P=0.026). Following eravacycline discontinuation, C/D ratios further increased by 8.0% within five half-lives (approximately 5 days) compared with the on-treatment period (P=0.003), requiring an additional 6.0% dose reduction. Thereafter, C/D ratios gradually declined approximately 10 days after eravacycline withdrawal (figure A, C).

In the tacrolimus group (n=14), C/D ratios progressively increased by 62.2% during eravacycline administration (P=0.019). A moderate positive correlation was observed between eravacycline exposure time and C/D elevation (ρ=0.47, P<0.001). After drug discontinuation, C/D ratios decreased compared with the on-treatment period but remained fluctuating and higher than baseline(figure B, D).
These trends persisted in patients with normal liver and kidney function. Subgroup analysis revealed that when co-administered azoles and letermovir, no significant changes in C/D ratio were observed between pre-treatment and during treatment both in cyclosporine group (n=18) and tacrolimus group (n=7). Molecular docking analysis indicated that eravacycline exhibited a higher affinity for CYP3A4 (binding energy: -9.125 kcal/mol) than CNIs, interacting via hydrogen bonds with the heme in the active site(figure E, F).
The infection-related mortality rate was 4.5% (2/44), with a clinical remission rate of 84.1% (37/44). During anti-infective treatment, hepatic and renal toxicities occurred in 13.6% (6/44) and 20.5% (9/44) , respectively. The cumulative incidence of aGVHD within 100 days post-eravacycline treatment was 34.1% (95% CI: 20.0%-48.8%).



Conclusions: This study provides the first clinical evidence of pharmacokinetic interaction between eravacycline with CNIs in allo-HSCT, characterized by increased CNI exposure during eravacycline administration and delayed post-cessation exposure elevation, with this effect waning within around 2 weeks. Despite its modest magnitude, Intensified CNI monitoring and stepwise dose adjustments are recommended throughout and after eravacycline therapy, particularly for tacrolimus during eravacycline administration.

Disclosure: Nothing to declare.

B112

GASTROINTESTINAL MUCOSITIS AS CONTRIBUTOR TO FEVER IN AUTOLOGOUS STEM CELL TRANSPLANT RECIPIENTS CONDITIONED WITH HIGH-DOSE MELPHALAN

Björn Reijnders[1], *Eva Molendijk*[1], *Roger Brüggemann*[1], *Nicole Blijlevens*[1]
[1]*Radboudumc, Nijmegen, Netherlands (the)*

Background: Aetiology of fever without confirmed infectious cause is often unclear in patients receiving intensive therapy for haematological malignancy. Gastrointestinal mucositis (GIM) may contribute via systemic inflammation. We analysed the relation of GIM to tympanic temperature (TT) and fever in autologous hematopoietic stem cell transplantation (auto-HCT)-recipients conditioned with high-dose melphalan (HDM).

Methods: We retrospectively studied auto-HCT-recipients conditioned with HDM (200 mg/m^2) at Radboudumc and UMC Groningen (2015–2025) who had ≥4 plasma citrulline measurements during admission as marker of GIM and were not on immune-dampening regimens. Data on demographics, treatments, blood cultures, TT (four times daily), and neutrophil counts were extracted from hospital records. Bloodstream infections (BSIs) were classified per CDC guidelines. Severe GIM was defined as citrulline ≤10 µmol/L; values >10 µmol/L indicated no to moderate GIM. Profound neutropenia was defined as ANC <0.5 × 10^9/L. Associations between GIM, mean and maximal daily TT, and fever status (TT≥38.5°C) on days of citrulline measurements were analysed including and excluding patients who experienced BSI during admission, using linear mixed-effects models, adjusting for relevant covariates.

Results: A total of 52 patients with 438 citrulline measurements were included. Plasma citrulline declined rapidly after HDM to a mean nadir of 9.4 ± 3.1 µmol/L on 13.5 ± 2.0 days post-HDM, and recovered thereafter. Severe GIM occurred in 63.9% of patients. Mean and maximal daily TT increased in parallel with declining citrulline, with citrulline accounting for 20.4% and 22.5% of variation, respectively (β = -0.03, p < 0.001; β = -0.04, p < 0.001). This remained significant after adjustment for sex, age, HDM-dose (mg/kg), days since HDM, and neutropenia (β = -0.02, p < 0.001; β = -0.02, p = 0.001), with citrulline and days since HDM as the only independent predictors.
Fever risk was significantly higher at lower citrulline concentrations (OR = 0.79, p < 0.001), as well as during severe GIM compared to days with no to moderate GIM (42/154 [27.3%] vs. 8/284 [2.82%], OR = 12, p < 0.001). After adjustment for covariates, fever risk remained associated with lower citrulline concentrations (OR = 0.83, p < 0.001) without other significant contributors, and with severe GIM (OR = 6.06, p < 0.001), with days since HDM and neutropenia also contributing significantly.
In analyses excluding 14 patients with BSI, citrulline levels also showed independent associations with mean and maximal daily TT (β = -0.02, p < 0.001; β = -0.02, p < 0.001), and with fever risk (OR = 0.86, p = 0.013). Severe GIM was also independently significantly associated with likelihood of fever compared to days with no to moderate GIM (OR = 5.56, p

= 0.006).

	Fever			Fever without BSI		
Predictors	*Odds Ratios*	*CI*	*p*	*Odds Ratios*	*CI*	*p*
- (Intercept)	0.00	0.00 - 0.09	0.008	0.00	0.00 - 1.61	0.063
- Severe GIM (≤10 µmol/L)	6.06	2.48 - 14.86	<0.001	5.56	1.64 - 18.91	0.006
- Sex (Male)	1.67	0.76 - 3.68	0.200	2.49	0.71 - 8.68	0.153
- Age (Years)	0.91	0.64 - 1.31	0.616	0.86	0.50 - 1.48	0.577

	Fever			Fever without BSI		
- HDM-dose (mg/kg)	1.95	0.58 - 6.59	0.282	1.61	0.28 - 9.17	0.591
- Time since HDM (Days)	1.08	1.00 - 1.17	0.041	1.06	0.96 - 1.18	0.247
- Neutropenic (Yes vs No)	2.98	1.16 - 7.64	0.023	5.09	1.16 - 22.33	0.031
Marginal R2 / Conditional R2	0.354 / 0.518			0.363 / 0.574		

Conclusions: GIM is strongly associated with higher TT and fever risk in auto-HCT-recipients conditioned with HDM, even in absence of BSI. This suggests that fever in this setting may frequently reflect GIM-driven systemic inflammation (febrile mucositis). Recognition of GIM as contributor to fever could refine diagnostic algorithms and improve supportive care. Future studies should validate citrulline-guided risk stratification to guide antibiotic stewardship and explore interventions to mitigate GIM-related systemic effects.

Disclosure: Nothing to declare.

CMV AND EBV REACTIVATION AFTER HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION IN ELDERLY PATIENTS WITH HEMATOLOGICAL MALIGNANCIES

*Mengqi Xiang[1], Jinjin Zhu[1], Jiaxin Li[1], Yuhua Ru[1], Mimi Xu[1], **Yuqing Tu**[1], Yi Fan[1], Xiang Zhang[1], Aining Sun[1], Huiying Qiu[1], Zhengming Jin[1], Xiaowen Tang[1], Yue Han[1], Chengcheng Fu[1], Suning Chen[1], Xiao Ma[1], Feng Chen[1], Yang Xu[1], Tiemei Song[1], Depei Wu[1], Jia Chen[1]*
[1]The First Affiliated Hospital of Soochow University, Suzhou, China

Background: Elderly patients undergoing haploidentical hematopoietic cell transplantation (haplo-HCT) exhibit an increased risk of cytomegalovirus (CMV) and Epstein-Barr virus (EBV) reactivation following immunosuppressive regimens. However, data regarding viral management and its prognostic impact specifically in elderly recipients remains limited. This study aimed to investigate the reactivation patterns of CMV and EBV, identify early risk predictors, and evaluate their impact on transplant outcomes in this population.

Methods: This multicenter retrospective study included patients aged≥60 years with hematologic malignancies undergoing their first haplo-HCT. The primary endpoint was overall survival (OS). Secondary endpoints included the incidence of CMV/EBV reactivation, graft-versus-host disease (GVHD), progression-free survival (PFS), cumulative incidence of relapse (CIR), and non-relapse mortality (NRM).

Results: A total of 74 patients were included in the analysis. The median age was 63 years (range, 60-75). Main diagnoses included acute myeloid leukemia (AML) in 58.1% (n=43) of patients and myelodysplastic syndromes (MDS) in 26.0% (n=20). Prior to HCT, 70.3% (n=52) of patients were in complete remission (CR), and 33.8% (n=25) had achieved measurable residual disease (MRD) negativity. Regarding GVHD prophylaxis, anti-thymocyte globulin (ATG) was used in 83.8% (n=62) of patients, and post-transplant cyclophosphamide (PTCy) was used in 17.6% (n=13). For pre-transplant antiviral prophylaxis, ganciclovir was administered to 89.2% (n=66) of patients and foscarnet to 21.6% (n=16). Letermovir was used for post-transplant CMV prophylaxis in 18.9% (n=14) of patients. The median time to CMV and EBV reactivation post-transplant was 1.7 months and 2.7 months, respectively. CMV reactivation occurred rapidly, peaking within 3 months post-transplantation (Figure 1A). Cumulative incidence of CMV was 45.9% (95% CI, 34.2%-56.9%) at 3 months and 52.8% (95% CI, 40.7%-63.5%) at 6 months (Figure 1B). In contrast, EBV reactivation exhibited a delayed onset, with 3- and 6-month cumulative incidences of 15.0% (95% CI, 7.9%-24.0%) and 21.7% (95% CI, 13.1%-31.8%), respectively. CMV-EBV co-reactivation occurred in 10.8% (95% CI, 5.0%-19.1%) by 3 months and 12.2% (95% CI, 6.0%-20.8%) by 6 months. In multivariate analysis, letermovir prophylaxis was identified as an independent protective factor for CMV reactivation (HR 0.37, P=0.039) but an independent risk factor for EBV reactivation (HR 3.14, P=0.015). CMV reactivation within 100 days had no significant impact on OS (HR 1.18, P=0.641), PFS (HR 1.31, P=0.422), or NRM (HR 0.81, P=0.614), although it was significantly associated with an increased risk of CIR (HR 5.50, P=0.031). In contrast, EBV reactivation within 180 days was associated with inferior OS (HR 3.51, P=0.006) and PFS (HR 2.60, P=0.033), but no significant differences were observed in CIR (HR 2.15, P=0.248) or NRM (HR 2.05, P=0.159).

Conclusions: In elderly haplo-HCT recipients, EBV reactivation correlates with inferior survival, whereas early CMV reactivation predicts disease relapse without compromising survival. Letermovir prophylaxis effectively mitigates CMV risk but is independently associated with increased EBV reactivation, presenting a clinical trade-off. These findings highlight the distinct prognostic implications of viral kinetics and underscore the necessity for balanced prophylactic strategies and vigilant monitoring in this vulnerable population.

Disclosure: Nothing to declare.

B114

EARLY DISCONTINUATION OF EMPIRIC ANTIBIOTIC THERAPY IN ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS

Aleksandr Siniaev[1], *Sardor Mukhammadiev*[2], *Marina Popova*[1], *Yuliya Rogacheva*[1], *Ivan Moiseev*[1], *Sergey Bondarenko*[1], *Alexander Kulagin*[1]
[1]*RM Gorbacheva Research Institute, Pavlov University, Saint-Petersburg, Russian Federation (the),* [2]*Republican Specialized Scientific Practical Medical Center of Hematology, Tashkent, Uzbekistan*

Background: Early discontinuation of empirical antibacterial therapy (EABT) for febrile neutropenia (FN) before neutrophil recovery to > 0.5 × 10^9/L is recommended in hematological patients in the absence of documented infection. However, the safety of this approach in recipients of allogeneic hematopoietic stem cell transplantation (allo-HCT) is insufficiently studied. Published data are limited to a few studies in mixed patient populations.

Methods: A study was conducted in 58 adult allo-HCT recipients between January 2022 and December 2024, who underwent early discontinuation of EABT before neutrophil recovery above 0.5 x 10^9/L and in the absence of documented infection. The study aimed to assess the safety of the early discontinuation approach in allo-HCT recipients, evaluating the following endpoints within 30 days of EABT discontinuation: FN recurrence, bloodstream infection, sepsis, transfer to the ICU, and mortality. Patient characteristics are presented in Table 1. The median follow-up was 409 days (15–1073).

	Study group (n = 58)
Age, median (range)	41 (19 - 65)
Sex Male Female	 27 (46.6%) 31 (53.4%)
Diagnosis AML ALL AA CML MDS nHL	 32 (55.2%) 7 (12.1%) 6 (10.3%) 6 (10.3%) 4 (6.9%) 3 (5.2%)
Indications for allo-HCT Standard Salvage	 45 (77.6%) 13 (22.4%)

Number of allo-HCT First allo-HCT Second allo-HCT	 57 (98.3%) 1 (1.7%)
Donor type MUD Haploidentical MMUD MRD	 18 (31.0%) 17 (29.3%) 12 (20.7%) 11 (19.0%)
Stem cell source PBSC BM	 51 (87.9%) 7 (12.1%)
Conditioning regimen RIC MAC	 40 (69.0%) 18 (31.0%)
Post-transplant cyclophosphamide GVHD prophylaxis	51 (87.9%)

Results: The median time to FN onset after allo-HCT was 2 days (-7 to 15). The median neutrophil count at FN onset was 0.39 x 10^9/L (0–2.88). As first-line EABT, carbapenem-containing regimens were used in 36 patients (62%), while 22 patients (38%) received regimens with inhibitor-protected cephalosporins. At the onset of FN, 35 patients (60.3%) were colonized with extended-spectrum beta-lactamase-producing strains. The median duration of EABT was 8 days (3–22). The median neutrophil count at the time of EABT discontinuation was 0.05 x 10^9/L (0–0.48). *Staphylococcus epidermidis* was identified in blood cultures of 12 patients (20.7%), but it did not meet the criteria for bloodstream infection diagnosis and did not affect the decision to discontinue EABT. FN recurrence was observed in 26 patients (44.8%). The median time to FN recurrence after EABT discontinuation was 3 days (0–15). The median neutrophil count at FN recurrence was 0 x 10^9/L (0–2.12). Carbapenem-containing EABT was resumed in 21 cases (80.7%), and therapy with protected cephalosporins was resumed in 5 cases (19.3%). Five patients (8.6%) were diagnosed with Gram-negative bloodstream infections (BSI) caused by Klebsiella *pneumoniae* (2/5, 40%), *Escherichia coli* (2/5, 40%), and *Pseudomonas aeruginosa* (1/5, 10%). The median time to BSI development from allo-HCT was 11 days (11–13), and from EABT discontinuation was 4 days (3 – 7). All of the BSIs were diagnosed after FN recurrence with a median time of 2 days (0 – 3). Two episodes (2/5, 40%) of sepsis in patients with BSI were recorded within 30 days after early EABT discontinuation, leading to subsequent transfer to the ICU (2/3, 66.6%). Additionally, 1 more patient (1/3, 33.4%) was transferred to the ICU due to cardiac arrhythmia. The overall 30-day survival from the time of early EABT discontinuation was 98.3% (95% CI 88.4–99.8). During the 30-day observation period, 1 allo-HCT recipient, who underwent transplantation as salvage therapy, died from sepsis with multiple organ failure.

Conclusions: The results of this retrospective study demonstrate the safety of early discontinuation of empirical antibacterial therapy in recipients of allo-HCT. However, this approach should be used with caution when performing allo-HCT as salvage therapy.

Disclosure: Nothing to declare.

THE ROLE OF PCR DETECTION OF CARBAPENEMASE GENES IN NATIVE SPECIMENS FOR ROUTINE COLONIZATION SCREENING IN THE EARLY POST–ALLO-HCT PERIOD

*Yuliya Rogacheva[1], Marina Popova[1], **Aleksandr Siniaev**[1], Yuliya Vlasova[1], Ivan Moiseev[1], Sergey Bondarenko[1], Alexander Kulagin[1]*
[1]RM Gorbacheva Research Institute, Pavlov University, Saint Petersburg, Russian Federation (the)

Background: The rising rates of multidrug-resistant pathogens and the limited timeliness of culture and susceptibility testing (CST/AST) complicate early selection of empirical antimicrobial therapy (EAT) based on colonization in allogeneic hematopoietic cell transplantation (allo-HCT) recipients. Polymerase chain reaction (PCR) detection of carbapenemase genes directly from rectal swabs may support colonization-guided febrile neutropenia (FN) protocols, but its place in routine screening and FN algorithms has not yet been clearly defined.

Methods: A total of 116 patients undergoing a first allo-HCT between 2022 and 2024 at the R.M. Gorbacheva Research Institute were prospectively enrolled in a study evaluating serial PCR-based detection of carbapenemase genes during the peri-transplant period. The median age was 40 years (range, 18–71); 46.5% were male (n=54). The underlying disease was predominantly acute leukemia – 73% (n=85). Patients and HCT characteristics are presented in Table 1. Colonization screening comprised standard CST/AST, rectal swabs plated on CHROMagar™ KPC plates, and PCR-based detection of carbapenemase genes directly from native rectal swab specimens from day −7 to day +35 of the allo-HCT period. EAT was administered according to the local colonization-guided protocol. We design the analysis in order to clarify should the PCR guide the upfront EAT strategy.

Results: Febrile neutropenia (FN) developed in 90% (n=104) of the cohort, with a median onset at day +10 (range, 1–18). On the day of FN onset, carbapenem-resistant organisms (CRO) colonization was detected in 11% (n=13) by CST/AST, 24% (n=28) by CHROMagar™ KPC, and 43% (n=50) by PCR: VIM 14% (n=16), IMP 2.5% (n=3), NDM 11% (n=13), OXA-48 1,5% (n=2), KPC 1% (n=1), OXA-48+KPC 2.5% (n=3), VIM+NDM 1% (n=1), NDM+KPC 6% (n=7), NDM+OXA-48 1,5% (n=2), NDM+OXA-48+KPC 1% (n=1), and VIM+NDM+OXA-48+KPC 1% (n=1). Concordance between CHROMagar™ KPC and PCR was 44%, between CST/AST and CHROMagar™ KPC - 77% and between PCR and CST/AST - 84%. Among patients with PCR-detected carbapenemase genes, FN occurred in 88% (n=44). An escalation strategy within EAT was used in 54.5% (n=24), with a treatment response

achieved in 50% (n=12); de-escalation was applied in 45.5% (n=20), with a response in 50% (n=10). In the PCR-positive colonized subgroup, Gram-negative bloodstream infection (GN-BSI) occurred in 20% (n=10): *Klebsiella pneumoniae* -50% (n=5), *Escherichia coli* 30% (n=3), *Klebsiella pneumoniae* + *Escherichia coli* + *Raoultella ornithinolytica* - 10% (n=1), and *Klebsiella pneumoniae* + *Pseudomonas aeruginosa* -10% (n=1). With an escalation strategy, BSI occurred in 16% (n=4), whereas with a de-escalation strategy - 30% (n=6), p=0,694. In 62,5% (n=5/8) of patients who developed GN-BSI, the carbapenemase genes detected during colonization screening matched the gene identified in the isolate causing the BSI (Figure 2). The 60-day overall survival in patients with PCR-detected carbapenemase-gene colonization was 95.9%, with one sepsis-attributable death.

Table 1. Patients' characteristics

Characteristics	Study group n=116
Period of HCT	01.2022-12.2024

8	*Escherichia coli*	S - Carb, AG, CAZ/AVI R - ATM	Not detected	NDM, KPC	Detected	Klebsiella pneumonia CRE	Carb, AG
9	*Klebsiella pneumonia,* *Pseudomonas monteilii*	R - Carb, ATM S - CMS, CAZ/AVI R - Carb, ATM S – AG, CMS	KPC, OXA-48 – *Kl. pneumonia* VIM, KPC, OXA-48 – *Pseudomonas aeruginosa*	NDM, KPC	Detected	Not detected	CAZ/AVI, ATM, CMS
10	*Klebsiella pneumonia, Escherichia coli, Raoultella ornithinolytica*	R - Carb, ATM S - CMS, CAZ/AVI	NDM, KPC	NDM, KPC	Detected	Not detected	CAZ/AVI, ATM, CMS

GN-BSI - Gram-negative bloodstream infection, CST/AST-culture and susceptibility testing, Carb - carbapenem(s), AG - aminoglycosides, CMS - colistin, CAZ/AVI - ceftazidime/avibactam , ATM - aztreonam, CRE - carbapenem-resistant *Enterobacterales*

Conclusions: Rectal-swab PCR detected carbapenemase genes in 43% of allo-HCT recipients at FN onset, potentially prompting overuse of antibiotics in upfront EAT. However, 27% (n=12/44) of PCR-positive cases responded on an escalation strategy, supporting that PCR positivity alone should have limited impact on upfront EAT strategy at FN. Larger prospective studies are needed to define its role in FN algorithms.

Background: Cytomegalovirus (CMV) remains one of the most significant infectious complications after allogeneic hematopoietic stem cell transplantation (allo-HSCT). The arrival of novel antivirals is transforming approaches to prophylaxis, monitoring, and treatment. To capture current nationwide practice, the Spanish Group for Cell Therapy and Hematopoietic Transplantation (GETH-TC) conducted a survey on CMV management in allo-HSCT recipients and in patients receiving new cellular therapies.

Methods: A structured online survey addressing 5 domains—use of letermovir (LMV), use of maribavir (MBV), advanced diagnostic tools, management of CAR-T/BITE recipients, and implementation of ECIL-10 recommendations—was distributed in May 2025 to adult and paediatric hematologists within the GETH-TC.

Results: Twenty-six HSCT units (22 adult, 3 paediatric, 1 mixed), representing 65% of Spanish transplant centers, completed the survey. All reported using LMV as primary prophylaxis, mainly restricted to high-risk CMV-positive recipients according to the Spanish Ministry of Health criteria (54%), while 23% administered LMV to all CMV-positive patients. Among recipients receiving post-transplant cyclophosphamide, 50% prescribed LMV only in

the presence of additional risk factors. Extended prophylaxis beyond day +100 is used by 81% of centers, particularly in cases of graft-versus-host disease (GVHD) or delayed immune reconstitution. LMV is used as secondary prophylaxis in 84% of units, usually in selected situations (65%).
MBV has been incorporated into routine management for refractory or resistant CMV, or when conventional antivirals are not tolerated, by 84% of centers. Four centers—three paediatric—do not use MBV.
All units have established monitoring protocols for CMV reactivation. More than half (54%) modify pre-emptive therapy thresholds when LMV prophylaxis is in place. Resistance testing is available in 65% of centers, while CMV-specific immune monitoring is performed in 19%. No center measures LMV plasma levels.
Systematic CMV monitoring in all CMV-positive individuals is performed by 60% of centers in CAR-T recipients and 8% in patients receiving BITE therapy. Pre-emptive therapy in cases of reactivation is systematically used in 88% and 74% of these patients, respectively. Use of LMV or MBV in these settings remains anecdotal.
Regarding the adoption of ECIL-10 CMV guidelines, 85% of centers plan to implement selected recommendations, particularly dual-time-point serology (65%), baseline CMV PCR testing (69%), and updated serostatus nomenclature (69%).

Conclusions: The 2025 GETH-TC survey demonstrates widespread adoption of modern CMV prevention and treatment strategies in Spain, including universal LMV use for primary prophylaxis and broad extension beyond day +100. MBV is increasingly integrated into the management of refractory or resistant CMV. Diagnostic practices are also evolving, with expanded use of resistance testing and immune reconstitution assessment. Nonetheless, heterogeneity persists in prophylaxis criteria, pre-emptive thresholds, and management of CAR-T and BITE recipients.

RISK OF BACTEREMIA IN LEVOFLOXACIN-RESISTANT EXTENDED-SPECTRUM B-LACTAMASE-PRODUCING ENTEROBACTERALES COLONIZED RECIPIENTS OF ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANT

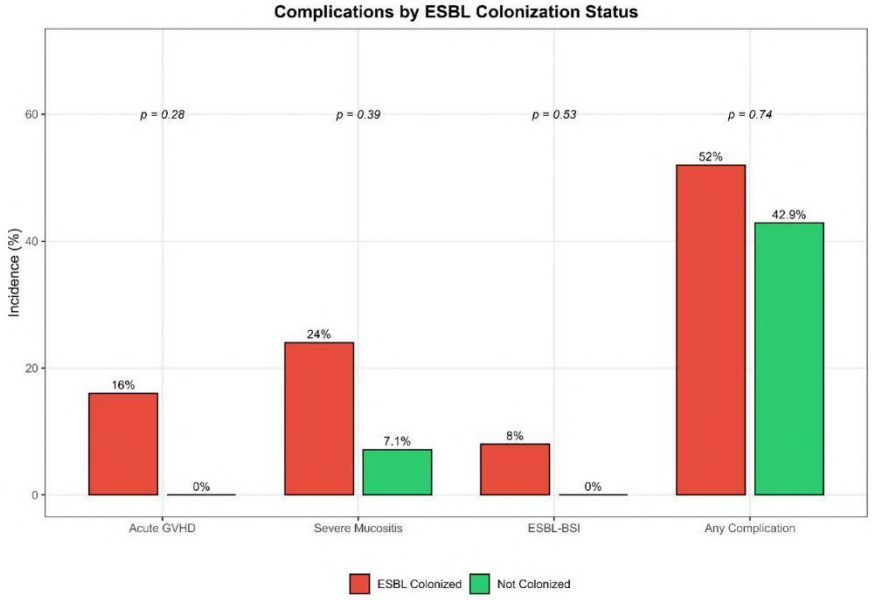
Umberto Pizzano[1], Russell Edward Lewis[2], Gabriella De Cicco[1], ***Dario Schiavo****[1], Bruna Puglisi[1], Damiano Rondelli[3], Marta Stanzani[1]*
[1]Stem Cell Transplant and Cell Therapies Program, Hematology, Ca' Foncello Hospital, Treviso, Italy, [2]Infectious Diseases, Department of Molecular Medicine, University of Padova, Padova, Italy, [3]Division of Hematology/Oncology, University of Illinois at Chicago-UI Health, Chicago, United States of America (the)

Background: Extended-spectrum beta-lactamase-producing Enterobacterales (ESBL-E) bloodstream infections (BSI) affect up to one-third of allogeneic hematopoietic stem cell

transplant (allo-HSCT) recipients with rectal colonization at the time of transplant. Patients with gastrointestinal ESBL-E colonization who receive levofloxacin prophylaxis may be at increased risk for ESBL-E BSI, particularly in settings with high ESBL prevalence and fluoroquinolone resistance.

Methods: We retrospectively analyzed 39 adult allo-HSCT recipients at our center in Treviso, Italy (January 2024–September 2025) in a region endemic for CTX-M ESBL Enterbacterales. No patients received levofloxacin prophylaxis. Weekly perianal swabs were cultured and tested by PCR for β-lactamase genes (CTX-M) and susceptibility testing. ESBL-colonized patients with neutropenic fever received empirical meropenem.

Results: Of the 39 patients transplanted patients, 25 (64%) were ESBL-colonized—9 detected by PCR only, 16 by culture. CTX-M was detected in 87.5% of swabs, and 94% of culture isolates were fluoroquinolone-resistant. Among colonized patients, 24/25 (96%) developed fever requiring empiric meropenem, with microbiological confirmation of pathogens in 13/24 cases. However, ESBL-E BSI accounted for only 2/24 (8%) of infections. Overall ESBL-E BSI incidence was low 2/39 (5%), and peaked at neutropenia nadir (10 days post-transplant), with an incidence density of 1.37 per 1,000 patient-days (95% CI: 0.00–3.43). No patients without prior ESBL-E colonization developed ESBL-E BSI. Both patients with ESBL-E BSI responded to empiric meropenem and survived without complications. ESBL-colonized patients had higher 90-day cumulative rates of acute GVHD (16% vs 0%) and severe mucositis (24% vs 7.1%) compared to non-colonized patients, irrespective if they developed BSI.



Conclusions: Despite high rectal colonization rates (64%) with CTX-M ESBL and fluoroquinolone-resistant Enterobacterales, ESBL-E BSI incidence was low (5%) after allogeneic HSCT in patients who did not receive fluoroquinolone prophylaxis. Acute GVHD and mucositis, beyond colonization alone, probably contributes to dysbiosis and ESBL-E BSI risk.

Disclosure: Nothing to declare

B120

DETERMINANTS OF EARLY AND LATE INFECTIONS AFTER CAR-T IN SECOND- AND THIRD-LINE LBCL

Ilaria Cutini[1], *Chiara Camerini*[1], *Giacomo Coltro*[1], *Antonella Gozzini*[1], *Edoardo Simonetti*[1], *Mirella Giordano*[1], *Gaia Mirabella*[1], *Alessio Mazzoni*[1], *Francesca Matani*[1], *Roberto Caporale*[1], *Sara Bencini*[1], *Benedetta Peruzzi*[1], *Luca Nassi*[1], *Benedetta Puccini*[1], *Benedetta Sordi*[1], *Francesco Annunziato*[1], *Alessandro Maria Vannucchi*[1], *Chiara Nozzoli*[1]
[1]*Careggi University Hospital, Florence, Italy*

Background: CD19-directed CAR T-cell therapy has moved into second-line (2L) treatment for relapsed/refractory large B-cell lymphoma (LBCL), whereas most historical data derive from more heavily pretreated third-line (3L) cohorts. The impact of line of therapy on immune reconstitution and infectious risk, including COVID-19, is not fully defined.

Methods: We retrospectively analyzed 53 adults with LBCL receiving commercial CAR T cells in 2L or 3L. Humoral and cellular immunity (IgG, IgA, IgM, $CD3^+CD4^+$ T-cells, $CD19^+$ B-cells) was evaluated at lymphodepletion (LD) and at 1, 3, 6, 9, and 12 months after infusion. Infections were recorded through 12 months, categorized as early (<30 days) or late (>30 days). No IgG replacement was given. Continuous variables were summarized as median and compared using with non-parametric tests; categorical variables were compared using Fisher's exact test; two-sided $p<0.05$ was considered.

Results: Fifty-three patients were included, 15 treated in 2L and 38 in 3L. At LD, 3L patients showed a more profound humoral immunodeficiency. Baseline IgG levels were significantly lower in 3L (4.69 g/L, IQR 3.90–5.99) than in 2L (6.63 g/L, IQR 5.94–9.36; p=0.0007), as were IgA (0.55 vs 1.15 g/L; p=0.018) and IgM (0.20 vs 0.48 g/L; p=0.0003). $CD3^+CD4^+$ T-cell counts at LD tended to be lower in 3L, while $CD19^+$ B cells were virtually absent in both groups.
Overall, 12/15 2L patients and 34/38 3L patients experienced at least one infectious episode, with a significantly higher overall infection rate in 3L (p=0.0009). Early infections occurred in 6.7% of 2L versus 18.4% of 3L patients (p=ns), whereas late infections were observed in 20.0% of 2L versus 71.1% of 3L patients (p=0.0015). In 2L, early infection was limited to a single fungal event, and late infections were uncommon (bacterial 13.3%, COVID 6.7%). In 3L, early infections were mainly bacterial or non-COVID viral (each 10.5%), while late infections were predominantly bacterial (28.9%) and viral, (COVID 39.5%, non-COVID 15.8%), with few fungal events (5.3%).
ICANS duration (r=0.48, p=0.021), use of corticosteroids for either ICANS (r=0.40, p = 0.010) or ICANS+CRS (r=0.40, p=0.015) were associated with increased risk of early infections. In multivariable analysis, ICANS duration and steroid use for management remained significantly associated with early infectious risk (AUC 0.85, p=0.00003). Beyond day 30, no CRS/ICANS-related predictors were associated with infections.
In 3L patients, IgG levels remained systematically lower at each time point (all $p\leq0.04$),

whereas $CD3^+CD4^+$ T-cell reconstitution from 3 to 12 months was comparable between 2L and 3L.
The overall 1-year cumulative incidence of first infection was 65.3% (26.7% in 2L vs 80.9% in 3L; log-rank p=0.00078). One-year overall mortality was 20.8%, including 15.1% lymphoma-related and 5.7% infection-related deaths.

Conclusions: 3L CAR T-cell therapy, compared to 2L, showed deeper and prolonged hypogammaglobulinaemia, with similar $CD3^+CD4^+$ T-cell recovery, resulting in a significantly higher overall and late infection burden in 3L, primarily due to bacterial and viral infections, especially late COVID. These data supporting intensified anti-infective strategies in heavily pretreated 3L patients.

Clinical Trial Registry: None.

Disclosure: No COI.

MANAGEMENT OF PEDIATRIC HCV-INFECTED PATIENTS UNDERGOING ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION: A MULTICENTER RETROSPECTIVE ITALIAN STUDY

Francesco Paolo Tambaro[1], *Maria Rosaria D'Amico*[1], *Maria Speranza Massei*[2], *Maura Faraci*[3], *Veronica Tintori*[4], *Francesco Cecere*[1], *Giulia Caddeo*[5], *Simone Cesaro*[5]
[1]*AORN Santobono Pausilipon, Naples, Italy,* [2]*Azienda Ospedaliera Perugia - Ospedale S.Maria della Misericordia, Perugia, Italy,* [3]*IRCCS Giannina Gaslini, Genova, Italy,* [4]*Azienda Ospedaliera Universitaria Meyer IRCCS, Firenze, Italy,* [5]*Azienda Ospedaliera Universitaria Integrata, Verona, Italy*

Background: Hepatitis C virus (HCV) infection is rarely diagnosed in children born in Italy but it can be observed in children from low-income countries referred to Italian centers for hematopoietic stem cell transplantation (HCT). HCV increases the risk of HCT- and immunosuppression-related complications. While direct-acting antivirals (DAAs) have improved the results of HCV treatment, published data in pediatric HCT patients remains limited and transplant urgency may preclude their use.
We report the outcomes of a series of pediatric HCT patients with active HCV infection who received DAAs before or after transplant.

Methods: This retrospective multicenter study was conducted by the Infectious Diseases Working Group of the Italian Association of Pediatric Hematology and Oncology (IDWG-AIEOP). Pediatric HCV patients undergoing HCT between 2002 and 2023 were included. Demographic, clinical, transplant, and virological data (HCV genotype, viral load at transplant, and HCV treatment) were collected by an anonymized paper case report form. Study follow-up was as 30 November 2025. Descriptive statistics were used; a p value <0.05 was considered statistically significant.

Results: Seventeen HCV patients (9 M, 8F) from five AIEOP were eligible. The patients were from Kyrgyzstan (3), Venezuela (9), Albania (3), Ukraine (2), and Libya (1). Underlying diagnoses were acute lymphoblastic leukemia (n=13), severe aplastic anemia (n=2), Diamond–Blackfan anemia (n=1), and Langerhans cell histiocytosis (n=1). Median age at transplant was 9.8 years (2.1–19.9).
Donors were HLA-matched related (n=1), matched unrelated (n=9) and mismatched related (n=7). All patients received myeloablative conditioning, including total body irradiation–based regimens (n=13) or busulfan/treosulfan-based regimens (n=3); one patient received thiotepa, fludarabine, and cyclophosphamide. Cyclosporine, ATG, and ATLG were administered in 9, 4, and 6 patients, respectively; ex vivo and in vivo T-cell depletion was performed in 6 and 1 patients.
HCV genotypes were 1 (n=7) and 2 (n=8). Five patients received pre-HCT treatment with lamivudine (n=2), ledipasvir/sofosbuvir(n=2), and ribavirin (n=1), while 9 patients were treated after HCT with sofosbuvir (n=2), ledipasvir/sofosbuvir (n=3), glecaprevir/pibrentasvir (n=3), and sofosbuvir/velpatasvir (n=1); three were never treated.
Median time to neutrophil and platelet engraftment was 19 (11–35) and 18 days (11–52), respectively. Acute grade II–IV GVHD occurred in 8 patients, chronic GVHD in 2, veno-occlusive disease in 1, untreated for HCV pre-HCT, and transplant-associated thrombotic microangiopathy in 1. All patients except one, who died from hemorrhage on day +8, were alive at a median follow-up of 3 years, (1.0 – 19.4)
Neither pre-HCT HCV viral load nor DAA treatment was associated with engraftment, aGVHD, TA-TMA, or VOD. An association was observed between higher pre-HCT viral load and cGVHD, but driven by a very limited number of events (point-biserial correlation r = 0.58, p = 0.037).

Libia	UK	16.3	BDA.	HAPLO	y	n	CD19- Tα/β depletion	no	1a	NA	Ledispasvi/ Sofosbuvir		Dead (day +8)

Conclusions: Our data suggest that HCT can be safely performed in pediatric patients with active HCV infection, even in the setting of intensive immunosuppression including in vivo

and ex vivo T-cell depletion. Pre-transplant HCV viral load and DAAs exposure did not negatively impact engraftment or early transplant-related complications. DAAs were well tolerated when administered before or after HCT, supporting timely transplantation without delay.

SURGICAL TREATMENT OF PULMONARY INVASIVE FUNGAL DISEASE IN PATIENTS AFTER ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

Marina Popova[1], Andrey Akopov[2], Radezh Mishra[2], Aleksander Shvetsov[1], Maksim Kondrashov[1], Yulia Rogacheva[1], Polina Tikhomirova[1], Polina Khorosheva[1], Ilya Nikolaev[1], Valentin Zagranchinov[2], Adema Kargabaeva[1], Artem Gusak[2], Ludmila Zubarovskaya[1], ***Alexander Kulagin***[1]
[1]*RM Gorbacheva Research Institute, Pavlov University, St. Petersburg, Russian Federation (the),* [2]*Pavlov University, St. Petersburg, Russian Federation (the)*

Background: The effectiveness and safety of surgical treatment for pulmonary invasive fungal disease (pIFD) after allogeneic hematopoietic cell transplantation (allo-HCT) remain undetermined, with only isolated cases of surgical intervention reported in the literature. This study presents the largest experience with surgical treatment of pIFD following allo-HCT to our knowledge.

Methods: A retrospective analysis was conducted on the outcomes of surgical treatment for pIFD in allo-HCT recipients from 2013 to 2025. The study included 12 patients who underwent 13 surgical interventions for probable and proven pIFD: children (n=2) and adults (n=10) with the median age 26 years (range 10-64), males (n=11), with diagnoses including chronic myeloproliferative disorders (5, 41.7%), acute leukemia (3, 25%), aplastic anemia (3, 25%), and lymphoma (1, 8.3%). Patient characteristics, allo-HCT, pIFD, and surgical interventions are detailed in Table 1.

Table 1. Characteristics of allo-HCT recipients with pIFD undergoing surgery n=12

Donor Type: MUD / MMUD / MRD / Haplo	2 (16,7) / 5 (41,7) / 1 (8,3) / 4 (33,3)
Conditioning Regimen: MAC / RIC	4 (33,3) / 8 (66,7)
Pulmonary invasive fungal disease: IA / MM / MM + IA	5 (41,7) / 4 (33,3) / 3 (25)
Bilateral lung involvement	6 (50%)

Median day of IM onset post-allo-HCT, days	96 (21-510)
Therapy with Voriconazole	5 (41,7)
Therapy with Amphotericin B ± voriconazole, posaconazole, isavuconazole	7 (58,3)
Median days of therapy pre-surgery, days	61 (13-526)
Median days from allo-HCT to surgery, days: IA / MM / IA+MM	182 (41-547) / 296 (133-547) / 138 (41-348)
Surgical Volume: Pneumonectomy / Lobectomy / Wedge resection / Atypical wedge resection / Chest wall resection	4 / 6 / 3/ 1 / 1
Surgical Approach: Thoracotomy / Endoscopic video-assisted thoracoscopy	11 / 2

Results: Surgical treatment for pIFD post-allo-HCT achieved a complete response (radical surgery) in 91.7% (n=11); one patient with mucormycosis underwent successful repeat surgery in 250 days after the first to remove a second lesion. pIFD recurrence post-surgery occurred in one patient (8.3%) with invasive aspergillosis 1.5 years later. At surgery, 2 patients (15.4%) had grade 3-4 neutropenia and 8 (61.5%) patients had grade 4 thrombocytopenia. Intraoperatively, a mean blood loss was 600 mL (0-2,600 mL). The duration of operation ranged from 60 to 290 min (median, 175 min). Minor complications were reported in two patients: hydropneumothorax and air leak syndrome n=1, 7.7%; pleural empyema n=1, 7.7%. One death in early period was registered (7.7%). Overall survival after first surgery at 30 days, 12 weeks, and 12 months was 83.3%, 83.3%, and 58.3%, respectively; five patients died within 1 year, 4 (80%) from underlying disease progression. Postoperative histology and mycology confirmed diagnoses in seven patients and increased pathogen species identification and antifungal susceptibility testing from 33.3% (4/12) to 66.7% (8/12), improving overall diagnostic precision to 91.7%.

Conclusions: Surgical treatment is effective and safe option in management of pulmonary invasive fungal disease among patients with hematological diseases after allo-HCT.

NOT ALL AUTOLOGOUS TRANSPLANTS ARE LOW RISK: DELAYED PLATELET ENGRAFTMENT SIGNALS THE NEED FOR CMV MONITORING

Ibrahim Ethem Pinar[1], *Fahir Ozkalemkas*[1], *Fatih Yaman*[2], *Tugcan Alp Kirkizlar*[3], *Fatma Aykas*[4], *Volkan Karakus*[4], *Mehmet Baysal*[5], *Narmin Jafarli*[1], *Muge Sahin*[1], *Vildan Gursoy*[1], *Tuba Ersal*[1], *Eren Gunduz*[2], *Vildan Ozkocaman*[1]
[1]*Bursa Uludag University, Bursa, Turkey,* [2]*Eskisehir Osmangazi University, Eskisehir, Turkey,* [3]*Trakya University, Edirne, Turkey,* [4]*University of Health Sciences, Antalya, Turkey,* [5]*Tekirdag Namik Kemal University, Tekirdag, Turkey*

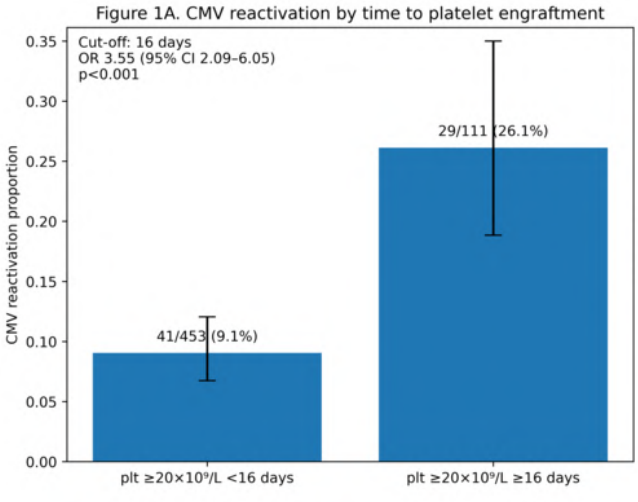
Background: Although CMV PCR monitoring is standard after allogeneic transplantation, it is not routinely recommended following autologous stem cell transplantation due to a perceived low risk. However, real-world data indicate that CMV risk after ASCT is heterogeneous, and the absence of simple clinical markers has hindered risk-adapted surveillance strategies.

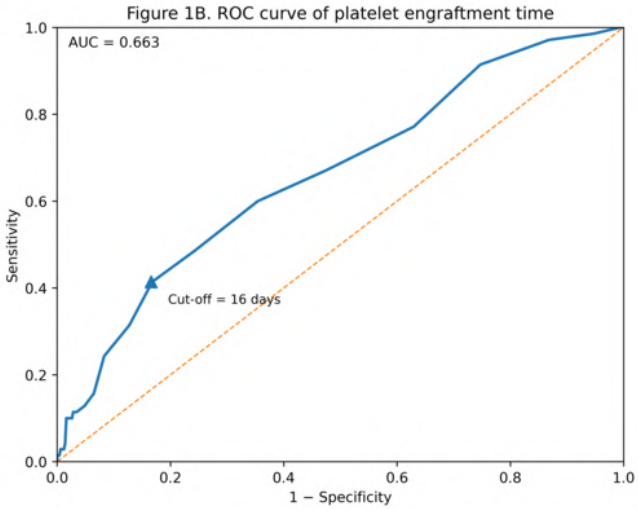
Methods: We conducted a retrospective multicenter cohort study including adult patients who underwent ASCT. CMV reactivation was defined as PCR-detected CMV DNAemia following transplantation. Baseline demographic, clinical, laboratory, and transplant-related variables were collected. Univariate analyses were performed to identify factors associated with CMV reactivation. Continuous variables were compared using the Mann–Whitney U test, and categorical variables using the chi-square or Fisher's exact test, as appropriate. Variables with $p<0.10$ in univariate analyses were further evaluated using receiver operating characteristic (ROC) curve analysis to determine optimal cut-off values based on the Youden index. A multivariable logistic regression model incorporating these variables was constructed to identify independent predictors of CMV reactivation. Results are reported as odds ratios (ORs) with 95% confidence intervals (CIs).

Results: A total of 614 adult patients undergoing ASCT were analyzed, of whom 77 (12.5%) developed CMV reactivation. The median age was 56 years, and 58.1% were male, with no significant differences in age or sex distribution between CMV-positive and CMV-negative groups. Baseline laboratory parameters, including neutrophil count, lactate dehydrogenase, beta-2 microglobulin levels, and infused $CD34^+$ cell dose, were comparable between groups. In contrast, hematopoietic recovery kinetics differed markedly. Patients with CMV reactivation exhibited significantly delayed platelet engraftment, defined as achievement of a platelet count $\geq 20\times10^9$/L, compared with CMV-negative patients (median 14 days [IQR 12–17] vs. 12 days [IQR 10–14]; $p<0.001$). Neutrophil engraftment was also modestly delayed in the CMV-positive group (12 vs. 11 days; $p=0.017$). Baseline lymphocyte counts were numerically lower among patients with CMV reactivation (1.17 vs. 1.30 $\times10^9$/L), although this difference did not reach statistical significance ($p=0.058$).
Among categorical variables, advanced disease stage ($p=0.012$), prior rituximab exposure ($p=0.008$), and the presence of comorbidities ($p=0.027$) were more frequent in CMV-positive patients, whereas conditioning intensity, radiotherapy exposure, and CMV serostatus were not associated with CMV risk.

ROC analysis identified time to platelet engraftment as the strongest discriminator of CMV reactivation. Using a Youden index–derived cut-off of approximately 16 days, delayed platelet

engraftment was associated with a substantially increased risk of CMV reactivation (Figure 1).





In multivariable logistic regression analysis adjusting for neutrophil engraftment time and baseline lymphocyte count, delayed platelet engraftment remained the only independent predictor of CMV reactivation (adjusted OR 2.4, 95% CI 1.5–3.9; p<0.001), whereas other variables lost statistical significance (Table 1).

Table 1. Univariate and multivariable analyses of factors associated with CMV reactivation after autologous stem cell transplantation

Variable	CMV+ (n = 77)	CMV− (n = 537)	Univariate p value	Multivariable OR (95% CI)	Multivariable p
Delayed platelet engraftment (≥16 days to plt ≥20×10⁹/L)	14 (12–17)	12 (10–14)	<0.001	2.4 (1.5–3.9)	<0.001
Neutrophil engraftment (days)	12 (11–13)	11 (10.8–12)	0.017	1.6 (1.0–2.6)	0.041
Baseline lymphocyte count (×10⁹/L)	1.17 (0.72–1.65)	1.30 (0.99–1.70)	0.058	1.4 (0.9–2.2)	0.11

Table 1. Univariate and multivariable analyses of factors associated with CMV reactivation after autologous stem cell transplantation

Rituximab exposure (%)	24.7	12.7	0.005	1.57 (0.77–3.20)	0.215
Stage 3 vs Stage 1 (%)	28.4	41.6	0.012	0.43 (0.20–0.92)	0.029

Univariate and multivariable analyses of factors associated with CMV reactivation after autologous stem cell transplantation. Delayed platelet engraftment was defined as ≥16 days to achieve a platelet count ≥20×10⁹/L, based on receiver operating characteristic analysis using the Youden index. Continuous variables are presented as median (interquartile range), and categorical variables as percentages. Adjusted odds ratios (ORs) with 95% confidence intervals (CIs) were obtained from a multivariable logistic regression model including variables with p<0.10 in univariate analysis.

Conclusions: Although ASCT is generally considered low risk for CMV reactivation, our findings show that CMV risk is heterogeneous. Delayed platelet engraftment emerged as the strongest independent predictor of CMV reactivation, supporting a risk-adapted approach in which targeted CMV PCR monitoring may be warranted in patients with delayed platelet recovery. Incorporating platelet engraftment kinetics into post-transplant surveillance could facilitate earlier CMV detection and optimize patient management.

RESPIRATORY VIRAL INFECTIONS AND NONINFECTIOUS PULMONARY COMPLICATIONS AFTER ALLOGENEIC STEM CELL TRANSPLANTATION

Frédéric Rivière[1], *Apolline Moussy*[1], *Sylvain Chantepie*[1], *Anna Fournier*[1], *Emmanuel Bergot*[1,2]
[1]*Caen University Hospital, Caen, France,* [2]*UNICAEN, Caen Normandie University, Caen, France*

Background: Allogeneic haematopoietic stem cell transplantation is a therapeutic alternative for many malignant and non-malignant blood disorders. Acute or chronic GVHD is a common complication with a prognostic impact. Post-allograft non-infectious pulmonary complications (NIPC) involves numerous entities, the most common of which is bronchiolitis obliterans syndrome (BOS), but also interstitial lung disease. NIPC occurring after allogeneic hematopoietic stem cell transplantation are a major cause of morbidity and mortality. Respiratory viral infections could play a triggering role in their occurrence.
The objective of our study was to evaluate the association between respiratory viral infection and the risk of NIPC, as well as to identify the viruses most commonly involved and compare them during the infectious episode.

Methods: We conducted a retrospective monocenter study at Caen University Hospital, including all patients who underwent allogeneic haematopoietic stem cell transplantation between 1st January 2014 and 31st December 2022, and collected data on transplant conditions, viral respiratory episodes and the occurrence of aCGHVD, cGVHD and NIPC.

Results: Among the 341 patients included, 147 had a first respiratory viral infection, and 19 developed NIPC, mainly of the bronchiolitis obliterans type.
The most prevalent community respiratory viruses in all infectious episodes were HRV/ENT (18%), SARS-CoV-2 (10%), coronaviruses (8%), parainfluenzas (7%), RSV and hMPV (6%) and influenza (6%).
After adjustment, the occurrence of acute GVHD (OR 3.3 [95% CI 1.08-10.27]), *Influenzavirus* infection (OR 4.7 [95% CI 1.29-17.19]), *Coronavirus* infection (OR 5.9 [95% CI 1.71-20.38]), *Rhinovirus* (OR 5.2 [95% CI 1.79-15.20]) or *Pseudomonas aeruginosa* superinfection (OR 10.5 [95% CI 1.20-92.56]) were significantly associated with the development of NIPC.
One hundred and eighty patients died, and nearly one-third of these deaths were respiratory in origin. Among the 19 patients with NIPC, 10 died, with NIPC which is not associated with an increased risk of death from any cause, but there is a significant link with death from respiratory causes (OR: 6.3 [95% CI: 1.56–25.36]).
The viruses associated with an increased, albeit non-significant, risk of death compared to HRV/ENT were parainfluenza (OR: 1.9 [95% CI: 0.6–6.0]), influenza (OR: 1.3 [95% CI: 0.4–4.3]) and 'other' viruses (OR: 1.6 [95% CI: 0.3–7.5]). Regarding deaths from respiratory causes, all viruses appear to offer protection against HRV/ENT.

Conclusions: In conclusion, our study once again confirms the link between respiratory viruses and the development of NIPC. It also highlights the impact of viral infection on the prognosis of NIPC and emphasises the seriousness of this diagnosis for patient survival. All respiratory viruses appear to be a trigger for NIPC, even if the acute episode is not very symptomatic and, from the first infection onwards, it is necessary to be vigilant about the need to document each viral infection in order to personalise respiratory function monitoring to track NIPC induced by this respiratory virus. The role of Pseudomonas aeruginosa co-infection as a potential factor in NIPC is an important new element to consider.

Clinical Trial Registry: This non-interventional study was approved by the Observational Research Protocol Evaluation Committee (Comité d'Evaluation des Protocoles de Recherche Observationnels, CEPRO) and the Institutional Review Board of the French Society of Respiratory Medicine (Société de Pneumologie de Langue Française, SPLF). HHV6 MONITORING AND DONOR ASSESSMENT IN PAEDIATRIC HAEMATOPOIETIC STEM CELL TRANSPLANT – A SINGLE CENTRE PROSPECTIVE STUDY

Antonio Grasso[1], *Khalid Sheeded*[1], *James Hatcher*[1], *James Burton*[1], *Judith Breuer*[2], *Julianne Brown*[1], *Alexander Lennon*[1], *Persis Amrolia*[1], *Kanchan Rao*[1], *Juliana Silva*[1], *Arina Lazareva*[1], *Archana Rauthan*[1], *Milena Balash Carulla*[1], *Macarena Oporto Espuelas*[1], *Jasmin Alloo*[1], *Robert Chiesa*[1]
[1]*Great Ormond Street Hospital, London, United Kingdom of Great Britain and Northern Ireland (the),* [2]*University College of London, London, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Human herpesvirus 6 (HHV-6) reactivation is a frequent complication after allogeneic haematopoietic stem cell transplantation (HSCT), but its clinical impact and need for PCR monitoring and treatment remain unclear. Cost-feasibility according to the clinical significance of HHV6 monitoring has not been studied in the paediatric setting.

Methods: We prospectively analysed paediatric patients who underwent transplantation at Great Ormond Street Hospital between June 2024 and May 2025. All donors were screened for HHV6 viremia and/or viral integration, while recipients were screened before HSCT and weekly until 6 months post-transplant. Variables included age at transplant, donor type (MUD/MSD/MFD/MMUD/haploidentical), stem cell source (BM vs PBSC), immune reconstitution (CD3 and CD4 counts at 3 and 6 months), and occurrence of post-transplant cytopenia, pneumonia, rash, or encephalitis. HHV6 reactivation was considered when persistent for at least 2 consecutive weeks, and viral load was measured as the number of PCR cycles required for detection (CT). Continuous variables were compared with Mann–Whitney tests, and categorical variables with Fisher's tests.

Results: We collected data from 51 patients with a minimum follow-up of 6-months. Sixteen patients reactivated HHV6 with a median CT of 35.19 (IQR 33.6–36.8) and a range from 29.03 to 38.87. Age at HSCT was higher in the Reactivated group (median 5.05 vs 1.79 years; p=0.065). Pre-transplant HHV6 positivity was strongly associated with subsequent HHV-6 reactivation (6/16 vs 2/35; OR 9.90, 95% CI 1.72–56.96; p=0.008). Donor type distribution and stem cell source were comparable between groups (p=0.513 and p=1.000, respectively; OR 0.96, 95% CI 0.29–3.18). There was no difference in CD3 and CD4 counts at 3 and 6 months between the groups (CD3 at 3 months: 310 vs 160 cells/μL, p=0.103; CD4 at 3 months: 163 vs 70 cells/μL, p=0.410). No differences were found in the timing of engraftment for neutrophils and platelets in both groups.
No viral DNA integration was found in the positive donors. Cytopenia was more frequent in reactivated patients (7/16 vs 4/33; OR 5.64, 95% CI 1.34–23.76; p=0.025), while other transplant-related variables were similar between groups. However, cytopenia was not clinically significant, and only 3/16 required treatment with G-CSF for more than a month, and all self-resolved with no treatment. No significant differences were found in bacterial infections, sepsis, or PICU admissions. Non-relapse mortality and overall survival were both

better in the reactivated group. No encephalitis or rash related to HHV6 occurred in both study groups.

Variable	Reactivated	Not Reactivated	p-value
Age at BMT (years)	n=16; median 5.05 (IQR 2.08–11.0)	n=33; median 1.79 (IQR 0.92–5.30)	0.065
CD3 at 3 months (cells/µL)	n=18; median 310 (IQR 75–607.5)	n=29; median 160 (IQR 70–320)	0.103
CD4 at 3 months (cells/µL)	n=18; median 163 (IQR 53–210)	n=29; median 70 (IQR 40–210)	0.41
CD3 at 6 months (cells/µL)	n=13; median 545 (IQR 340–1100)	n=21; median 350 (IQR 190–770)	0.489
CD4 at 6 months (cells/µL)	n=13; median 190 (IQR 140–350)	n=21; median 190 (IQR 80–530)	0.79
Donor type (Haplo/MFD/MMUD/MSD/MUD)	MUD 7 (44%) MSD 6 (38%) MFD 1 (6%) MMUD 2 (12%)	MUD 20 (60%) MSD 6 (19%) MMUD 2 (6%) Haplo 5 (15%)	ND
Stem cell source (BM vs PBSC)	BM=9, PBSC=7	BM=20, PBSC=15	1
HHV6 pre-BMT positive	6/16 (37%)	2/35 (6%)	0.008
Cytopenia	7/16 (43%)	4/33 12%)	0.025
Non-Relapse Mortality	0/16 (0%)	7/33 (21%)	0.08
Overall Survival	16/16 (100%)	25/33 (75%)	0.041

Conclusions: In this cohort, HHV-6 reactivation was not associated with donor type, stem cell source, or clear differences in early T-cell reconstitution, but showed strong associations with pre-transplant HHV-6 positivity and a higher incidence of post-transplant cytopenia. These findings suggest that pre-BMT HHV-6 status may help identify patients at increased risk of reactivation and cytopenias. Also, the low clinical impact of HHV6 in our cohort, with

no clinical events associated and no differences in bacterial infections, sepsis, and PICU admissions in the reactivated patients, does not justify regular HHV6 PCR monitoring in patients with no HHV6 positivity before transplant.

Disclosure: No disclosure

B126

CHANGES IN ANTIBODY TITERS AND PREDICTIVE FACTORS FOR SEROCONVERSION FOLLOWING LIVE VACCINATION IN ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION RECIPIENTS

Misaki Hada[1], *Noriyoshi Yoshinaga*[1], *Junya Kanda*[1], *Mizuki Watanabe*[1], *Tomomi Oka*[1], *Yasuyuki Arai*[1], *Toshio Kitawaki*[1], *Mari Morita*[1], *Kohei Yamashita*[1], *Akifumi Takaori-Kondo*[1]
[1]*Kyoto University, Kyoto, Japan*

Background: Hematopoietic stem cell transplant (HSCT) recipients often experience a reduction or loss of pre-existing immunity. Although revaccination after immune reconstitution is recommended, the optimal conditions for achieving effective seroconversion remain unclear. This study retrospectively evaluated changes in antibody titers before and after live attenuated vaccine (LAV) administration and identified factors associated with seroconversion.

Methods: We retrospectively analyzed data from 67 patients (28 for varicella, 27 for rubella, 34 for measles, and 47 for mumps) who underwent allogeneic HSCT at Kyoto University Hospital between August 2018 and July 2025, received at least one LAV, and had antibody titers measured before and after vaccination. Seropositivity was defined as an IgG antibody titer of 4 or greater for each virus, as determined by the Enzyme Immunoassay (EIA) for measuring various viral IgG antibody titers, following the vaccination guidelines established by the Japan Society for Transplantation and Cellular Therapy. Logistic regression was used to identify factors associated with seroconversion. Optimal cutoff values for the IgG levels and lymphocyte counts were determined using receiver operating characteristic curve analysis.

Results: The median age of the subjects was 47 years, with 39 males and 28 females. Donor sources included 4 cases of related bone marrow transplantation (BMT), 9 cases of related peripheral blood stem cell transplantation (PBSCT), 20 cases of unrelated BMT, and 34 cases of umbilical cord blood transplantation (UCBT). The seroconversion rates for each vaccine were: varicella 32.1%, rubella 96.3%, measles 91.2%, and mumps 25.5%. For the mumps vaccine, preserved IgG levels (≥1000 mg/dL) were associated with seroconversion in both univariate (odds ratio [OR], 4.7; P=0.067) and multivariate analyses (OR, 8.9; P=0.039). Conversely, lower total lymphocyte counts (<1950/μL) were associated with reduced seroconversion (OR, 0.09; P=0.003). Detailed lymphocyte subset analyses could not be performed due to insufficient available data.

Conclusions: Seroconversion rates after LAV administration in allogeneic HSCT recipients varied depending on the vaccine type. Markers of immune reconstitution, particularly preserved IgG levels, were strongly associated with improved seroconversion following mumps vaccination. These findings suggest that successful revaccination in HSCT survivors depends primarily on the recovery of antibody-mediated immunity, underscoring the importance of individualized assessment based on immune status rather than timing alone.

B127

MANAGEMENT OF CMV INFECTION WITH MARIBAVIR IN PATIENTS TREATED WITH CAR-T THERAPY

Cristian Gutierrez-Padilla[1], *Jose Maria Sanchez-Pina*[1], *Maria Sanchez-Tabernero*[1], *Adolfo Saez-Marin*[1], *Guillermo Ramos-Moreno*[1], *Daniel Gil-Alos*[1], *Magdalena Corona*[1], *Nieves Lopez-Muñoz*[1], *Pilar Martínez-Sánchez*[1], *Silvia Chacon*[1], *Maria Puy-Goyache*[1], *Joaquin Martinez-Lopez*[1], *Maria Calbacho*[1]
[1]*Hospital Universitario 12 Octubre, Madrid, Spain*

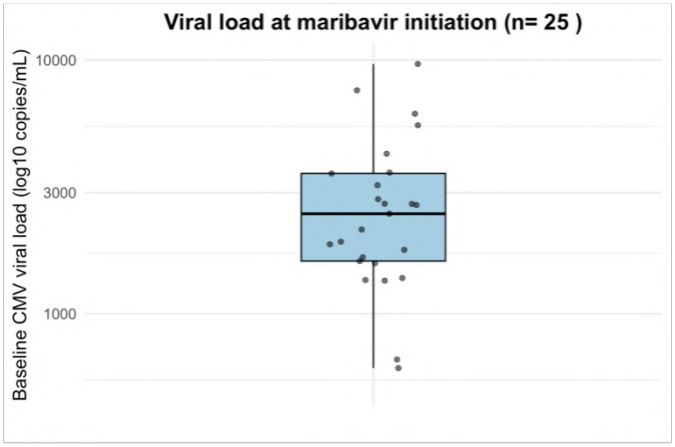
Background: Clinically significant cytomegalovirus (CMV) reactivation in patients undergoing CAR-T therapy represents a therapeutic challenge due to the combined toxicities of both the cellular product and conventional antivirals. Our objective was to evaluate the effectiveness and toxicity of maribavir in this patient population.

Methods: We conducted a single-center retrospective study including patients treated with CAR-T therapy who developed CMV reactivation and received pre-emptive maribavir between September 2020 and September 2025. CMV viral load was monitored twice weekly during the first month after infusion. Maribavir was initiated in cases with DNAemia ≥1,500 copies/mL (measured in plasma by qPCR) and a viral doubling time ≤2 days. Viral clearance was defined as at least one undetectable viral load measurement.

Results:

Table 1: **BASELINE CHARACTERISTICS (N=25) AND RESULTS**		
	n(%)	Median (IQR)
Sex, Female	15 (60)	
Age (years)		68 (64-73)
Underlying disease		

Diffuse Large B-cell Lymphoma		19 (76)
Multiple myeloma		6 (24)
CRS ≥ 2	11 (44)	
ICANS ≥ 2	8 (32)	
Tocilizumab use and cumulative dose (mg)	18 (72)	1200 (600 – 1,600)
Corticosteroid use and cumulative dose (mg)	23 (92)	180 (70-360)
Other CRS/ICANS treatments	14 (58)	
Days from CAR-T infusion to first CMV reactivation		16 (5-23)
Days from first reactivation to initiation of maribavir		7 (2-11)
Viral load at first post–CAR-T reactivation (UI/mL)		1,499 (1,045-2,477)
Viral load prior to maribavir initiation		2,477 (1,613-3,573)
Days on maribavir treatment		14 (11-18)
Days to viral clearance		7 (28)
Death	7 (28)	
Median follow-up (days)		220 (97-335)



We analyzed 25 patients, including 19 with B-cell non-Hodgkin lymphoma and 6 with multiple myeloma. The most frequently infused CAR-T product was axicabtagene ciloleucel (80%), and the median number of prior treatment lines was 2 (IQR, 1–2). Grade ≥2 CRS and ICANS occurred in 44% and 32% of patients, respectively, with frequent use of corticosteroids (92%), tocilizumab (72%), and other immunomodulators (58%), such as siltuximab and anakinra. *Table 1.*

Following CAR-T infusion, CMV reactivation occurred at a median of 16 days (IQR, 5–23), with a median viral load of 1,499 copies/mL (IQR, 1,045–2,477). Maribavir was used as first-line antiviral therapy in 84% of patients. *Figure 1* shows the distribution of CMV viral load at the time of maribavir initiation (median 2,477 copies/mL; IQR, 1,613–3,573). In 80% of cases, the indication for maribavir was grade 3–4 cytopenias, followed by toxicity (12%) and refractoriness (8%) to other antivirals.

Viral clearance was achieved in 100% of patients after a median of 8 days of treatment (IQR, 6–15). Median treatment duration was 14 days (IQR, 11–18). Only 12% of patients experienced a subsequent CMV reactivation after achieving initial viral clearance, and no cases of primary treatment failure with maribavir were observed. No maribavir-related toxicities were reported, and no CMV-related hospital admissions, CMV disease, or CMV-related deaths occurred.

Median progression-free survival (PFS) and overall survival (OS) were not reached due to the short follow-up period. A total of 7 patients (28%) died during follow-up, mainly due to progression of the underlying disease (16%), with additional deaths attributed to non-CMV infections (4%) and other causes (8%).

Conclusions: In this small cohort, maribavir demonstrated rapid and effective viral control with minimal toxicity. These findings suggest that maribavir may represent a safe and effective option for the management of CMV reactivation in severely immunocompromised CAR-T recipients, who frequently experience concomitant treatment-related toxicities.

Disclosure: Nothing to declare.

NORMAL IGG DOES NOT EQUATE TO IMMUNE COMPETENCE AFTER HSCT IN PEDIATRIC SICKLE CELL DISEASE

Alonzo Needum[1], Erin Doherty[1,2], John Craddock[1,2], Baheyeldin Salem[1,2], Anil George[1,2], Khaled Yassine[1,2], Gabriela Llaurador Caraballo[1,2], Megha Thakkar[1,2], David Steffin[1,2], Bilal Omer[1,2], Helen Heslop[1,2], Robert Krance[1,2], Caridad Martinez[1,2], ***Alexander Ngwube***[1,2]
[1]*Baylor College of Medicine, Houston, United States of America (the),* [2]*Texas Children's Hospital, Houston, United States of America (the)*

Background: Invasive pneumococcal disease (IPD) is a persistent threat after allogeneic hematopoietic stem cell transplantation (HSCT). Clinical practice commonly assumes that normal serum IgG levels reflect adequate humoral immunity, yet this has never been validated in pediatric sickle cell disease (SCD), a population characterized by functional asplenia, dysregulated antibody quality, and pre-transplant hypergammaglobulinemia. Emerging institutional observations and published reports suggest that normal IgG levels may mask profound vaccine-specific vulnerability. We evaluated the relationship between total serum IgG and pneumococcal serotype-specific protection after matched sibling donor HSCT in pediatric SCD.

Methods: We conducted a retrospective cohort study of 57 pediatric SCD HSCT recipients with available post-vaccination pneumococcal titers (2005–2024). Data included IgG levels at days 30–365, pneumococcal titers at ~1 year, vaccination type, immune reconstitution (CD3, CD4, CD8, CD19 counts), splenectomy status, and days between vaccination and titer assessment. Protective immunity was defined per standardized serotype threshold. Analyses included correlation testing, diagnostic performance of IgG thresholds, and penalized multivariable logistic regression incorporating clinical and immunologic covariates.

Results: Normal or elevated IgG levels did not reliably predict protective pneumococcal titers.

Primary objective:

- Correlation between IgG and percentage of protective serotypes was weak across all timepoints (r = 0.15–0.35; day-365 r ≈ 0.25).
- Diagnostic performance of IgG was poor:
    - At commonly used thresholds (400–600 mg/dL), the specificity was 0%, despite high sensitivity (0.96).
    - Even at 1000–1200 mg/dL, specificity remained limited (0.50–0.79), with no clinically actionable cut-point.
        - IgA and IgM levels were not associated with protection (|r| < 0.12).

Secondary immune predictors:

- Day-180 lymphocyte reconstitution was more informative than immunoglobulins:
    - CD19 mean: 798 vs. 623 cells/μL (protective vs. non-protective)
    - CD3: 1220 vs. 885 cells/μL
    - CD4: 496 vs. 373 cells/μL
    - CD8: 631 vs. 452 cells/μL

- Splenectomy was associated with 0% protective immunity (n=4) versus ~59% in non-splenectomized patients.

Multivariable modeling (N=54):

A penalized logistic model incorporating IgG, immune reconstitution, timing of titer assessment, vaccine type, splenectomy, and genotype achieved AUC = 0.76, outperforming IgG alone (AUC = 0.63). Strongest predictors included:

- Splenectomy (OR ~0.33, reduced protection)
- IgG 365d (OR ~1.61)
- CD3 recovery (OR ~1.28)
- Days from vaccination to titer (OR ~1.44)

Conclusions: In pediatric SCD, normal total IgG levels do not equate to pneumococcal protection after HSCT. Vaccine-specific immunity correlates more strongly with cellular immune reconstitution and spleen function than with bulk immunoglobulin levels. Reliance on IgG as a surrogate marker results in substantial misclassification and may delay recognition of vulnerable patients. These findings support transitioning from IgG-based monitoring to routine serotype-specific antibody assessment and risk-adapted revaccination strategies, particularly for patients with poor lymphocyte recovery or splenectomy. Prospective multicenter evaluation is warranted to establish evidence-based guidelines for post-HSCT pneumococcal immunity in SCD.

PHYSICIAN SURVEY OF REAL-WORLD MARIBAVIR USE AND TREATMENT DECISION MAKING IN REFRACTORY CYTOMEGALOVIRUS INFECTION AFTER TRANSPLANTATION

Johan Maertens[1], *Nassim Kamar*[2], *Regino Rodríguez-Álvarez*[3], *Oliver Witzke*[4], *Ilaria Albieri*[5], *Sylvie Fernandez*[6], *Bojana Milovanović*[5], *Tien Bo*[7]
[1]*UZ Leuven, Leuven, Belgium,* [2]*Toulouse Rangueil University Hospital, INFINITY-Inserm U 1291-CNRS U 5051, University Paul Sabatier, Toulouse, France,* [3]*Cruces University Hospital, Barakaldo, Spain,* [4]*West German Centre of Infectious Diseases, University Medicine Essen, University Duisburg-Essen, Essen, Germany,* [5]*Takeda Pharmaceuticals International AG, Zürich, Switzerland,* [6]*IQVIA Solutions S.r.l, Modena, Italy,* [7]*Takeda Development Center Americas, Inc., Cambridge, United States of America (the)*

Background: Cytomegalovirus (CMV) infection increases morbidity and mortality in transplant recipients. Refractory or resistant (RR) CMV infection, or intolerance to anti-CMV agents, complicates disease management. Guidelines and protocols for treatment vary across countries and institutions and can be difficult to apply in real-world practice. The anti-

CMV agent maribavir has shown higher clearance rates and lower incidence of myelosuppression compared with ganciclovir/valganciclovir in transplant recipients with RR CMV infection in a randomized clinical trial (NCT02931539). The ARISE study aims to describe the real-world use, effectiveness and safety of maribavir in transplant recipients with RR CMV infection, and to explore factors influencing CMV management decisions, including potential gaps between guidelines and clinical practice.

Methods: ARISE is a multinational, non-interventional, retrospective cohort study across Europe that includes a cross-sectional survey of physicians from 43 participating sites. The survey was issued during the study conduct and the database was extracted in September 2025. Data were validated for consistencies through edit checks and queries. Descriptive statistics were used for analysis. Statistical analyses were performed using SAS Enterprise Guide 8.2 and SAS 9.4 for Windows.

Results: Thirty-nine physicians from 10 European countries participated in the survey. Most specialized in hematology or nephrology (both n=13, 33.3%), followed by infectious disease (n=8, 20.5%); median (Q1–Q3) experience in management of CMV infection was 15.0 (10.0–20.0) years. Most physicians followed international guidelines (n=30, 76.9%), with 15 (38.5%) and 14 (35.9%) following hospital protocols and/or national guidelines, respectively. Half of physicians (n=20, 51.3%) did not perceive a gap between the guideline/literature definition of refractory patients and clinical practice, whilst 8 (20.5%) did, and 11 (28.2%) were unsure. The availability of new treatment options was confirmed to influence the treatment approach to refractory CMV in terms of switching before 2 weeks if current treatment seemed ineffective (n=28, 71.8%), using regimens with lower toxicity risk (n=28, 71.8%), and/or switching at initial signs of toxicity (n=22, 56.4%). Characteristics considered most important for guiding treatment management were dynamic change in CMV viral load (n=12, 31.6%), followed by absolute viral load level, and donor/receiver CMV serostatus (both n=6, 15.8%). Most physicians (n=27, 71.1%) reported factors/barriers to decision making, most frequently patient-specific clinical factors not related to CMV (n=21, 77.8%). Regarding maribavir treatment, the most common reason for discontinuing maribavir was undetectable or sub-quantifiable viral load (n=26, 66.7%; Table). The most common reason to prolong maribavir treatment after clearance was to avoid recurrent CMV infection (n=25, 65.8%; Table), and the most common reason to prolong maribavir treatment past 8 weeks was persistent viral load (n=28, 73.7%; Table).

Question	Answer	Physicians (N=39)[a]
Main clinical reasons to discontinue treatment with maribavir in refractory patients	CMV viral load that is undetectable or under the lower limit of quantification	26 (66.7%)
	Detection of resistance	6 (15.4%)
	Achieved CMV-viremia control (sustained	5 (12.8%)

with or without resistance	reduction of CMV viral load)	
	Adverse events and treatment toxicities	2 (5.1%)
Main clinical reasons to prolong treatment with maribavir after confirmation of CMV viremia clearance	Avoid recurrent CMV infection	25 (65.8%)
	CMV-specific immune reconstitution status	6 (15.8%)
	None	6 (15.8%)
	Other	1 (2.6%)
	Missing	1
Main clinical reasons to prolong treatment with maribavir in refractory patients with or without resistance beyond 8 weeks	Persistent CMV viral load (clearance not achieved)	28 (73.7%)
	Maintain CMV-viremia control	14 (36.8%)
	Avoid recurrent CMV infection	13 (34.2%)
	CMV-specific immune reconstitution status	3 (7.9%)
	None	1 (2.6%)
	Other	2 (5.3%)
	Missing	1

[a]Physicians were able to select more than one answer.
CMV, cytomegalovirus

Conclusions: Survey findings indicate variability and perceived gaps between guidelines and clinical practice in the management of RR CMV infection following transplantation. Following the introduction of new treatment options, physicians reported a tendency to switch earlier to maribavir if the current agent was ineffective or to avoid toxicity. These results highlight the need for treatment options that achieve CMV clearance with fewer treatment-related toxicities, and for practical guidance on optimizing maribavir use in real-world practice.

B130

COMPARATIVE ANALYSIS OF CYTOMEGALOVIRUS REACTIVATION AFTER HAPLOIDENTICAL VS MATCHED SIBLING DONOR ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Marco Alejandro Jiménez-Ochoa[1], *María Margarita Contreras-Serratos*[1], *Carlos Daniel Reyes-Morales*[1]
[1]*Centro Médico Nacional Siglo XXI. Instituto Mexicano del Seguro Social, Mexico City, Mexico*

Background: Cytomegalovirus (CMV) reactivation remains one of the most frequent infectious complications after allogeneic hematopoietic stem cell transplantation (HSCT), particularly in settings of delayed immune recovery. The increasing use of haploidentical donors with post-transplant cyclophosphamide (PTCy) has broadened access to HSCT but is commonly associated with slower myeloid and platelet engraftment, impaired early T-cell reconstitution, and consequently higher rates of viral reactivation. Comparatively, matched sibling donor (MSD) transplants typically show faster engraftment and more robust immune recovery, potentially leading to lower CMV-related morbidity. This study compares the incidence, timing, and outcomes of CMV reactivation after haploidentical versus matched sibling donor HSCT, aiming to clarify clinically relevant differences that may guide surveillance and preemptive management.

Methods: We conducted a retrospective, comparative study including all allogeneic HSCTs performed at a national referral center in Mexico between January 2018 and December 2024. Conditioning regimens included myeloablative (BuCy2, BuFlu) and reduced-intensity

approaches (BuCy, MelFlu, CYATG). GVHD prophylaxis consisted of cyclosporine plus methotrexate for MSD transplants, and post-transplant cyclophosphamide on days +3/+4 followed by cyclosporine and mycophenolate for haploidentical HSCT. Peripheral blood stem cells were used as the sole graft source. CMV surveillance followed a preemptive strategy with weekly qPCR monitoring, and reactivation was defined as >1,000 copies/mL. No patient received letermovir prophylaxis, as it only became available in Mexico after 2025. Outcomes analyzed included overall survival (OS), disease-free survival (DFS), and non-relapse mortality (NRM). Statistical analyses were performed using SPSS v25.

Results: A total of 182 transplanted patients were analyzed. The median age was 34 years (range, 17–67), and 58% were male. Acute lymphoblastic leukemia was the most frequent indication for transplantation, followed by acute myeloid leukemia in both donor groups. Overall, 106 patients (58%) received a matched related donor transplant and 76 patients (42%) underwent haploidentical transplantation.
CMV reactivation was significantly more frequent in the haploidentical donor group compared with the matched related donor group (53% vs. 19%, p <0.01). The median time to CMV reactivation was similar between groups (41 vs. 40 days, respectively). Most cases were detected as asymptomatic viremia, while a minority developed CMV-related end-organ disease, mainly pneumonia and gastrointestinal involvement. Peak CMV viral load varied widely, with no significant differences in median viral load or duration of antiviral therapy between groups.
Five-year overall survival was comparable between donor types (59% in matched related vs. 53% in haploidentical transplants). Relapse of the underlying hematologic malignancy was the leading cause of death (49%), followed by infections (23%). In contrast, five-year overall survival was significantly lower in patients with CMV reactivation compared with those without reactivation (50% vs. 60%, p = 0.01).

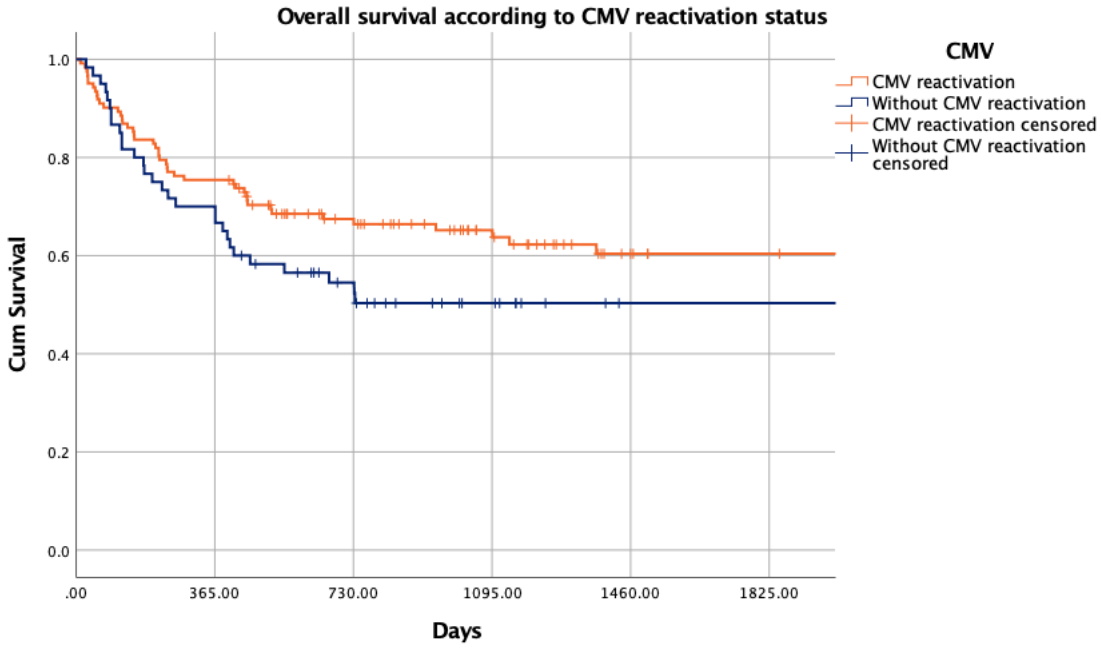

Table 1. Baseline epidemiological and CMV-related characteristics of the population			
Variable	Matched related donor	Haploidentical donor	Significance (p)
	106 (58%)	76 (42%)	
Age (years)	34 (17-64)	32 (17-66)	>0.05
Sex (male)	61 (58%)	46 (60%)	>0.05
Diagnosis			
ALL	54 (50%)	45 (58%)	>0.05
AML	21 (20%)	13 (17%)	>0.05
MDS	12 (11%)	2 (3%)	0.001
AA	8 (8%)	0	NA
CML	8 (8%)	14 (19%)	0.001
Myelofibrosis	3 (3%)	2 (3%)	>0.05
$CD34^+$ cell dose ($\times 10^6$/kg)	5.6 (2.0-17.5)	6.1(2.1-15.4)	>0.05
Day of engraftment	12 (9-29)	16 (13-25)	0.003
CMV reactivation	20 (19%)	40 (53%)	0.001
Peak CMV viral load (copies/mL)	9943 (1210-183,000)	8239 (1406-419,000)	>0.05
Day of CMV Diagnosis	41 (11-124)	40 (25-307)	>0.05
Time to CMV remission (days)	20 (5-43)	23 (7-44)	>0.05

Conclusions: CMV reactivation was significantly more frequent after haploidentical transplantation, although the timing of reactivation and CMV-related clinical presentation were similar across donor types. Overall survival did not differ according to donor type; however, CMV reactivation was associated with inferior long-term survival. These findings suggest that CMV reactivation represents a clinically relevant event influencing outcomes after allogeneic hematopoietic stem cell transplantation, beyond donor type alone

HOSPITAL EXEMPTION USE OF VIRUS-SPECIFIC T-LYMPHOCYTES IN CHILDREN: EARLY EXPERIENCE WITHIN THE ALLOVISTA FRAMEWORK

Marek Ussowicz[1], *Aleksandra Ślęzak*[1], *Marta Myszka-Kozłowska*[1], *Kornelia Gajek*[1], *Karol Jopek*[2], *Marta Bukowska*[3], *Alicja Bukowska*[3], *Justyna Jureczek*[1], *Wioletta Jarmużek*[4], *Maksymilian Deręgowski*[2], *Katarzyna Derwich*[2], *Anna Czyż*[1], *Anna Bogacz*[2]
[1]*Wroclaw Medical University, Wrocław, Poland,* [2]*Poznan University of Medical Sciences, Poznań, Poland,* [3]*Regional Blood Center, Poznań, Poland,* [4]*Children's Memorial Health Institute, Warsaw, Poland*

Background: Adoptive transfer of virus-specific T lymphocytes (VST) is an emerging strategy for refractory viral infections in immunocompromised individuals and is being prospectively evaluated in the ALLOVISTA trial. Here we describe our experience with hospital-exemption advanced therapy medicinal product (ATMP-HE) VST in six pediatric transplant recipients.

Methods: Six children and adolescents (median age 4.5 years, range 2.5–17.5; HLH n=2, SAA, GCD, HL, AML n=1 each) treated in two Polish centers received VST for refractory viremia: adenovirus (ADV) in three cases, EBV-driven disease (EBV/PTLD or HL relapse with EBV reactivation) in three, including one patient with concomitant CMV/EBV/ADV infection. All had failed conventional antiviral and/or immunochemotherapy (cidofovir, rituximab, chemotherapy). VST_RCKiK were generated from HSCT or related donors using automated CliniMACS Prodigy Cytokine Capture System (IFN-γ CCS, Miltenyi Biotec) following antigenic stimulation with viral peptide pools and released as ATMP-HE according to the ALLOVISTA protocol. A single intravenous infusion of 1.01×10^5–1.85×10^6 VST (median 2.5×10^5) was administered. Virological response was assessed by quantitative PCR up to 4 weeks post-infusion, acute GVHD (aGVHD) and survival were recorded.

Results: Virological outcomes were evaluable in five patients. A virological response defined as ≥1-log viral load reduction was achived in four patients (80%). Complete viral clearance by week 4 occurred in two cases (33% of all, 40% of evaluable; one EBV and one ADV). Two additional patients had marked but incomplete or transient viral load reductions, one patient showed minimal virological change. Despite biological activity, four children died: from progressive EBV disease (n=1), ADV infection (n=1), relapse of HL (n=1) and multi-organ failure with invasive fungal disease in a child with multi-viral infection (n=1). Two patients with complete virological responses are alive with sustained remission of viremia at last follow-up. No new-onset or worsening aGVHD was documented after VST infusion.

Conclusions: VST administered as an ATMP-HE are feasible in routine clinical practice and demonstrate rapid antiviral activity in heavily pretreated pediatric patients. However, advanced viral disease and competing complications limit overall survival, underscoring the need for earlier intervention and advocate for treatment within the ongoing ALLOVISTA trial.

Clinical Trial Registry: EUCT number: 2024-517696-21-01

B132

IMPACT OF LETERMOVIR PROPHYLAXIS ON CYTOMEGALOVIRUS EVENTS AND RELAPSE AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR AML AND MDS

Sin Young Park[1], *Dong Hyun Kim*[1], *Hyunsoo Cho*[1,2,3], *Ja Min Byun*[1,2,3], *Youngil Koh*[1,2,3], *Dong-Yeop Shin*[1,2,3], *Inho Kim*[1,2,3], *Jun Shik Hong*[1,2,3]
[1]*Seoul National University Hospital, Seoul, Korea (the Republic of),* [2]*Cancer Research Institute, Seoul, Korea (the Republic of),* [3]*Center for Medical Innovation, Biomedical Research Institute, Seoul, Korea (the Republic of)*

Background: Early cytomegalovirus reactivation (ECMVR) has been inversely associated with relapse after allogeneic hematopoietic stem cell transplantation (allo-HSCT), but whether this association persists in the letermovir era remains uncertain.

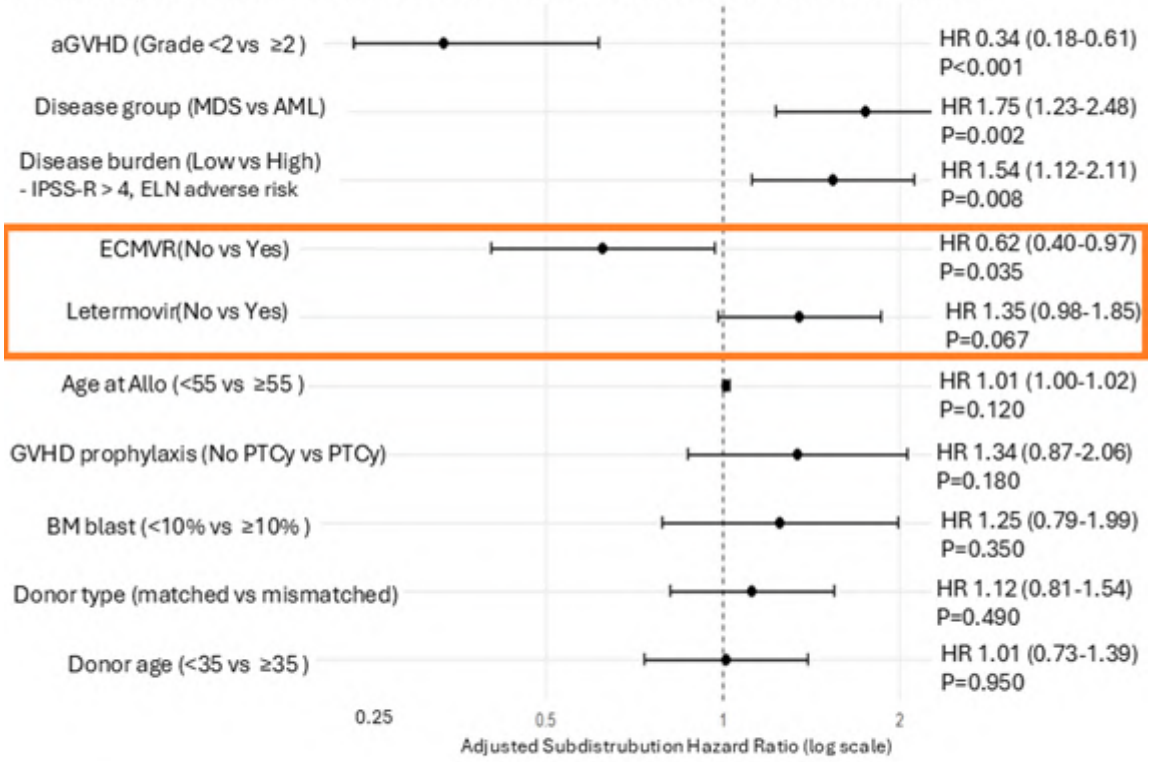
Methods: We conducted a single-center retrospective study of adult patients with acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS) who underwent first allo-HSCT with uniform fludarabine/busulfan-based conditioning between January 2016 and September 2024. Letermovir prophylaxis from day +7 to +100 was administered to CMV-seropositive recipients with undetectable CMV DNA at transplantation (letermovir group, LG), while patients transplanted before its introduction comprised the non-letermovir group (NLG). CMV reactivation and disease were prospectively monitored using quantitative PCR or antigenemia assays. ECMVR was defined as CMV reactivation before day +100. A day +100 landmark analysis was performed among patients alive and relapse-free at day +100. Competing-risk regression and multivariable Cox models were used to assess relapse, non-relapse mortality (NRM), and overall survival (OS), adjusting for clinically relevant covariates.

Results: A total of 397 patients were included, of whom 171 (43.1%) received letermovir prophylaxis. The median follow-up was 49.0 months (95% CI, 44.2–56.3). Baseline characteristics were largely balanced, although the LG more frequently received contemporary transplant approaches, including haploidentical donors and PTCy. For the overall cohort, 3-year and 5-year OS were 56.8% and 53.4%, respectively. One-year NRM was 16.0% (95% CI, 12.5–19.7), and 1-year cumulative incidence of relapse was 27.8% (95% CI, 23.5–32.3).
Letermovir prophylaxis significantly reduced CMV events. The cumulative incidence of CMV reactivation by day +100 was markedly lower in the LG compared with the NLG (6.4% vs. 40.0%, P<0.001), and CMV disease was also reduced (1.16% vs. 8.44% at day +100, P=0.013).
Despite comparable 2-year OS between the LG and NLG (56.2% vs. 57.1%, P=0.99), the 2-year cumulative incidence of relapse was higher in the LG (40.0% vs. 29.7%, P=0.034), whereas NRM did not differ significantly. The 100-day cumulative incidence of grade ≥2 acute GVHD was significantly lower in the LG (19.4% vs. 28.3%, P=0.028).
The inverse association between ECMVR and relapse was evident in the NLG, but not in the LG, in which ECMVR events were markedly reduced, limiting the ability to detect an ECMVR–

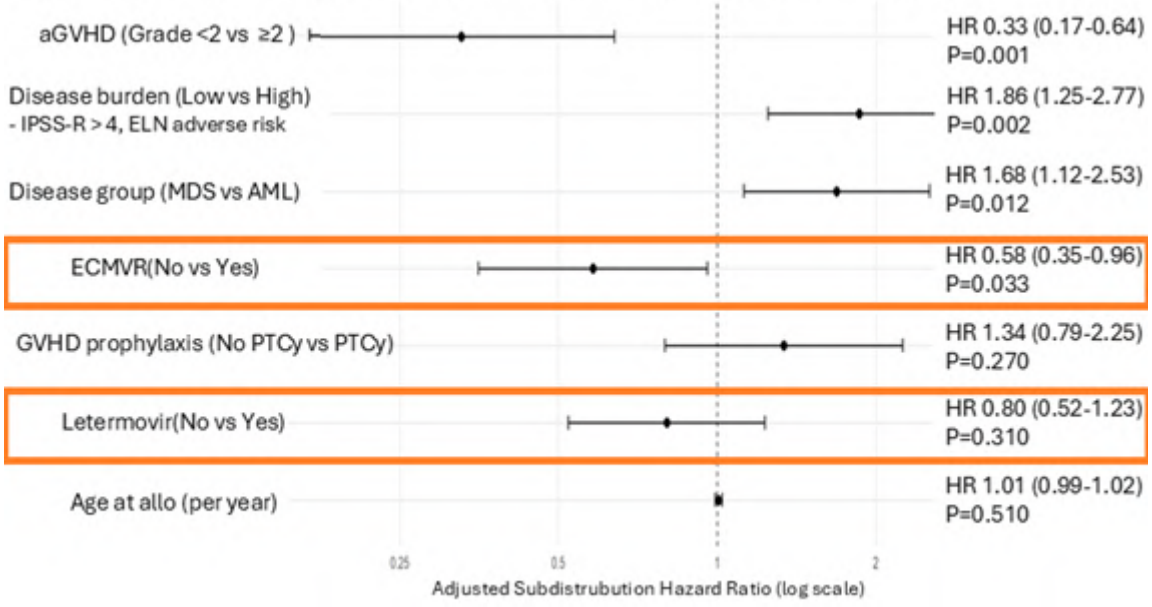
relapse association. In univariable analyses, letermovir prophylaxis appeared to be associated with a higher relapse incidence; however, in multivariable models adjusting for ECMVR, GVHD, disease risk, and transplantation-related factors, letermovir prophylaxis was no longer independently associated with relapse. In contrast, ECMVR remained independently associated with a reduced risk of relapse (Figure).

Figure

a) Fine-Gray univariate cox analysis of association between relapse and clinical characteristics



b) Fine-Gray multivariate cox analysis of association between relapse and clinical characteristics



Conclusions: Letermovir prophylaxis fundamentally reshapes the post-transplant CMV landscape, uncoupling ECMVR from routine clinical observation. Although letermovir use was associated with higher unadjusted relapse incidence, this association disappeared after accounting for ECMVR and transplant-related covariates, while ECMVR itself remained independently protective against relapse. These data suggest that letermovir does not promote relapse but rather may obscure a CMV-associated immune signal linked to graft-versus-leukemia effects.

Disclosure: Nothing to declare.

B133

ADDITION OF ANTITHYMOCYTE GLOBULIN TO CYCLOSPORIN AND MYCOPHENOLATE IN UNMANIPULATED HAPLO-TRANSPLANT WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE IN CHILDREN AND TEENAGERS. RESULTS OF A SERIE OF 40 PATIENTS

Angela Maria Trujillo-Gaviria[1], *Amado Karduss-Urueta*[1], *Angelica Maria Cardona-Molina*[2], *Gloria Elena Suarez-Vallejo*[1], *Monica Maria Ramirez*[1], *Jose Alberto Betancur*[1]
[1]*Clinica Las Americas AUNA, Medellin, Colombia,* [2]*Fundacion Ideas, Clinica Las Americas AUNA, Medellin, Colombia*

Background: The addition of anti-thymocyte globulin (ATG) to classic platform of cyclosporine, mycophenolate and post-transplant cyclophosphamide (PTCy) in the setting of haplo transplantation has shown good results in adults, however, it has not been well described in children. We present here the long-term results with this combination in a pediatric population.

Methods: From March 2017 to May 2025, forty patients between 1 and 15 years underwent Haplo-PTCy. Written informed consent from parents or legal guardians was obtained previous to the procedure and before the data collection. Twenty-four had acute lymphoblastic leukemia and sixteen had acute myeloid leukemia. Cellular source was peripheral blood stem cell (PBSC) in older than 10 years old and/or patients with ABO group incompatibility while it was bone marrow (BM) in the others. Patients received melphalan 140 mg/m2 day −7, fludarabine 160 mg/m2 in 4 days and TBI 200 cGy day -2, children aged 3 years or less received thiotepa instead of TBI. The GVHD prophylaxis consisted of PTCy 50 mg/kg days +3+4, cyclosporine days 0 to +180, mycophenolate days +1 to +60 and ATG 2 mg/kg/day on days -8-7. Since June 2023, methotrexate at 7.5 mg/m2/d days +1+5+8+11 was added. Regarding the donor, it was a parent in 85% of the cases and a sibling in 15%. The cellular source was BM in 18 and PBSC in 22.

Results: Neutrophil recovery day +30 was 100%, median 15 days (range 11-26), and 97% for platelets, median 19 days (range 13-27). Chimerism at D+100 was available in 30/34 patients alive. It was performed in 13 patients by cytogenetics and in 14 by short tandem repeat; all had 100% donor hematopoiesis. In the remaining, a blood red cell group change

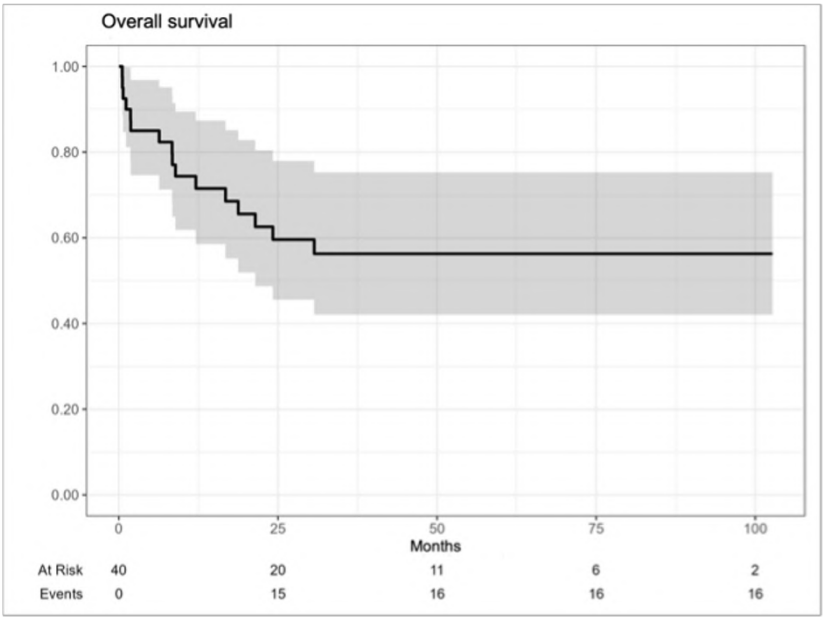
was documented. Infections are described in table 1; the pathogens were bacteria (62%), virus (41%), fungus (7%). Infection was the cause of death in 4 patients (10%).

Cause	Number (%)
Bacteria	25 (62%)
Bacteremia	20 (50%)
Urinary tract infection	2 (5%)
Clostridioides	3 (7%)
Fungus	3 (7%)
Pulmonary aspergillosis	2 (5%)
Candidemia	1 (2%)
Virus	17 (41%)
BK virus	1 (2%)
Adenovirus	2 (5%)
Respiratory syncytial virus	2 (5%)
Human metapneumovirus	3 (7%)
Parainfluenza	4 (10%)
Rhinovirus	4 (10%)
Epstein Barr virus associated post trasplant lymphoproliferative disease	1 (2%)
Citomegalovirus reactivation	24 (60%)
Citomegalovirus colitis	3 (7%)
Related infection deaths	4 (10%)

1. E. coli - Stenotrophomonas maltophilia: Multiple organ dysfunction syndrome
2. Serratia marcescens and rhinovirus: Pulmonary sepsis
3. Klebsiella pneumoniae group, KPC NDM Ceftazidime avibactam resistant sepsis. Rhinovirus/Enterovirus, parainfluenza virus pneumonia. Proven pulmonary aspergillosis

4.	Urinary tract infection/sepsis resistant S. aureus. Adenovirus, rhinovirus, CMV pneumonia

The median follow-up for the whole group was 34 months (range 1-103) and for surviving patients was 48 months (range 1-103). The incidence of aGVHD II-IV and III-IV for the whole group was 60% and 12%; and the cumulative incidence of moderate-severe cGVHD at 2 years was 27%. The incidence of relapses was 25% and the mortality related to transplant was 17%. The overall and event-free survival (Kaplan-Meier) at 36 months was 56% and 54% respectively (Figure 1).



Conclusions: The addition of ATG to the standard PTCy platform in haplo transplant in a pediatric population could decrease the incidence of severe aGVHD, however, it was not observed a protective effect against the less severe cases. The relapse rate was not higher than expected, but the incidence of viral infections is a concern. It is necessary to explore new alternatives.

Disclosure: No conflicts of interest.

B134

OUTCOMES OF HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS REQUIRING INTENSIVE CARE: A RETROSPECTIVE COHORT STUDY

Andres Yesid Bonilla-Salcedo[1], *Fredy Vazquez-Hernandez*[1], *Rosa Adriana Alvidrez-González*[1], *Grecia Pamela Martínez-Vázquez*[1], *Vicky Margarita Moncada-Gadea*[1], *Mistral Castellanos-Mares*[1], *Victor Iván Salinas-Herrera*[1], *Irma Karen Pellon-Tellez*[1], *Luis Manuel Valero-Saldaña*[1], *Pamela Alatorre-Fernández*[1]
[1]*Instituto Nacional de Cancerología, Mexico City, Mexico*

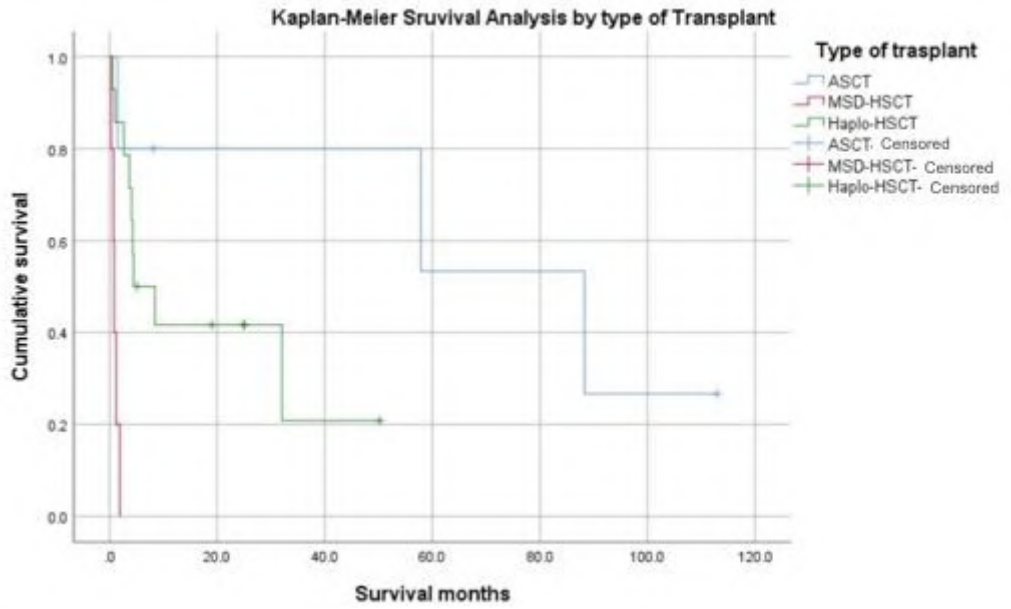
Background: Hematopoietic stem cell transplantation (HSCT) is a potentially curative therapy for a wide range of hematologic malignancies and non-malignant disorders. Despite improvements in supportive care, HSCT is associated with profound but transient immunosuppression, which predisposes patients to severe infections and other life-threatening complications. Admission to the intensive care unit (ICU) after HSCT is uncommon but represents a critical clinical event associated with high morbidity and mortality. Data describing the clinical characteristics and outcomes of HSCT recipients requiring ICU admission in Latin American transplant centers are limited.

Methods: We conducted a retrospective observational cohort study including all hematopoietic stem cell transplant (HSCT) recipients admitted to the intensive care unit (ICU) at the Instituto Nacional de Cancerología, Mexico, between January 2009 and December 2025. Demographic data, underlying diagnosis, transplant characteristics, conditioning intensity, graft-versus-host disease, timing and indication for ICU admission, infectious complications, organ support requirements, and outcomes were collected from electronic medical records. During the study period, 1,178 HSCTs were performed, including 600 autologous and 578 allogeneic transplants. Conditioning regimens were classified as myeloablative or reduced-intensity, and transplant modality was categorized as ASCT, MRD-HSCT, or Haplo-HSCT.

Results: Twenty-four patients required ICU admission, representing a small proportion of the total transplanted population. Thirteen patients (54%) were male, and the median age was 33.5 years. Acute leukemia was the most frequent underlying diagnosis, present in 16 patients (67%). Other indications for HSCT included Hodgkin lymphoma, multiple myeloma, and myelodysplastic syndrome (each 8%), as well as non-Hodgkin lymphoma and T-cell lymphoma (each 4%).
Regarding transplant modality, five patients (21%) underwent ASCT, five (21%) MRD-HSCT, and fourteen (58%) Haplo-HSCT. MAC was used in 22 patients (92%), while RIC was administered in two patients (8%). Acute GVHD (aGVHD) occurred in 11 patients (46%), with severe disease (grade III–IV) in seven cases. Gastrointestinal involvement was the most common manifestation. Thirteen patients (54%) were admitted to the ICU within the first 100 days after transplantation.
All patients had suspected infection at the time of ICU admission. The main indications for ICU admission were respiratory failure (42%), multiorgan failure (29%), septic shock (21%), and sepsis or metabolic disturbances (8%). Seventeen patients (71%) required invasive mechanical ventilation, and 19 patients (79%) required vasopressor support.
The most frequent infectious syndromes were pneumonia (62%) and bloodstream infection

(42%). Invasive fungal infection and cytomegalovirus infection were each documented in 29% of patients, while colitis occurred in 25%. Overall ICU mortality was 70%. Bivariate analysis comparing survivors and non-survivors is presented in Table 1. Survival analysis according to transplant modality (ASCT, MRD-HSCT, and Haplo-HSCT) showed no statistically significant differences (Figure 1).

Variable	Alive (n = 7) n (%)	Dead (n = 17) n (%)	*p* value
Severe pre-transplant infection	2 (28.6)	9 (52.9)	0.386
Conditioning intensity (MAC)	5 (71.4)	17 (100)	0.076
Transplant type			0.461
ASCT	2 (28.6)	3 (17.6)	
MRD-HSCT	0 (0)	5 (29.4)	
Haplo-HSCT	5 (71.4)	9 (52.9)	
ICU admission < 100 days post-HSCT	2 (28.6)	11 (64.7)	0.182
SOFA score ≥ 8 at ICU admission	4 (57.0)	10 (59.0)	1.000
Acute GVHD (any grade)	3 (60.0)	8 (57.0)	1.000
Acute GVHD grade III–IV	5 (83.3)	4 (30.8)	1.000
Mechanical ventilation	3 (42.9)	4 (23.5)	0.374
Vasopressor support	2 (28.6)	3 (17.6)	0.608
Pneumonia	5 (71.4)	10 (58.8)	0.669
Invasive fungal infection	2 (28.6)	5 (29.4)	1.000
Bloodstream infection	3 (42.9)	7 (41.2)	1.000
CMV infection	0 (0)	7 (41.2)	0.065



Conclusions: Admission to the ICU after hematopoietic stem cell transplantation (HSCT) is a rare but high-risk event. Infections were the leading cause of admission, and mortality remained extremely high. Recipients of haplo HSCT and patients transplanted for acute leukemia predominated. These findings underscore the need to improve infection prevention, early detection of clinical deterioration, and optimize intensive care strategies to improve outcomes in this vulnerable population within contemporary transplant programs worldwide.

LONG TERM COVID-19 VACCINE EFFECTIVENESS AND ANTY-SARS-COV-2 IGG DYNAMICS IN CHILDREN AND YOUNG ADULTS AFTER ALLOGENEIC HSCT

Joanna Owoc-Lempach[1], Agnieszka Matkowska-Kocjan[1], Anna Król-Kołodziej[1], Monika Mielcarek-Siedziuk[1], Elżbieta Wawrzyniak-Dzierżek[1], Katarzyna Gul[1], Leszek Szenborn[1], Krzysztof Kałwak[1], ***Marek Ussowicz***[1]
[1]Medical University, Wrocław, Poland*

Background: Children and young adults after allogeneic haematopoietic stem cell transplantation (allo-HSCT) are at increased risk of severe COVID-19, but long-term data on vaccine effectiveness in this population are limited. We aimed to assess clinical effectiveness and 36-month humoral responses to COVID-19 vaccination, and to examine their relationship with immune reconstitution in allo-HSCT recipients.

Methods: We conducted a single-centre, retrospective observational study including 425 allo-HSCT recipients below the age of 30 who were monitored throughout the COVID-19 pandemic. COVID-19 vaccination status (CovVac+ vs CovVac−), anti–SARS-CoV-2 IgG concentrations (CovAb, BAU/mL), and SARS-CoV-2 infections (CovInf+ vs CovInf−) were recorded over 36 months. Primary endpoints were the incidence of confirmed SARS-CoV-2 infection and CovAb geometric mean concentrations (GMCs) at 6, 12, 18, 24, 30 and 36 months. Secondary endpoints included COVID-19 severity, complications and associations between CovAb levels and immune reconstitution.

Results: Overall, 187/425 patients (44%) were vaccinated (CovVac+), and 202/425 (48%) had at least one confirmed SARS-CoV-2 infection. Infection occurred in 35/187 CovVac+ versus 120/238 CovVac− patients (18.7% vs. 50.4%, p = 0.03). Vaccination was associated with a markedly lower risk of documented SARS-CoV-2 infection (OR 0.23, 95% CI 0.14–0.35). Six patients (1.4%) died from COVID-19, and four developed serious non-fatal complications. Across all timepoints, CovVac+ patients demonstrated substantially higher CovAb GMCs than CovVac− patients. A three-dose primary series yielded significantly higher GMCs at 18, 24, 30 and 36 months compared with one/two doses. In vaccinated patients, higher long-term CovAb levels were associated with older age at vaccination, a longer interval since allo-HSCT, higher baseline CD4+ and B-cell counts, and absence of regular immunoglobulin replacement therapy (in 6,24,30,36 months p=0.01, p=0.05, p=0.02, p=0.004 respectively; test Wilcoxon Rank Sum).

Conclusions: COVID-19 vaccination, particularly a three-dose primary schedule, is associated with a lower incidence of SARS-CoV-2 infection and with durable anti–SARS-CoV-2 IgG responses over 36 months. These findings support the concept of risk-adapted prevention strategies in allo-HSCT recipients.

Disclosure: Nothing to declare.

B136

RISK OF INFECTIONS AFTER CAR-T CELLS IS HIGH AND DIFFICULT-TO-PREDICT

Héctor Cruz Barquín[1], *Miriam Sánchez Escamilla*[1], *Juan Manuel Cerezo Martín*[1], *Begoña Mendibil Esquisabel*[2], *Lucía España Herreros*[1], *Leddy Patricia Vega Suárez*[1], *Guillermo Martín Sánchez*[1], *Cristina Alburquerque Prieto*[1], *María Puente Pomposo*[1], *María de las Mercedes Colorado Araujo*[1], *Carmen Montes Gaisán*[1], *Sonia González de Villambrosia*[1], *Javier Nuñez Céspedes*[1], *Jose Iñigo Romón Alonso*[1], *Enrique María Ocio San Miguel*[1,3], *Izaskun Zeberio Etxetxipia*[2], *María Aránzazu Bermúdez Rodríguez*[1,3]
[1]*U.H Marqués de Valdecilla, Hematology Department - IDIVAL, Santander, Spain,* [2]*U.H. Donostia, Hematology Department, Donostia, Spain,* [3]*University of Cantabria, Santander, Spain*

Background: Although CAR-T cell has emerged as a potent treatment for relapsed or refractory (R/R) haematological malignancies, infection is increasingly recognized as a significant cause of morbidity and mortality after the procedure.

Methods: In this retrospective multicenter study we aim to describe the characteristics of infections in patients with R/R DLBCL and MM after antiCD19 or antiBCMA CAR-T cells. We also aim to analyze possible risk factors associated with infections.

Results: We included 94 patients who received CAR-T cells from august-22 to September-25 in two CAR-T centres of Spain (H. Marqués de Valdecilla and H. Donostia). Median age at infusion was 66-yo (range 36-81) and 48% were females. Sixty-two patients had lymphomas (66%) [56 DLBCL and 6 other B cell lymphomas] and 32 MM (34%). Prior autologous HSCT was performed in 31 (33%). Median number of lines prior CAR-T was 2 (range 1-5). Eleven patients (12%) were in complete remission (CR) at infusion, 42 (45%) in partial response (PR) an 41 (43%) were in (R/R).
Fifty-three patients (56%) developed 164 episodes of infections after CAR-T. Median number of episodes per patient was 2 (0-11) for lymphoma, and 5 (0-14) for MM patients. Majority of patients had respiratory tract infections [92 episodes (56%)], urine [21 (13%)], bloodstream [19(12%)] or GI infections [17(10%].
Microbiological documentation was detected in 114 (69%) of the episodes [64 (39%) bacterial, 44 (29%) viral, 5 (3%) fungal and 1 (1%) parasite]. In lymphoma patients, bacterial was the main cause (46 episodes [53%]) and unknown origin in MM (33 [43%]). Taken isolations into account, viral origin was the main cause in the MM (22 [29%]). Most common bacterial isolations were: *E. coli* 12 (18%), *K. pneumoniae* 10 (15%) and *P. aeruginosa* 8 (12%). In the viral group, *Rhinovirus* 10 (22%), *COVID-19* 9 (20%) and *Influenza A* 7(15%). Fungi isolations mainly were oral *C. glabratra* (2 patients). Cumulative incidence of bacterial, viral and fungal infections are shown in TABLE 1.
With a median follow up of 12 months (IQR 2-21) 1-year non-relapsed-mortality (NRM) in the lymphoma and MM group was: 10% (CI95% 4-19) and 3% (CI95% 1-17). At last follow-up 21 patients (22%) died: 12 due to disease (13% of all patients) and 9 due to NRM. Among those nine, infections were attributed as main cause of NRM with 6 patients (7%) and 3 (3%) due to other causes. The 100-day infection-related mortality (IRM) was 7% (95% CI 3–15%), 8% for lymphomas and 3% for myelomas. A total of 6 patients died due to infections, causes of death were: septic shock in 4 patients (3 with gram –negative pneumonia and 1 with polymicrobial bloodstream infection from abdominal focus) and global respiratory insufficiency in 2 patients. Univariate analysis of potential risk factors did not show statistically significant differences (FIGURE 1).

TABLE 1	TOTAL			LYMPHOMA			MYELOMA		
	D30 % (CI95%)	D30-90 % (CI95%)	D>90 % (CI95%)	D30 % (CI95%)	D30-90 % (CI95%)	D>90 % (CI95%)	D30 % (CI95%)	D30-90 % (CI95%)	D>9 % (CI9

FIGURE 1. Univariate analysis of potential risk factors for infections

Variable	HR (95% CI)	p-value
Age <65 vs >65	1.5 (0.9-2.7)	0.1
Myeloma vs lymphoma	1.6 (0.9-2.9)	0.1
Response prior to CART	0.8 (0.5-11.1)	0.1
Prior lines	0.9 (0.6-1.2)	0.4
Basal EASIX	0.8 (0.4-1.7)	0.7
Basal mEASIX	1 (0.7-1.5)	0.7
D1 EASIX	1.5 (0.7-3)	0.3
D1 mEASIX	1.2 (0.6-2.3)	0.6
Basal Hipogamma <400	0.6 (0.3-1.3)	0.2
Neutropenia <500 D7	1.6 (0.8-3.1)	0.2
Lymphocyte count D10	1 (0.9-1.1)	0.8
Grade 3-4 CRS	0.8 (0.2-3.2)	0.8
Grade 3-4 ICANS	1.1 (0.5-2.3)	0.8

Values are hazard ratio (HR) with 95% confidence interval (CI).
Abbreviations: CRS, cytokine release syndrome; ICANS, immune effector cell–associated neurotoxicity syndrome; CAR-T, chimeric antigen receptor T-cell therapy.

Conclusions: In our study, infections were the most frequent cause of NRM, observing an infection-related mortality (IRM) of 7% (95% CI 3–15%). No significant risk factors or association with CAR-T toxicities (CRS/ICANS) were identified, suggesting a multifactorial and difficult-to-predict infection risk.

Disclosure: Nothing to declare.

B137

METAGENOMIC NEXT-GENERATION SEQUENCING AS A DIAGNOSTIC TOOL TO DETECT PATHOGENS IN IMMUNOCOMPROMISED PATIENTS WITH PULMONARY INFECTIONS - A SINGLE CENTER PROSPECTIVE STUDY

Anna Ruckdeschel[1], *Sophie Hoffmann*[1], *Jochen Frietsch*[1], *Hermann Einsele*[1], *Daniel Teschner*[1]
[1]*Universitätsklinikum Würzburg, Würzburg, Germany*

Background: Immunocompromised patients with hematologic malignancies, particularly recipients of allogeneic hematopoietic stem cell transplantation (allo-HSCT), are at high risk for severe pulmonary infections that significantly contribute to morbidity and mortality. Broad-spectrum anti-infective therapy is frequently initiated early, but conventional standard-of-care (SOC) microbiological diagnostics from bronchoalveolar lavage (BAL) and blood often remain negative or inconclusive, especially under ongoing prophylactic or empiric treatment. Metagenomic next-generation sequencing (mNGS) has emerged as a culture-independent diagnostic approach that may increase pathogen detection and may help differentiate between inflammation or (clinically relevant) infection in this high-risk population. The aim of this single-centre prospective study is to evaluate the additional diagnostic yield and potential clinical impact of mNGS from BAL and blood on top of comprehensive SOC diagnostics in hematologic patients with suspected pulmonary infection, with a particular focus on those after cellular therapy such as allo-HSCT.

Methods: Adult patients with hematologic malignancies, with or without prior allo-HSCT, who underwent clinically indicated BAL for suspected pulmonary infection were prospectively enrolled. SOC diagnostics from BAL comprised microscopy, culture including fungi, galactomannan, *Pneumocystis jirovecii* PCR, respiratory virus multiplex PCR and targeted mycobacterial/bacterial PCRs as well as cytology and immunophenotyping of leukocytes. SOC blood diagnostics included blood cultures (including fungi), galactomannan, beta-D-glucan and basic laboratory parameters such as procalcitonin and interleukin-6. In parallel, mNGS (DISQVER, Noscendo) was performed on BAL and blood samples to detect DNA-based bacterial, fungal and viral pathogens. Clinically relevant pathogens were adjudicated by experienced clinicians integrating clinical, radiological and laboratory findings, with careful distinction between infection and colonization.

Results: So far, BAL episodes from 20 patients (median age 54 years; 50% after allo-HSCT; 60% neutropenic; 40% treated at ICU; 100% on systemic antibiotics; 30-day mortality after BAL was 25%) were analysed. Clinically relevant pathogens were identified in 10/20 episodes. Comparing episode-based diagnostic yield, SOC negative/mNGS negative occurred in 10 cases, SOC negative/mNGS positive in 1, SOC positive/mNGS positive in 7, and SOC positive/mNGS negative in 2 episodes, indicating a modest increase in diagnostic yield through mNGS. Across BAL and blood, mNGS and SOC showed comparable detection rates for bacteria and fungi, whereas RNA viruses could only be detected by multiplex PCR, as the mNGS assay is able to detect DNA only. In 1 of 8 patients with mNGS-detected pathogens, mNGS lead to modification of anti-infective therapy (escalation to meropenem and linezolid

after detection of *Nocardia elegans* in BAL and blood), concordant with later SOC culture findings in pleural fluid.

Conclusions: In this prospective single-centre cohort of high-risk hematologic patients mNGS findings influenced anti-infective management in selected cases, underlining its potential therapeutic relevance. Careful clinical adjudication remains essential, and larger controlled studies are needed to learn more about and define the role of BAL- and blood-based mNGS-diagnostic tools in immunocompromised hosts. mNGS from BAL and blood provided plausible results with a small but clinically meaningful additive diagnostic yield.

TRANSPLANTING THROUGH UNCERTAINTY: SINGLE CENTER EXPERIENCE OF HEMATOPOIETIC STEM CELL TRANSPLANTATION IN CHILDREN WITH SEVERE APLASTIC ANEMIA AND POSSIBLE PULMONARY INVASIVE FUNGAL INFECTION

Ayad Ahmed Hussein[1], *Marah Dannoun*[1], *Bayan Majed Alaaraj*[1], *Ala' Al Qhaiwi*[1], *Dyala M. Alfryjat*[1], *Ahmed Mahmoud Rawashdeh*[1], *Tariq ahmed Abdelghani*[1]
[1]*Bone Marrow and Stem Cell Transplantation Center, Istishari Hospital, Amman, Jordan*

Background: Invasive fungal infection (IFI) represents a serious cause of morbidity and even mortality in pediatric patients undergoing hematopoietic stem cell transplantation (HSCT), particularly those with severe aplastic anemia (SAA). The presence of pulmonary infiltrates suspicious for IFI prior to HSCT poses a significant clinical dilemma. While delaying transplantation may worsen outcomes related to prolonged marrow failure and infections, proceeding with HSCT under intense immunosuppression may increase the risk of fungal progression. This challenge is further complicated in children, where invasive diagnostic procedures such as bronchoalveolar lavage or lung biopsy are often not feasible resulting in many cases being classified as "possible" IFI. Evidence guiding transplant decisions in this context remains challenging.

Methods: This is a retrospective descriptive review of medical files of children with SAA who underwent allogenic HSCT with radiologic findings suggestive of possible pulmonary IFI, at the Bone Marrow and Stem Cell Transplantation Center, Istishari Hospital, Jordan, between June 2016 and June 2025.

Results: Four patients, with a median age of 6 (1–16) years were included, one was male. All patients had persistent fever unresponsive to broad-spectrum antibiotics and suspicious pulmonary infiltrates on chest CT scan, including nodular lesions, ground-glass opacities, halo or reverse-halo signs, and subpleural consolidations. Bronchoalveolar lavage or tissue biopsy was not performed in any case due to clinical instability. Following comprehensive evaluation, all patients were initiated on dual antifungal therapy with an echinocandin and

azole according to institutional protocol. Immediately after achieving clinical stabilization and radiological response/non-progression, antifungal therapy was de-escalated to single-agent treatment, and patients proceeded to HSCT . Two patients received matched sibling donor HSCT conditioned with Cyclophosphamide (200 mg/kg) and rATG (7.5 mg/kg), while the other two underwent T-replete haploidentical HSCT with post-infusion Cyclophosphamide (100 mg/kg) and conditioning with rATG (5 mg/kg), Fludarabine (150 mg/kg), Cyclophosphamide (29 mg/kg) and 300 cGy single fraction total body irradiation. Three patients received bone marrow as stem cells source. The median CD34 cell dose was 4.9 (2.2-10.2) $\times 10^6$/kg .
Neutrophil engraftment was documented in all patients between 11 and 18 days post-HSCT. All patients showed significant clinical response after neutrophil engraftment, and none required ICU admission. All patients demonstrated complete radiological resolution of pulmonary findings, the earliest was 30 days post-HSCT. All patients received at least 3 months of therapeutic antifungal treatment post-HSCT and continued on proper secondary fungal prophylaxis. At a median follow-up of 52 (12-68) months all patients are alive, doing well and transfusion independent.

Conclusions: Our findings suggests that proceeding with HSCT in carefully selected pediatric patients with SAA and radiological evidence of possible pulmonary IFI is feasible and associated with favorable outcomes. Customized HSCT and antifungal strategies appear to be key factors in mitigating infection-related risks. Larger multicenter pediatric studies are needed to better define risk stratification and optimize management strategies in this high-risk population.

Disclosure: Nothing to declare.

B140

ACCURATE CMV IGG DETECTION USING BUCCAL SWABS IN STEM CELL DONOR SCREENING

*Paula Juan-Pardo[1], Xènia Lorente[1], **Alejandra Martinez Trillos**[2,3], Ana Albert[4], Sonia Tejedor[4], Pilar Monleon[4], Eva Alonso-Nogués[4], Felipe Macias[2,3], Nuria Mariages[2,3], Sergi Querol[2,3], Maria Angeles Marcos[1]*
[1]Microbiology Department, Centro Diagnóstico Biomédico (CDB), Hospital Clínic, Barcelona, Spain, [2]Spanish Bone Marrow Registry (REDMO), Barcelona, Spain, [3]Fundacion Josep Carreras, Barcelona, Spain, [4]Blood Bank, Banc de Sang i Teixits (BST), Barcelona, Spain

Background: Cytomegalovirus (CMV) serostatus assessment is a key component of donor evaluation for hematopoietic stem cell transplantation, as CMV mismatch increases the risk of viral reactivation and survival. Standard CMV IgG determination requires serum obtained by venipuncture, which may limit its use in rapid triage, early donor registration and selection, or large-scale screening. Buccal swab–based serology has emerged as a promising alternative for these situations; however, comparative data with validated serum assays remain limited. This study assessed the diagnostic performance, concordance and

reproducibility of buccal swab CMV IgG testing relative to serum-based serology, considered the reference standard.

Methods: Matched samples were obtained from volunteer donors, consisting of paired buccal swabs and serum specimens collected simultaneously. Buccal swab CMV IgG testing was performed using the DRG ELISA CMV IgG Buccal Swab (DRG Instruments GmbH, Marburg, Germany) and serum CMV IgG was determined using the Elecsys CMV IgG assay (Roche Diagnostics International AG, Rotkreuz, Switzerland). Buccal swabs were collected during planned mobile blood donation campaigns (BST), and after a standardized drying protocol were placed in paper envelopes to ensure safe transport. Samples were traceable and accompanied by donor's signed informed consent. Samples were processed within 24-72h (Hospital Clínic Barcelona) and serum fractions was stored at -20°C and buccal swabs at 4°C.
Diagnostic accuracy metrics included sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and overall accuracy. Agreement between methods was assessed using Cohen's Kappa coefficient. When discordant results were observed, new samples were obtained for confirmation. Reproducibility was evaluated by testing duplicated buccal swabs one and three months after initial collection. The study received approval from the CEIM: HCB/2025/0627.

Results: A total of 222 volunteer donors were included. Among paired samples, 115 had positive results in both serum and buccal swab (51.8%), and 91 were negative by both methods (41.0%). Five samples (2.3%) were positive in serum but negative in swab, considered potential false negatives. Eleven samples (5.0%) were positive in swab but negative in serum; seven corresponded to grey zone values and four were clearly positive. New samples (swabs and serum) were obtained in seven of the eleven discordant cases. Two discrepancies were resolved upon retesting, while five maintained their initial results.
The diagnostic performance metrics for CMV IgG detection using buccal swabs after repeating discordant results were as follows: sensitivity 96.8%, specificity 90.1%, PPV 92.1%, NPV 95.8%, and overall accuracy 93.7%. Cohen's Kappa was 0.873, indicating almost perfect agreement between the two methodologies.
Reproducibility analysis showed consistent results in 50/54 buccal swabs (92.6%) at one month and in 28/28 samples (100%) at three months after sample's collection.

Conclusions: Buccal swab CMV IgG detection demonstrated excellent concordance with serum-based serology with high sensitivity, specificity, and reproducibility. These findings support the use of buccal swabs as a reliable, minimally invasive alternative for CMV serostatus determination, particularly in stem cell donor screening scenarios requiring rapid or simplified logistics.

B141

LATE CYTOMEGALOVIRUS REACTIVATION AFTER ALLOGENEIC HSCT PERSISTS IN THE ERA OF LETERMOVIR PROPHYLAXIS – A SINGLE-CENTRE REAL WORLD STUDY

Louis Peters[1,2], Charlotte Brierley[1,2], Sheila Lumley[1,2], Louise Downs[1,2], Reegan Robertson[2], Wen Yuen Lim[1], Roberty Danby[1,3], Katie Jeffery[1,2], ***Kirsty Sharplin***[1,4]
[1]*Oxford University Hospitals, Oxford, United Kingdom of Great Britain and Northern Ireland (the),* [2]*University of Oxford, Oxford, United Kingdom of Great Britain and Northern Ireland (the),* [3]*Anthony Nolan Research Institute, London, United Kingdom of Great Britain and Northern Ireland (the),* [4]*NHS Blood & Transplant, Oxford, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Patients undergoing allogeneic haematopoetic stem cell transplantation (allo-HSCT) have impaired virus-specific immunity. Cytomegalovirus (CMV) reactivation, if untreated, can lead to clinically significant manifestations including colitis, pneumonitis and retinitis. Letermovir, a CMV-specific viral terminase complex inhibitor, is indicated as prophylaxis against CMV reactivation in adult CMV seropositive recipients (R+) of an allo-HSCT, and has been funded for the first 100 days post allo-HSCT by the UK National Institute for Health and Care Excellence (NICE) since 31st July 2019.

Methods: We performed a retrospective analysis of all patients who underwent allo-HSCT at a single UK centre between 1st Jan 2016 – 31st Dec 2024 and aimed to observe the relationship between letermovir administration and the occurrence of clinically significant CMV reactivation (csCMV). csCMV was defined as two consecutive positive PCR results >3log(10) in patients with a negative PCR at baseline.

Results: During the study period 480 patients underwent allo-HSCT, 192/480 (40%) pre-, and 288/480 (60%) post-letermovir introduction. The most common indications for allo-HSCT were AML (182/480; 37.9%), MDS (83/480; 17.3%) and non-Hodgkin lymphoma (59/480; 12.2%). Median age was 55 (range 18-75) and 293/480 (61%) were male. 413/480 (86%) received reduced intensity conditioning regimens, and 397/480 were T-cell deplete (Campath 226/480; 47.1%, ATG 93/480; 19.4%, PTCy 79/480; 16.5%). In the pre-letermovir cohort, 98/192 (51.0%) of patients were R+ and 37/98 (37.8%) developed csCMV. In the post-letermovir cohort, 140/288 (48.6%) patients were R+, all received letermovir prophylaxis, and 27/140 (19.3%) developed csCMV. In letermovir-ineligible CMV negative recipients (R-) receiving a CMV positive graft, 4/36 (11.1%) reactivated.
In a multivariate competing risk model to test whether T-cell depletion increased the risk of CMV reactivation (treating death without reactivation as a competing event), T depletion increased the risk of csCMV (HR 2.64, 95%CI 1.05-6.6, *p=0.03*). This remained significant after adjusting for age, sex, diagnosis and treatment era.
The median time to first reactivation pre-letermovir was 40 days (range 13-525). Post-letermovir, the median time to first reactivation was 155 days (range 26-778). Pre-letermovir, 37/98 (37.8%) at-risk patients reactivated by D100 post-allograft, compared to 2/140 (1.4%) post-letermovir (*p<0.01*). The median peak viral load did not significantly differ between groups.

33/37 (89.2%) of the pre-letermovir reactivators required treatment with an anti-viral agent, most commonly Valganciclovir; 4 patients required admission for treatment with foscarnet (2 having been pre-treated with valganciclovir). Clinically significant colitis occurred in 2 patients. 20/27 (74.1%) of the post-letermovir reactivators required treatment with an additional anti-viral agent (*p=0.52*); 3 required admission for treatment with foscarnet (2 having been pre-treated with valganciclovir). Clinically significant colitis occurred in 1 patient. No patients had clinical pneumonitis or retinitis in either group. The median duration of treatment with valganciclovir was 26 days (range 7-186) in the pre-letermovir cohort, and 30 days (range 12-54) in the post-letermovir cohort (*p=0.21*). Patients with csCMV frequently had concurrent GvHD (18/37; 48.6% in pre-letermovir cohort; 15/27; 55.6% in post-letermovir cohort) and associated immunosuppression.

Conclusions: CMV reactivation remains a frequent issue post-allo-HSCT. Letermovir defers the median onset of csCMV to post-D100, but does not reduce the need for further anti-viral treatment.

Disclosure: Nothing to declare.

IMPACT OF HUMAN PARVOVIRUS B19 INFECTION ON THE OUTCOME OF PEDIATRIC HCT FOR HEMOGLOBINOPATHIES AND OTHER HEREDITARY ANEMIAS

Stella Muscianisi[1], *Stella Boghen*[1], *Francesca Compagno*[1], *Jennifer Zumelli*[1], *Marica De Cicco*[1], *Oriana Montana Lampo*[1], *Eleonora Bozza*[1], *Carolina Gabetta*[1], *Santina Recupero*[1], *Alessandra Tolva*[1], *Elena Bergami*[1], *Eliana Barbato*[1], *Irene Cassaniti*[1,2], *Stefania Paolucci*[1], *Fausto Baldanti*[1,2], *Patrizia Comoli*[1], *Marco Zecca*[1]
[1]*Fondazione IRCCS Policlinico San Matteo, Pavia, Italy,* [2]*University of Pavia, Pavia, Italy*

Background: Hematopoietic cell transplantation (HCT) exposes the recipient to a high risk of viral reactivations especially during the first weeks after transplant. Human Parvovirus B19 (B19V) is a common DNA virus with tropism forerythroid progenitors, but also for megakaryocytes and endothelium. Infection in immunocompetent individuals is mostly asymptomatic, but in immunocompromised hosts it may cause hematological disorders including anemia and aplastic crisis. B19V disease is a rare complication after HCT, however, the virus has been described to persist after primary infection, raising questions on its clinical impact on the outcome of HCT. Therefore, we evaluated B19V infection before and longitudinally after allogeneic pediatric HCT for hemoglobinopathies and other congenital anemias.

Methods: Thirty-nine pediatric subjects given HCT from a matched family donor (MFD, 18%), a matched unrelated donor (MUD, 77%) or a partially matched family donor (PMFD, 5%) for hereditary anemias between 2019 and 2025 were evaluated for B19V serology, the presence of viral DNA on bone marrow precursors before transplantation, and on peripheral blood samples collected in the first year after HCT. Donor serology was also evaluated.

Results: Seropositivity for B19V was observed in 13 of 39 patients (33%) and in 28 of 39 donors (72%), respectively. We identified 7 out of 39 patients (18%) with B19V DNA in the bone marrow before transplantation, and 17 of 39 (43%) recipients were found to be positive for blood B19V DNA in the first year post transplantation. B19V infection/reactivation onset was generally observed within the first 3 months after transplantation. The peak viral load was a median of 315 cp/mL (range 1– 46362 cp/mL). Viral loads >100 cp/mL were observed in 11 patients (28%), with a median value of 630 cp/mL. Transmission from the donor was not a common event, as only in 4/17 cases seronegative recipients with negative viral load on pretransplant BM received HSCs from B19V-positive donors. The occurrence of B19V infection, considered as a categorical variable, did not affect transplant outcome, in particular neutrophil and platelet engraftment, acute and chronic GvHD, rejection, OS, EFS and TRM. However, two patients with high posttransplant load (7353 and 26389 cp/ml) developed B19V-related complications, such as severe anemia and rejection, respectively.

Conclusions: We observed an increased incidence of B19V infection in our pediatric population, that may be due to both longitudinal post-HCT monitoring and the recent B19V outbreak in the years 2023-2024. However, this occurrence did not result in an increased incidence of virus-related disease, and symptomatic B19V infection following HCT remains a rare, though potentially challenging, complication. Based on the results obtained, B19V infection/reactivation does not seem to have an impact on HCT outcomes. Therefore, routine viral monitoring may not give added benefit in the pediatric HCT setting. However, in selected populations, such as hereditary anemia patients transplanted with an alternative donor, early monitoring may identify HCT recipients at risk of B19V-related disease, that may benefit from IVIG therapy.

Clinical Trial Registry: Not applicable.

COMPARATIVE STUDY OF RESPIRATORY SYNCYTIAL VIRUS BURDEN AND TREATMENT POLICIES IN HAEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS

Justin du Toit[1], *Marco Goeijenbier*[1], *Jurjen Versluis*[2]
[1]*University of the Witwatersrand, Johannesburg, South Africa,* [2]*Spaarne Gasthuis, Haarlem, Netherlands (the),* [3]*Erasmus Medical Centre, Rotterdam, Netherlands (the)*

Background: Respiratory syncytial virus (RSV) is a significant cause of morbidity in haematopoietic cell transplant (HCT) recipients, yet comparative data from diverse international settings remain scarce. We evaluated RSV incidence, clinical characteristics, management practices, and outcomes across three HCT centres in South Africa and the Netherlands.

Methods: This retrospective multicentre cohort included adults (≥18 years) with PCR-confirmed RSV infection following HCT between January 2015 and December 2024. Incidence was calculated as a proportion of all transplants and per 100 person-years. Demographic and clinical characteristics, treatment strategies, and outcomes were assessed. Centre roles were considered: Erasmus MC and Wits Donald Gordon Medical Centre (WDG) function as full transplant centres, whereas Spaarne Gasthuis serves as a referral centre for early post-HCT follow-up.

Results: Among 1,189 transplants, 82 RSV infections were identified (65 Erasmus MC; 9 Spaarne; 8 WDG). Centre-level rates ranged from 4.2–7.7%, corresponding to 1.2–1.5 cases per 100 person-years; these reflect overall centre populations rather than true transplant-type specific incidence. Most infections (65%) occurred within 15 months post-HCT, peaking between 0–9 months. Co-infections were documented in 16–33%. Treatment practices varied, with ribavirin ± IVIG used exclusively at Erasmus MC (51% of cases). Hospitalisation occurred in 25–56% of patients, ICU admission in 3–22%, and in-hospital mortality remained low (3–13%) across all centres.

Conclusions: RSV infection was infrequent and associated with relatively low morbidity and mortality across geographically and economically diverse HCT centres. Universal pre-transplant RSV prophylaxis appears unnecessary; however, targeted preventive strategies may benefit patients at highest risk. These findings provide a contemporary benchmark for developing harmonised RSV management pathways in HCT recipients.

HOW DO DEFINITIONS FOR NOSOCOMIAL INVASIVE ASPERGILLOSIS PERFORM IN HEMATOPOIETIC CELL TRANSPLANT RECIPIENTS?

Paulina Vega[1,2], *Seth Cohen*[2], *David N. Fredricks*[1,2], *Amanda Phipps*[1,2], *Marie Wilson*[1], *Catherine Liu*[1,2], *Denise J. McCulloch*[1,2], *Steven A. Pergam*[1,2]
[1]*Fred Hutchinson Cancer Center, Seattle, United States of America (the),* [2]*University of Washington, Seattle, United States of America (the)*

Background: Invasive aspergillosis (IA) is the most common invasive fungal infection in hematopoietic cell transplant (HCT) recipients. However, there are no standardized definitions for nosocomial invasive aspergillosis (nIA) to guide when to conduct comprehensive infection prevention (IP) investigations in this population, which may include costly engineering assessments and mitigation measures.

Methods: We conducted a retrospective review of HCT recipients diagnosed with IA at our center between 3/2021-6/2025. IA cases were defined using consensus guidelines; galactomannan (GM) enzyme immunoassays were considered positive if confirmed levels were ≥0.5. We collected demographic and clinical data including oncologic and transplant history, fungal diagnostics, and mortality outcomes at 30 and 90 days. Incident IA was defined by the date of first positive mycologic test for *Aspergillus* spp. For primary analyses,

we applied a conservative, admission-based definition of nIA, defined as IA diagnosed > 14 days after hospital admission. Cases diagnosed ≤14 days after admission were classified as community-acquired IA (cIA). This definition was used to compare baseline characteristics, clinical outcomes and GM values between groups. For secondary analyses we applied additional proposed definitions, including the Centers for Disease Control and Prevention (CDC) definition for possible nIA (>7 days post-admission) and another expanded definition classifying probable nIA if diagnosed >14 days after admission or if discharged from the hospital within 14 days prior to the current admission. These alternative definitions were used to estimate the proportion of IA cases that would meet criteria for IP investigation.

Results: A total of 40 HCT recipients with IA were included; 22 (55%) were diagnosed ≤14 days after hospital admission and 18 (45%) were diagnosed >14 days post-admission. Baseline characteristics were similar between nIA and cIA cases, except for the median time from HCT to IA diagnosis for cIA cases was longer (255 days; IQR [interquartile range]: 53-879) compared with nIA cases (20 days; IQR: 14-39; p<0.001; Table 1). The median time from admission to diagnosis was 27 days (IQR: 20-34) in the nIA group. While there were no significant differences in serum GM between the 2 groups (p = 0.11), bronchoalveolar lavage fluid (BALf) GM values were significantly higher in the nIA group (p = 0.024; Figure 2A). All-cause mortality at day 30 was 32% for cIA and 28% for nIA cases, and mortality at day 90 was 36% and 44%, respectively. When applying the expanded 14-day plus recent hospitalization definition, 28 cases (70%) were classified as probable nIA whereas the CDC definition classified 21 (53%) as possible nIA(Figure 2B).

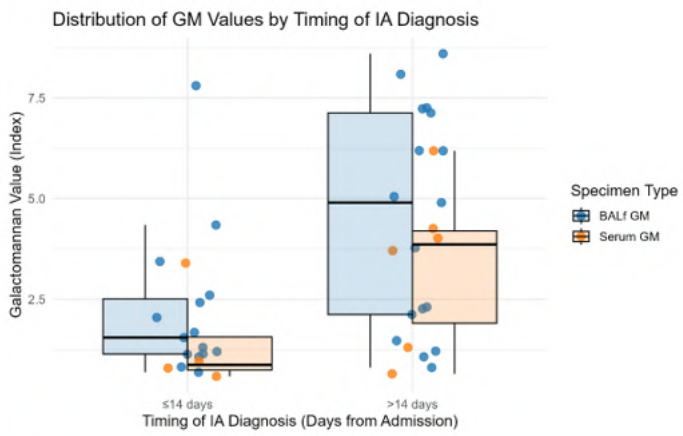
Table 1. Baseline Characteristics by timing of IA diagnosis

Characteristic	**≤14 days** N = 22[1]	**>14 days** N = 18[1]	**p-value**[2]
Age (years)			
Median [Q1, Q3]	57 [50, 67]	58 [45, 66]	
Time from hospital admission to IA (days)			<0.001
Median [Q1, Q3]	4 [1, 6]	27 [20, 34]	
Time from HSCT to IA (days)			<0.001
Median [Q1, Q3]	255 [53, 879]	20 [14, 39]	
History of GVHD	12 (55%)	5 (28%)	
Steroid receipt in prior 90 days	8 (38%)	5 (28%)	
Neutropenia at diagnosis	13 (59%)	11 (61%)	
Neutropenia duration (days)			0.804

Characteristic	**≤14 days** N = 22[1]	**>14 days** N = 18[1]	**p-value**[2]
Median [Q1, Q3]	31 [5, 49]	22 [15, 40]	
Antifungal prophylaxis	18 (82%)	18 (100%)	
Fluconazole	10 (45%)	10 (56%)	
Posaconazole	3 (14%)	4 (22%)	
Isavuconazole	4 (18%)	1 (5.6%)	
Voriconazole	1 (4.5%)	3 (17%)	
Antifungal ppx duration (days)			0.476
Median [Q1, Q3]	32 [15, 61]	24 [19, 30]	

[1]n (%) [2]Wilcoxon rank sum test

Figure 1A.



1B.

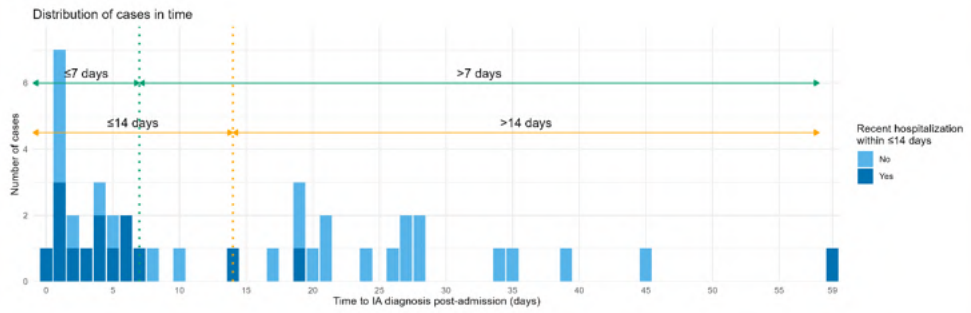


Figure 1A. Shows BAL and serum GM values by diagnosis ≤14 vs >14 days after admission. Figure 1B shows time to IA diagnosis, with markers indicating 7- and 14-day thresholds and recent hospitalization status.

Conclusions: In this HCT cohort, the application of proposed nIA definitions classified 50-70% of IA cases as nosocomial. Cases classified as nIA (>14 days after admission) were diagnosed earlier post-transplant and had higher BALf GM at diagnosis when compared to cIA cases. Given the prolonged and complex hospital courses of HCT recipients, current guidelines for costly and often unrevealing IP investigations may be overly sensitive in this population. Clinically-based nIA definitions that incorporate host risk factors and degree of immunosuppression are needed.

Background: Bacterial infections during neutropenia remain a major cause of morbidity in allogeneic hematopoietic cell transplantation (allo-HCT) recipients. Several international guidelines address antibacterial prophylaxis in this setting; however, most recommendations are conditional, intended for selected high-risk patients, and supported by low-quality evidence, particularly regarding survival outcomes. Evidence demonstrating a reduction in mortality is lacking, and thus routine prophylaxis remains controversial in the context of rising antibiotics resistance and microbiota disturbance associated risks. Thus, management strategies for antibacterial prophylaxis and first-line treatment of febrile neutropenia (FN) vary considerably between centers. To better understand current Canadian practice, we conducted a pan-Canadian survey of adult allo-HCT programs.

Methods: A cross-sectional electronic survey was distributed to Canadian allo-HCT centers in October 2025. The questionnaire consisted of eleven items and assessed center characteristics and province, transplant volume, use of routine antibacterial prophylaxis, antimicrobial selection, duration, and first-line empirical therapy for FN, as well as monitoring of resistant bacteria colonization. Data were analyzed descriptively.

Results: The eleven Canadian centers performing adult alloHCT responded. Provincial distribution included British Columbia (n=1), Alberta (n=1), Saskatchewan (n=1), Manitoba (n=1), Ontario (n=3), Quebec (n=3), and Nova Scotia (n=1). Most were adult-only programs (n=10); one treated both adults and pediatric patients. Annual alloHCT volume was 20–50 procedures in four centers, 51–100 in two, and >100 in five.
Routine prophylaxis was reported by six centers (54.5%), while five centers (45.5%) reported no prophylaxis. Among centers using prophylaxis, three administered it to all patients, one restricted it to non-myeloablative outpatient procedures, one exclusively to cord blood transplant recipients, and one to patients with sickle-cell hemoglobinopathy.

Fluoroquinolones were the most used prophylactic agents (n=5), followed by cephalosporins (n=1), with duration typically maintained until neutrophil engraftment. No center modified prophylaxis based on conditioning regimen or haploidentical transplant. Overall, 72.7% (8/11) of centers reported no routine antibacterial prophylaxis for most patients. Piperacillin–tazobactam was the most frequently used empirical therapy across centers (n=10); while one center used cefepime. Initial antimicrobial regimens were not stratified according to conditioning intensity (myeloablative vs. non-myeloablative) or donor type (including haploidentical transplants).
Routine multidrug-resistant organism surveillance cultures were performed in six centers; one center obtained them only at admission to the transplant unit, while four centers reported no routine surveillance.

Conclusions: Considerable heterogeneity exists in antibacterial prophylaxis strategies across Canadian allo-HCT programs, with the majority opting against routine universal prophylaxis. Empirical management of FN was largely uniform, with piperacillin–tazobactam as the preferred agent. Importantly, while antibacterial prophylaxis may reduce early infectious complications, potential harms—including antimicrobial resistance, *Clostridioides difficile* infection, and disruption of the gut microbiome—must be weighed against uncertain benefits on survival outcomes. These findings support the need for evidence-informed, standardized guidance to optimize risk-adapted infection prevention strategies in allo-HCT recipients.

MANAGEMENT OF PROTRACTED CLOSTRIDIOIDES DIFFICILE INFECTION IN CHILDREN WITH GI-GVHD AFTER ALLOGENEIC HSCT: A SINGLE-CENTER PEDIATRIC EXPERIENCE

Jaroslava Adamčáková[1], *Mária Füssiová*[1], *Dominika Dóczyová*[1], *Janette Čemická*[2], *Tomáš Sýkora*[1], *Júlia Horáková*[1], *Ivana Boďová*[1], *Miroslava Pozdechová*[1], *Veronika Dobšinská*[1], *Peter Švec*[1], *Alexandra Kolenová*[1]
[1]*National Institute of Children's Diseases, Bratislava, Slovakia,* [2]*Institute of Predictive and Personalized Medicine, Tovarníky (Topoľčany), Slovakia*

Background: Clostridioides difficile infection (CDI) occurs in approximately 8–15% of children after allogeneic hematopoietic stem cell transplantation (allo-HSCT). Major risk factors include gastrointestinal graft-versus-host disease (GI-GvHD), mucosal injury, immunosuppression, and broad-spectrum antibiotic exposure. CDI is often severe in this population, with recurrence rates of 15–20%. According to ECIL-10 recommendations, bezlotoxumab and fecal microbiota transplantation (FMT) may be considered in recurrent CDI after vancomycin or fidaxomicin therapy in high-risk patients.

Methods: We report three immunosuppressed pediatric patients after allo-HSCT with severe GI-GvHD and transplant-associated thrombotic microangiopathy (TA-TMA), illustrating a complex, individualized management of protracted and severe CDI. Therapeutic strategies included antibiotic therapy, bezlotoxumab, FMT, and support of intestinal mucosal regeneration with teduglutide.

Results: **Case 1:** An 18-year-old boy after matched sibling donor HSCT for Ph+ B-ALL developed grade IV acute GI-GvHD from day +37. Persistent CDI was documented from day +55 despite intensive immunosuppression (cyclosporine A, corticosteroids, ruxolitinib, mesenchymal stromal cells, extracorporeal photopheresis, vedolizumab). Fidaxomicin was ineffective, with recurrent pseudomembranous colitis. Long-term oral vancomycin and two doses of bezlotoxumab were administered. Three FMTs via enema and four additional FMTs via PEJ were performed. TA-TMA was confirmed and treated with ravulizumab. CDI resolved after repeated FMTs; however, long-term gastrointestinal dysfunction persisted, with progression to moderate chronic GI-GvHD.
Case 2: A 2-year-old boy with alphamannosidosis after mismatched unrelated donor HSCT developed grade IV acute GI-GvHD and TA-TMA. CDI persisted despite fidaxomicin, vancomycin, metronidazole, and two doses of bezlotoxumab, with recurrent pseudomembranous colitis and paralytic ileus. The course was complicated by *Pseudomonas aeruginosa* sepsis and prolonged intestinal failure. Teduglutide enabled enteral nutrition. Four FMTs via enema resulted in rapid CDI eradication after the first FMT, with sustained remission.
Case 3: A 17-year-old boy with CML after mismatched unrelated donor HSCT (PBSC, HLA 9/10) developed grade IV acute GI-GvHD. Severe CDI occurred on day +32 and was treated with fidaxomicin and intravenous metronidazole. Two FMTs led to CDI eradication. A single relapse occurred during concomitant Escherichia coli sepsis and was successfully treated with oral vancomycin. Bezlotoxumab was administered, with no further CDI recurrence.

Conclusions: Management of CDI after allo-HSCT requires a comprehensive and highly individualized approach, as CDI frequently coexists with GI-GvHD and TA-TMA. CDI may exacerbate GI-GvHD, while immunosuppression increases infection severity. Protracted CDI can lead to long-lasting intestinal dysfunction requiring supportive interventions, including teduglutide. Careful antibiotic selection is essential: microbiota-sparing agents should be preferred for CDI whenever possible, while broad-spectrum antibiotics are often unavoidable in sepsis. FMT represents a promising option even in HSCT recipients (reported success rates 78–86%) but carries a risk of severe complications, including sepsis (up to 9%). Bezlotoxumab appears safe; however, according to ECIL-10 recommendations, its efficacy in pediatric patients remains limited.

Disclosure: Nothing to declare

B147

MICAFUNGIN AS ANTIFUNGAL PROPHYLAXIS DURING THE PRE-ENGRAFTMENT PERIOD OF ALLO-HSCT. ANALYSIS OF A 450-PATIENT COHORT

Bernardo Soto Román[1], *Blanca García Mezo*[1], *Laura Contreras Rujas*[1], *Guillermo Morán Cortés*[1], *Ainhoa Gutiérrez*[1], *María Auxiliadora Semiglia*[1], *Adrián Alegre Amor*[1], *Beatriz Aguado Bueno*[1]
[1]*La Princesa University Hospital, Madrid, Spain*

Background: Allogeneic hematopoietic stem cell transplant (allo-HSCT) recipients are at high risk of invasive fungal infections (IFI) during the pre-engraftment period. Although azoles are widely used, hepatotoxicity and drug-drug interactions may limit their applicability. Micafungin, a once-daily echinocandin with excellent tolerability, has demonstrated efficacy comparable to azoles; however, real-world evidence in large cohorts remains limited.

Methods: We conducted a single-center, retrospective study including all adult allo-HSCT recipients between January 2010 and June 2025 who received systematic primary antifungal prophylaxis with micafungin from day 0 (50 mg/day) throughout the pre-engraftment period until neutrophil recovery. Baseline characteristics (*Table 1*), duration of prophylaxis, breakthrough IFI, toxicity, and need for antifungal escalation were recorded. Primary endpoints were proven IFI incidence, IFI-free survival, and IFI-related mortality. Descriptive analyses were performed with SPSS® v16.0.

Results: **Table 1: *"Baseline characteristics of patients undergoing allo-HSCT receiving micafungin prophylaxis"*; n = 450**

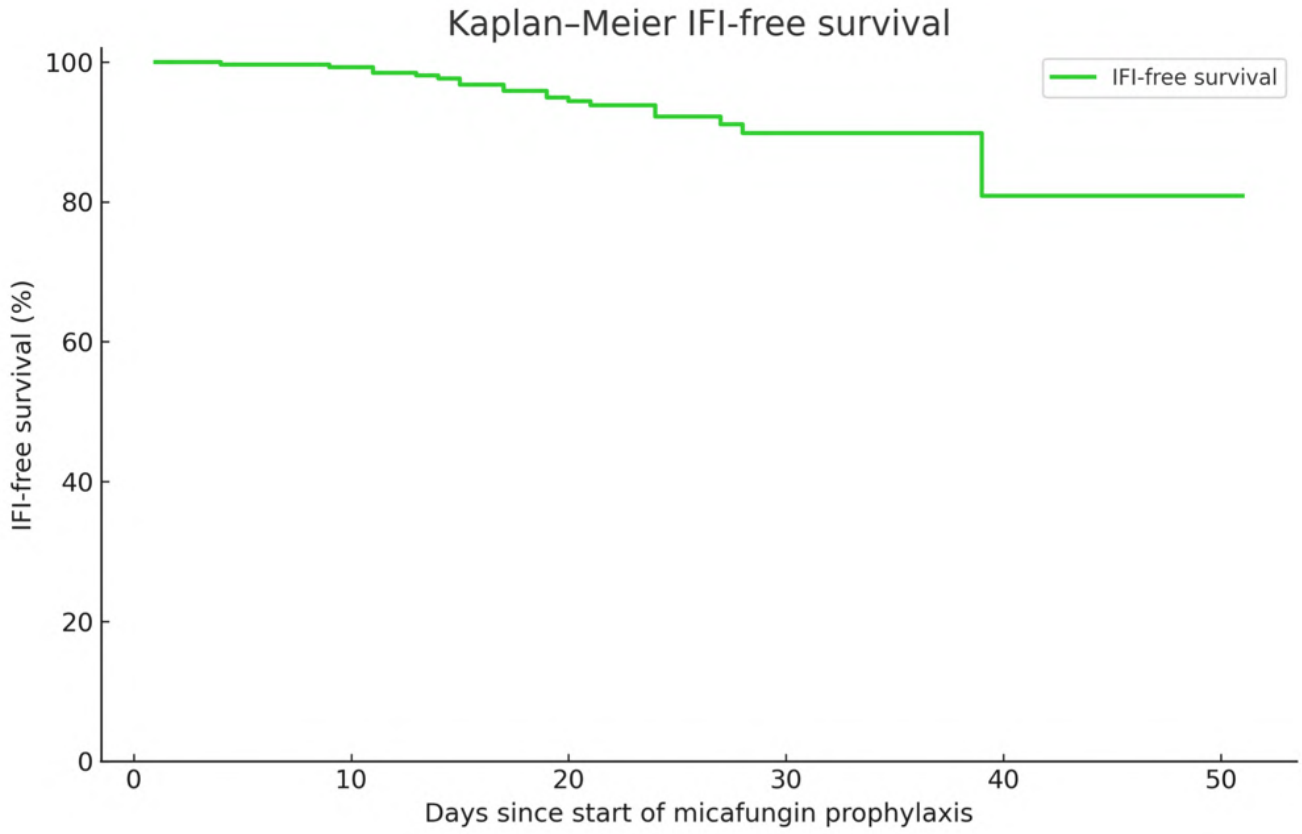
Sex (M/F)	245 (54.4%) / 205 (45.6%)

Median age at HSCT	50 years (range 19 – 73)
Underlying disease	AML 44.9%; ALL 10.9%; MDS 20.2%; Lymphomas 11.6%; aplastic anemia 3.3%; others 9.1%
Donor type	Unrelated 50.7%; Related 47.1%; Haploidentical 2%
Stem cell source	Peripheral blood: 96.9%; Bone marrow: 3.1%
Conditioning regimen	MAC 32.9%; RIC 66.2%; Sequential 0.9%
GVHD prophylaxis	Cs+MTX 45.69%; Cs/MF/CF post 19.2%; Cs/CF post 16.5%; Cs alone 7.2%; ATG: 1.3% Others 10.11%

HSCT: Hematopoietic stem cell transplantation; AML: Acute myeloid leukemia; ALL: Acute lymphoblastic leukemia; MDS: Myelodysplastic síndrome; GVHD: Graft-versus-host disease; MAC: Myeloablative conditioning; RIC: Reduced-intensity conditioning; Cs: Cyclosporine; MTX: Methotrexate; MF: Mycophenolate mofetil; CF post: Post-transplant cyclophosphamide; ATG: Antithymocyte globulin.

A total of 450 patients were included. Median duration of micafungin prophylaxis was 21 days (range 1–51). Micafungin was maintained throughout the pre-engraftment period in 75.2% of patients; 24.8% required a switch, mainly due to proven or possible IFI (16.1%) or liver function abnormalities (8.7%).
The incidence of proven IFI was 4.2% (19/450). Most infections were caused by yeasts (84.2%), predominantly *Candida spp* (73.7%). Among the 14 patients with *Candida* isolation, 8 (57.1%) had positive cultures from central venous catheter blood samples; all were receiving parenteral nutrition and required intensive care support at diagnosis. Two azole-resistant and one anidulafungin-resistant *Candida* isolates were detected. Filamentous fungi accounted for 15.8% of cases: *Aspergillus spp* (2/19) and multiresistant *Acremonium sclerotigenum* (1/19), isolated from bronchoaspirate (BAS) or central line blood cultures; all showed positive galactomannan (AGA) screening. Additionally, 12 patients (2.7%) were managed as possible IFI due to positive AGA results without microbiological confirmation. Empirical antifungal escalation was required in 43 patients (9.6%) due to pulmonary infiltrates or clinical deterioration with negative AGA tests. Among patients with proven or possible IFI (n=34), 26.5% had received corticosteroids during the pre-engraftment period. Antifungal treatments were heterogeneous: liposomal amphotericin B (37.9%), isavuconazole (24.1%), and double-agent combinations (24.1%), mainly in critically ill patients with severe pneumonia or intensive care needs.
IFI was the primary cause of death in 3 of 19 patients (15.8%). IFI-free survival at day +21 was 93.8% *(Figure 1).*

Figure 1*: "Invasive fungal infection–free survival"*



Conclusions: In this large real-world cohort, micafungin prophylaxis during the pre-engraftment period of allo-HSCT was associated with a low incidence of proven IFI, IFI-free survival above 90% during the first post-transplant month, and a highly favorable safety profile. Proven *Candida* infections were closely linked to critical illness, severe mucositis and parenteral nutrition. Overall, in our experience, micafungin is an effective and safe antifungal prophylactic strategy in allo-HSCT recipients.

Disclosure: Nothing to declare.

B148

SEROPREVALENCE OF HBV IN UNRELATED DONORS AT CONFIRMATORY TYPING STAGE AND ITS IMPACT ON THE CHOICE OF HEMATOPOIETIC CELL DONOR – DATA OF DKMS POLAND

Przemyslaw Szymanski[1], *Grzegorz Hensler*[1], *Patrycja Uchal*[1], *Anna Jarnicka*[1], *Aleksandra Nowak*[1], *Tigran Torosian*[1]
[1]*DKMS Poland, Warsaw, Poland*

Background: Hepatitis B virus (HBV) infection has a significant impact on hematopoietic cell (HPC) donation safety, and therefore post-exposure serological status may influence donor choice due to the risk of occult hepatitis B infection.

Methods: We retrospectively analyzed 26542 unrelated HPC donors within DKMS Poland Donor Center at confirmatory typing (CT) stage between 2020 and 2024. Donor blood samples were tested for anti-HBc antibodies and HBs antigen (HBsAg). Donors were stratified by age groups to assess the frequency of positive anti-HBc and positive HBsAg in Polish unrelated donors (UD) requested for CT. In addition, the number of donors with positive anti-HBc antibodies at Work-Up stage was analysed to check whether the presence of these antibodies affects the probability of positive selection of this group for HPC donation. Transplant centres always received CT infectious disease markers, with a proactive communication in case of serological signs of past HBV infection.

Results:

Age group	AntiHBc (-)	AntiHBc (+)	Prevalence	HBSAg (+)	Total
18-25	10482	39	0,37%	5	10521
26-30	5970	62	1,03%	7	6033
31-35	4145	96	2,26%	5	4242
36-40	2957	100	3,27%	4	3057
41-60	2553	136	5,06%	6	2689
Total	26107	433	1,63%	27	26542

Among 26542 donors analyzed, 433 (1,63%) were positive for anti-HBc, indicating past HBV exposure. Positive HBsAg with accompanying anti-HBc indicating active, acute or chronic, HBV infection was positive in 27 donors (0,10%). As for the seroprevalence of anti-HBc, the older the age group, the higher was the percentage of anti-HBc-positive donors, with statistically significant differences ($p < 0,05$). The age group between 18-25 years old had the lowest (0,37%), while the 41-60 y.o. donors had the highest (5,06%) anti-HBc prevalence. Proportion of HBsAg-positive blood samples seemed to be similar in all age groups and no statistical correlation was found ($p > 0,05$). A comparison of the proportion of anti-HBc–seropositive donors at the CT and Work-Up stages demonstrated a statistically significant difference ($p < 0.05$), with rates of 1.40% and 1.07%, respectively. Overall 98 donors were selected for HPC collection, despite the seropositivity (anti-HBc (+), HBsAg (-)),

with negative HBV NAT at physical examination. None of the transplant centers informed DKMS Poland of possible HBV transmission.

Conclusions:

- Presence of anti-HBc suggesting past HBV exposure is important for donor selection and recipient safety due to the risk of chronic occult hepatitis B and donor-recipient viral transmission. This may influence donor choice.
- In Poland, universal HBV vaccination was introduced in 1996, which influences seroprevalence patterns among donors of different age groups. Our findings confirm that past HBV infection markers are more prevalent among older donors, which probably reflects pre-vaccination era exposure.
- In all age groups there was similar proportion of HBs-Ag positive donors. These results underscore the importance of comprehensive HBV screening during CT to ensure transplant safety and inform donor selection policies.
- The results show that donors with past HBV infection, albeit somewhat less frequently, are selected for HPC donation with no reported cases of transmitted HBV infection among patients who received HPC form the analyzed group of donors.
- WMDA Donor Suitability recommendations regarding past HBV infection state that anti-HBc(+), HBsAg(-) donors can be accepted at the discretion of transplant centers, with the recommended anti-HBs level ≥100 IU/l.

Disclosure: Nothing to declare.

B149

EPIDEMIOLOGY OF CATHETER-RELATED BLOODSTREAM INFECTIONS IN STEM CELL TRANSPLANTATION

*Elba Vélez Blanco[1], Irene Fernández Bardón[1], **Juan Manuel Cerezo Martín**[1], Irene Gorostidi Álvarez[1], Jose Antonio Flores García[1], María Terán Díaz[1], Olga Zamanillo Algorri[1], Patricia Retuerta Agudo[1], Esther López Ramos[1], Enrique María Ocio San Miguel[1,2], María Aranzazu Bermúdez Rodríguez[1,2], Lucrecia Yañez San Segundo[1,2]*
[1]Hospital Universitario Marqués de Valdecilla, Santander, Spain, [2]University of Cantabria, Santander, Spain

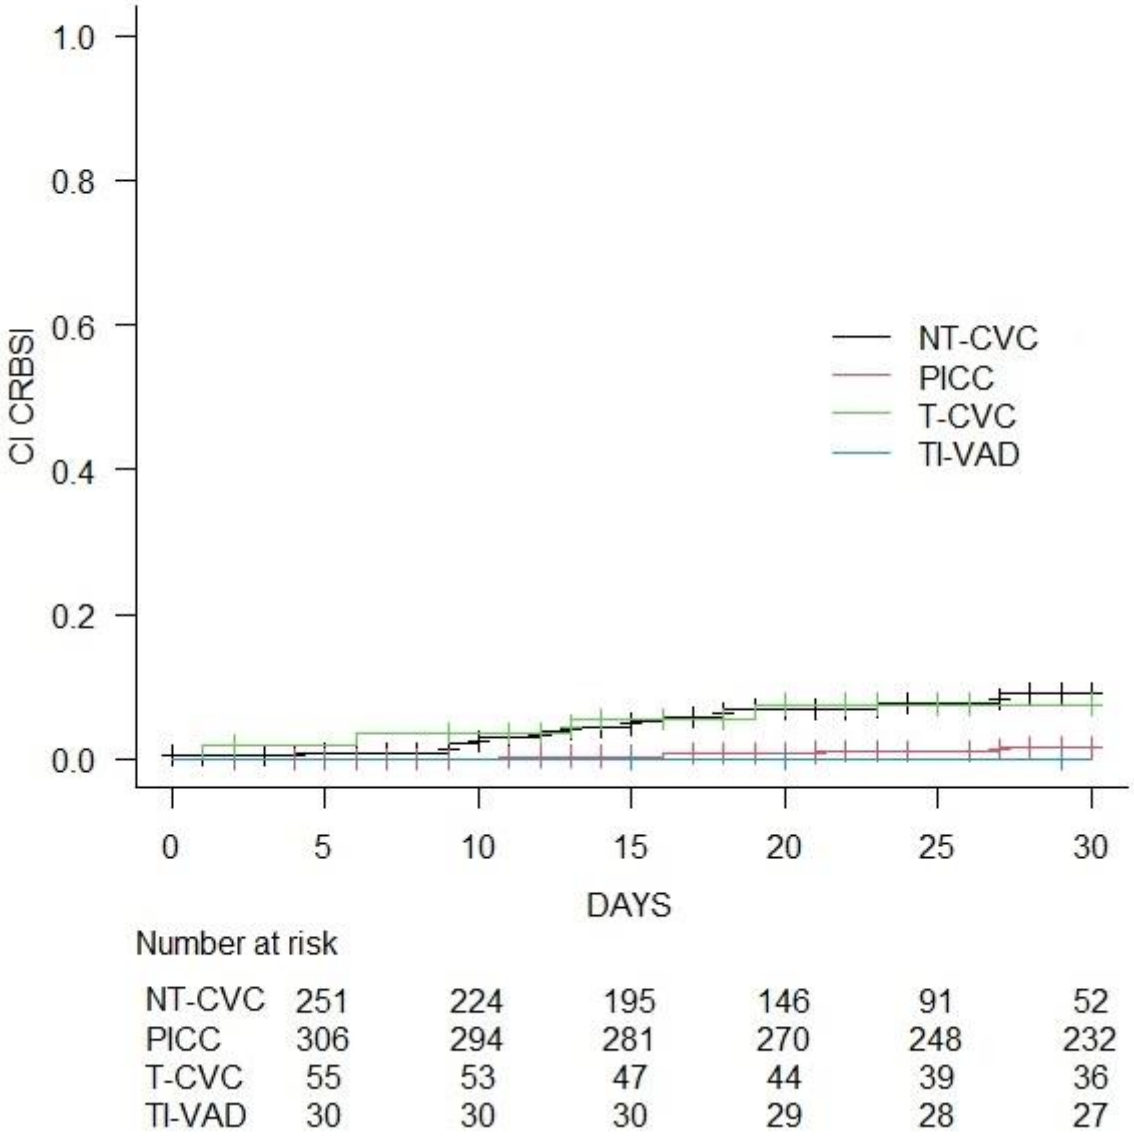
Background: The use of a central venous catheter (CVC) is essential for patients undergoing an allogeneic hematopoietic stem cell transplant (SCT) but it comes with a higher risk for catheter-related bloodstream infections (CRBSI). Updated data is limited in this context.
The aim of this study was to identify the incidence of CRBSI, the causative agents, and describe risk factors for its development in SCT.

Methods: This was a single-center, retrospective, observational study on all SCT consecutively performed in our center between 2015 and 2024. Type (PICC: peripherally inserted central catheter, NT-CVC: non-tunneled central venous catheter, T-CVC: tunneled central venous catheter and TI-VAD: totally implanted venous access device) and number of catheters were collected both at the time of transplantation and afterwards. CRBSI was

defined as definite CRBSI according to the EBMT Infectious Diseases Working Party and PHG Committee criteria (EBMT, *Clin Microbiol Infect*. 2025), which adopt the microbiological definitions of the IDSA 2009 guidelines. Only definite CRBSI episodes were included in the analysis.

Results: We included 432 patients. The median age was 56 years (2-82) and 62.3% were male. The most frequent underlying diseases were AML (37%), MDS (13%) and ALL (12%) and HCT-CI was ≥3 in 48% of patients. Myeloablative conditioning was used in 51.6% patients, the most common donor was HLA matched unrelated 10/10 (53%) and the main stem source was the peripheral blood (59%). Most common GVHD prophylaxis was CNI+MTX/MMF in 43% of patients and PTCy+CNI+MMF in 33% of them.
A total of 694 catheters were collected. PICC was the leading option (45%) followed by jugular CVC (27%), subclavian CVC (8%), T-CVC (8%), TI-VAD (6%) and femoral CVC (4%). The main reasons for withdrawal were end of treatment (62%) and persistent fever (10%).
We identified a total of 47 definite CRBSI. The most frequent agents were Gram-positive cocci (61%), Gram-negative bacilli (33%) and others (6%). Twenty-six (55%) were caused by *Staphylococcus coagulase-negative*, 3 by *Enterobacter spp* (6%), 3 were caused by *E. coli* (6%), 1 by *S. aureus* (2%), and 1 by *P. aeruginosa* (2%). One patient died due to CRBSI.
The cumulative incidence of CRBSI at 7, 15 and 30 days since catheter insertion were 1% (95% CI 0-2), 2.4% (95% CI 1-5) and 4.7% (95% CI 3-7). CI at days 7, 15, and 30 for PICC was 0 / 0.3% / 1.5%, for NT-CVC 0.8% / 4.3% / 8.9%, for T-CVC 3.5% / 5.4% / 7.5%, and no CRBSI was observed at day 30 for TI-VAD ($p<0.01$). (Figure 1).
Among the different risk factors for CRBSI, age > 65 years HR 1.4 (1.1-1.9) $p=0.04$ and type of catheter HR 1.2 (1.1-1.4) $p<0.01$ showed statistical significance in the multivariable

analysis.



Conclusions: CRBSI remains a significant complication in SCT. PICC and TI-VAD appear to be the safest options, and its choice should be considered above other types of intravascular devices.

REAL-WORLD UTILIZATION AND EFFICACY OF BIOEQUIVALENT GENERIC LETERMOVIR PROPHYLAXIS IN ALLOGENEIC HSCT RECIPIENTS: PEDIATRIC SUBGROUP ANALYSIS FROM DEFENDER STUDY

Santanu Sen[1], *Gaurav Kharya*[2], *Rajat Bhattacharyya*[3], *Kasi Viswanathan*[4], *Sameer Ramesh Melinkeri*[5], *Chintan Vyas*[6], *Nataraj KS*[7], *Vaibhav Chadha*[2], *Garima Nirmal*[2], *Anusree Prabhakaran*[5], *Suyash Bharat*[8]
[1]*Kokilaben Dhirubhai Ambani Hospital and Medical Research Institute, Mumbai, India,* [2]*Indraprastha Apollo Hospital, New Delhi, India,* [3]*Apollo Multispeciality Hospital, Kolkata, India,* [4]*Meenakshi Mission Hospital & Research Centre, Madurai, India,* [5]*Deenanath Mangeshkar Hospital & Research Center, Pune, India,* [6]*Narayana Health SRCC Children's Hospital, Mumbai, India,* [7]*HCG Cancer Centre, Bangalore, India,* [8]*Zydus Lifesciences Ltd, Ahmedabad, India*

Background: Prior to introduction of Letermovir prophylaxis, Cytomegalovirus (CMV) reactivation was a major cause of morbidity and mortality among paediatric allogeneic hematopoietic stem cell transplantation (allo-HSCT) recipients. Letermovir access was an issue in India. Hence, real world data of letermovir prophylaxis in Indian paediatric patients was limited. With launch of Bioequivalent Generic Letermovir, this study is to evaluate, its real-world utilization and efficacy in Paediatric Population of DEFENDER study group.

Methods: This multicenter retrospective observational study evaluated Generic letermovir tablets (Anvimo) utilization patterns and outcomes in 101 pediatric patients who underwent allo-HSCT across 10 centers in India between Januvary 2025 and December 2025. For optimal pediatric dose, Letermovir 240 mg and 480 tablets were cut. Outcomes assessed included CMV reactivation incidence, clinically significant CMV reactivation, adverse events, and 100-day survival using Kaplan-Meier analysis.

Results: Mean age of study participants was 7.49±4 years, and mean weight was 22±10.77 kg. Primary indications included thalassemia (54.46%), sickle cell disease (14.85%), and acute leukemias (18.81%). Most patients (66.34%) were high CMV risk, with 67.33% being D+/R+ serostatus. Haploidentical transplants constituted 60.39% (32.67% T-cell depleted, 27.72% T-cell replete), while 29.70% received HLA-matched related transplants. Myeloablative conditioning was used in 82.18% of patients, and 83.17% received anti-thymocyte globulin. Letermovir was administered primarily as primary prophylaxis (95.05%) with weight-based dosing: 120 mg (55.45%), 240 mg (32.67%), and 480 mg (6.93%) (Table 1).

Dose of Letermovir in Paediatric patients	Frequency	Percentage
480 mg	7	6.93%

240 mg	33	32.67%
120 mg	56	55.45%
80 mg	1	0.99%
60 mg	4	3.96%
Total	101	100%

Median prophylaxis duration was 70 days (IQR 59-95), with 69.31% receiving planned 100-day prophylaxis. Dose modification occurred in 58.42% of cases. CMV reactivation post-transplant occurred in 23 patients (22.77%), experiencing reactivation while on letermovir prophylaxis, in 8 patients, lower CMV viral copies (Letermovir Blip) subsided in 1-2 weeks. While progression to clinically significant CMV reactivation was observed in 15 patients (14.85%). Kaplan-Meier analysis for time to CMV reactivation demonstrated a mean event-free survival of 164.5±8.0 days (95% CI: 148.9-180.2), with 85.15% of patients remaining CMV reactivation-free. Post-transplant acute GVHD occurred in 19 patients (18.81%), with one case of Grade 1. Most patients (77.23%) completed their planned prophylaxis duration. Discontinuation reasons included clinically significant CMV reactivation (4.95%), death (10.89%), physician decision (4.95%), and patient withdrawal (0.99%). Adverse events were minimal, with nausea reported in only 3 patients (2.97%). Pre-emptive therapy was required in 13 patients (12.87%), primarily ganciclovir (10.89%) and cidofovir (1.98%).

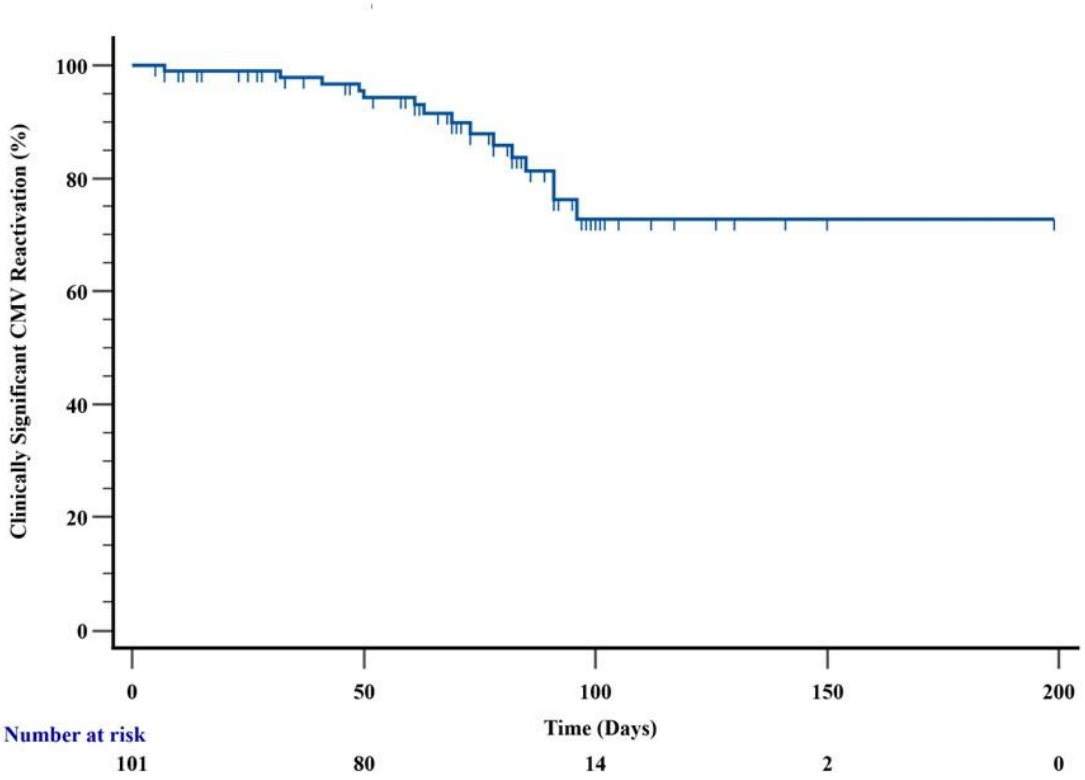

Figure 1: CMV-infection-free survival with CMV Letermovir (bioequivalent generic) prophylaxis in Paediatric Allo-HSCT patients

Conclusions: Letermovir prophylaxis demonstrated acceptable efficacy and excellent tolerability in pediatric allo-HSCT recipients, with low adverse event rates and high completion rates. Real-world data support letermovir use in pediatric transplant populations and highlight the need for individualized dosing strategies.

LETERMOVIR CYTOMEGALOVIRUS PROPHYLAXIS IN ALLOGENIC HEMATOPOIETIC-CELL TRANSPLANTATION: REAL-WORLD EVIDENCE FROM HIGH-ENDEMIC REGION

Sandipkumar Kheni[1], Grishma Sukhwal[1], Neha Motwani[1], Chaitrangi Rohekar[1], Raj Gabani[1], Yoshaan Joshi[1], Dhara Shah[1], Vijaykumar Shirure[1], Sanjay Gupta[1], ***Velu Nair***[2]
[1]Apollo Hospital International Limited, Gandhinagar, Gujarat, India, [2]Head of Department and Chief Consultant at Apollo Hospital International Limited, Gandhinagar, Gujarat, India*

Background: Cytomegalovirus (CMV) reactivation is a significant infectious complication following allogeneic hematopoietic stem cell transplantation (allo-HSCT), contributing substantially to morbidity, graft-versus-host disease (GVHD), prolonged hospitalisation, and transplant-related mortality (TRM). Letermovir, a novel CMV terminase inhibitor, has shown remarkable efficacy as primary CMV prophylaxis in CMV-seropositive recipients; however, real-world comparative data from mixed-donor, resource-limited transplant programs are limited. Our centre introduced routine Letermovir prophylaxis in 2024. This retrospective study compares CMV outcomes, GVHD, survival, and TRM between allo-HSCT recipients who received Letermovir prophylaxis and those who did not.

Methods: We conducted a retrospective review of all CMV-seropositive allo-HSCT recipients transplanted between 2019 and 2025 at Apollo Hospital International Limited, Gujarat, India. Patients were divided into two cohorts: the Letermovir prophylaxis group (n = 17) and the non-Letermovir group, also known as the control group (n = 58). Data extracted included demographics, diagnosis, donor type, graft source, conditioning intensity, engraftment kinetics, CMV viremia episodes, clinically significant CMV infection (csCMVi), CMV recurrence, steroid-treated GVHD, overall survival (OS), and TRM. Categorical variables were compared using Fisher's exact test or Chi-square test, and continuous variables using Mann–Whitney U test. Statistical significance was defined as $p<0.05$.

Results: The groups were comparable at baseline. Letermovir prophylaxis significantly reduced early CMV events. csCMVi by week 12 was 35% vs 75.9% (p=0.004), and CMV recurrence was 12% vs 38.4% (p=0.03). Total CMV viremia episodes were markedly lower (9 vs 73). No patient on Letermovir developed CMV disease. Steroid-treated GVHD was lower (17.6% vs 34.4%). Overall survival was significantly higher with Letermovir (94% vs 62%; p=0.01), and TRM was reduced from 9% to 0%.

Conclusions: In this real-world cohort from a high CMV endemic region, letermovir prophylaxis substantially lowered the incidence of clinically significant CMV infection in high-risk allo-HCT recipients. Patients receiving letermovir showed reduced CMV infection rates at both Week 12 and Week 24, reduced CMV viremia burden, and absence of CMV disease. These findings reinforce Letermovir's role as an effective and valuable addition to antiviral prophylaxis strategies for high-risk post-transplant patients.

P150

HHV-6 REPLICATION AS A RISK FACTOR FOR GRAFT LOSS IN ALLO-HSCT: A COHORT STUDY AT A REFERENCE CENTER

Raquel García-Talavera Hernández[1], María del Mar Perera Álvarez[1], ***Leslie González Pinedo****[1], Jorge Gayoso Cruz[1], Alejandro Morales Curbelo[1], María José Pena López[1], Cynthia Acosta Fleitas[1], Luz María González del Castillo[1], Luisa Guerra Domínguez[1], Amagoia Ruiz Martín[1], Concepción Sánchez Chamizo[1], Minia Grobas Sebio[1], Carol Herrera Hernández[1], Natalia López Esteban[1], Mónica Betancor Pérez[1], José Antonio Moreno García[1], Guillermo*

Rodríguez Rodríguez[1], María Teresa Gómez Casares[1]
[1]Hopital Universitario de Gran Canaria Doctor Negrín, Las Palmas de Gran Canaria, Spain

Background: Reactivation of human herpesvirus type 6 (HHV-6) is a common complication in patients undergoing allogeneic hematopoietic stem cell transplantation (allo-HSCT). This reactivation has been linked to an increased risk of graft loss and delayed hematological recovery. Likewise, a higher incidence of graft-versus-host disease (GVHD) has been documented, suggesting a possible immunomodulatory effect of HHV-6 in the post-transplant setting.

Methods: Retrospective cohort study including all patients receiving allo-HSCT at our center in 2024, dividing them into two groups: patients with clinical suspicion of graft loss due to HHV-6 reactivation (intervention group) and patients without clinical suspicion who underwent viral load determination by the microbiology service in frozen samples obtained between days +14 and +35 post-allo-HSCT (control/blind group), therefore without clinical intervention by our HSC Transplant Unit.
The frequencies of graft loss, acute and chronic GVHD in both groups and their association with HHV-6 VL were analyzed.

Results: Forty-four patients were included, 84% with myelodysplastic syndromes (MDS)/acute leukemias (AL) and 16% with lymphoproliferative syndromes (LS), mainly males (66%) with a mean age of 53 years (range 20–71). In 23% (10/44) an HLA-identical (HLA-i) donor was used, in 27% (12/44) an unrelated donor (URD) and in 50% (22/44) a haploidentical donor.
The descriptive analysis of results according to VL +/- is shown in Table 1. Forty per cent (18 patients) had a positive HHV-6 VL in at least one determination, with a mean VL of 4709 (R 250–25267). Of these patients, 2/18 (11%) with VL+ presented primary graft failure as a complication, compared to 0/26. In the bivariate analysis, categorically defining HHV-6 VL replication, an association was found with the presence of cGVHD (OR=8) p 0.006 and a trend, although not significant, with aGVHD. No association was found with VOD, IFI or hemorrhagic cystitis.
The descriptive analysis of results by group (suspicion/control) is described in Table 1. Thirteen patients were included in the suspicion group and 31 in the control/blind group. Replication for HHV-6 was confirmed in 38.4% of the intervention group vs. 41.9% in the control/blind group. The mean HHV-6 VL in the intervention group was 2061.6 (SD = 3661.935) and 5812.67 (R 250 -25267) in the control group, with no significant differences. The specificity and PPV of the HHV-6 VL were 62% and 11% for graft loss. If we add the clinical suspicion condition and HHV-6 VL, the E and PPV rise to 72% and 40%, respectively.

Table 1. Analysis.

Analysis by viral load		
	VL +	VL -
Total	18 (40%)	26 (60%)

Average VL HHV-6	4709 (R 250-25267)	0
% Graft failure	2 (11%)	0
Days to graft	18.33 (13-26)	17.92 (14-30)
Analysis by groups		
	VL+ in supected group	VL + in control/blind group
Total	5/13	13/31
Mean VL HHV-6	2061 (R 268-8603)	5812.67 (R250-25267)
% Graft failure	2/5	0/13
Days until grafting	18 (16-22)	17.38 (13-26)
aGVHD	2/5	3/13
cGVHD	0/5	9/13
NPV VL HHV-6	100	
PPV VL HHV-6	11	
NPV VL HHV-6 and clinical suspicion	100	
PPV VL HHV-6 and clinical suspicion	40	

Conclusions: HHV-6 replication was as frequent in the group with suspected graft loss as in the control group, without being able to identify a mean HHV-6 viral load value that would indicate the risk of graft loss. In a cohort with a high prevalence of VHH-6-positive VL, the highest specificity and PPV are obtained by combining the presence of HHV-6 replication with clinical suspicion.

Disclosure: No conflict of interest.

P151

VIRUS-SPECIFIC LYMPHOCYTE THERAPY FOR PHARMACOLOGICALLY REFRACTORY VIRAL REACTIVATIONS IN PEDIATRIC IMMUNOCOMPROMISED PATIENTS: A 13-YEAR SINGLE-CENTER EXPERIENCE

Giulia Ferrando[1], Federica Sabatini[1], Claudia Cocco[1], Patrizia Comoli[2], Sabrina Basso[2], Stefano Giardino[1], Stefano Giardino[3], Filomena Pierri[1], Sara Pestarino[1], Lanceri Maddalena[1], Francesca Dagliano[1], ***Maura Faraci***[1]
[1]*IRCCS Istituto G. Gaslini, Genova, Italy,* [2]*IRCCS San Matteo, Pavia, Italy,* [3]*IRCCS Istituto Giannina Gaslini, Genova, Italy*

Background: Viral reactivations are a potentially life-threatening complication in pediatric immunocompromised patients, particularly following hematopoietic cell transplantation (HCT). Adoptive transfer of virus-specific lymphocytes (VSLs) has emerged as a promising therapeutic approach.

Methods: We retrospectively analyzed pediatric patients treated at the Giannina Gaslini Institute (Genoa, Italy) between 2012 and 2025 who received parental- or third-party–derived VSLs for viral reactivations due to cytomegalovirus (CMV), Epstein–Barr virus (EBV), adenovirus (ADV), or JC polyomavirus (JCV). Patients were included regardless of whether they had undergone HCT or were immunocompromised due to other conditions.
All patients had previously received at least one line of antiviral pharmacologic therapy without achieving adequate virological response. Clinical data, treatment characteristics, and outcomes were collected.

Results: Eighteen patients received VSL infusions for a total of nineteen viral reactivations. Underlying conditions included malignant disorders (n=8), severe combined immunodeficiency (SCID, n=3), congenital bone-marrow failure syndromes (n=5), acquired aplastic anemia (n=1), and mucopolysaccharidosis type I (n=1). Seventeen patients had undergone allogeneic HCT; three required a second transplant for graft failure. One patient with SCID received VSLs without prior HCT. Among patients undergoing more than one transplant, all but one developed viral reactivation after the second procedure. One patient developed viral reactivation after the first transplant, and the viremia persisted after the second, with VSL infusion administered following the latter procedure.
Documented infections included adenovirus (ADV, n=10), cytomegalovirus (CMV, n=4), Epstein–Barr virus (EBV, n=2), JC polyomavirus (JCV, n=1), and one ADV/CMV co-infection (n=1). Eleven patients received a single infusion, one received two separate infusions—one anti-ADV and one anti-CMV—and three patients received two infusions each; three additional patients received four infusions each. In total, 31 VSL infusions were administered. Thirteen products were third-party–derived and eighteen were family-donor-derived; twenty-five were manufactured in Pavia and six in Genoa.
The median time from first documented viremia to the initial VSL infusion was 27 days (mean 52.2 days). The median first-dose infusion was 2×10^5 cells/kg (mean 5.1×10^5 cells/kg).
At last follow-up, nine patients were alive and nine had died. Five deaths were attributable to

adenovirus. The remaining four deaths were unrelated to viral replication: among these, three patients had achieved complete viral clearance following VSL infusion, whereas one remained CMV-positive and died of bacterial sepsis (Table 1).
Among patients treated for adenovirus infection, those who achieved viral clearance (6/11) received their first VSL infusion after a mean of 13 days (range: 8–15), whereas the five

patients who died received VSLs later, with a mean interval of 42 days (range: 14–122).

	Sex	TCE	2°TCE	Virus	Time from dection of viremia to VSL infusion (days)	>1 infusion of VSL	Viral clearance	Cause of death, where applicable
Pt 1	F	Haplo αβ/CD19 -depl		ADV	122		NO	ADV
Pt 2	M	Haplo αβ/CD19 -depl	YES MUD	ADV	30		NO	ADV
Pt 3	M	MUD		ADV	15		YES	
Pt 4	F	UCB		ADV	30		NO	ADV; HHV6
Pt 5	M	MUD		ADV	18		YES	
Pt 6	F	Haplo PTCy		ADV	10		YES	
Pt 7	M	-	-	ADV	14		NO	ADV
Pt 8	F	Haplo PTCy		ADV	14		YES	
Pt 9	M	Haplo αβ/CD19 -depl		ADV	14	YES	NO	ADV
Pt 10	F	Haplo αβ/CD19 -depl		ADV	14	YES	YES	
Pt 11	M	MUD		ADV	8		YES	Sepsis
				CMV	90		NO	
Pt 12	F	MUD		CMV	30	YES	YES	
Pt 13	F	Haplo PTCy		CMV	165	YES	YES	Relapse of LMA
Pt 14	M	MUD		CMV	24		YES	
Pt 15	M	MUD	YES Haplo αβ/CD 19	CMV	13		YES	Pulmonary insufficiency due to DC
Pt 16	F	UCB	YES Haplo PTCy	EBV	15		YES	Graft failure
Pt 17	M	MUD		EBV	220	YES	YES	
Pt 18	M	Haplo αβ/CD19 -depl		JC	46	YES	YES	

Conclusions: VSL infusion showed encouraging effectiveness, achieving complete viral clearance in 13 of 19 cases (68.4%) of refractory viral reactivations. Adenovirus infection was associated with the highest mortality (5/18, 27.8%), particularly among patients who received VSLs later. These findings underscore the importance of early availability and timely administration of VSLs in patients who fail to respond to conventional therapies.

Clinical Trial Registry: Not applicable.

PREDICTIVE BIOMARKERS OF SARS-COV-2 VACCINE SEROCONVERSION IN PATIENTS WITH HAEMATOLOGICAL MALIGNANCIES

Andrea Henden[1], *Sophie Hamann*[2], *Katie Lineburg*[2], *Louise Ng*[2], *Stuart Olver*[2], *Justine Leach*[1], *Christine Bristow*[1], *Corey Smith*[2], *Kristyan Guppy-Coles*[1], *Kirk Morris*[1], *Michelle Spanevello*[1], *Siok Tey*[1]
[1]*Royal Brisbane and Women's Hospital, Brisbane, Australia,* [2]*QIMR Berghofer, Herston, Australia*

Background: SARS-CoV-2 vaccination is crucial in protecting against severe COVID-19 disease, however, patients with haematological malignancies (HM) respond poorly to vaccination due to immunosuppression driven by chemotherapy, targeted cell depletion and immune dysregulation. We sought to define novel biomarkers that predict for effective vaccination in patients with HM.

Methods: HM patients and healthy controls received SARS-CoV-2 vaccines and were followed for six months post vaccination. Virus-specific humoral and cellular immune response were analysed in serum and whole blood pre-and post-vaccination and serum proteomics analysed pre-vaccination to identify potential biomarkers for vaccine response. 24 participants were included who had any haematological malignancy and have received treatment with a range of therapies including B-cell targeted therapy and both autologous and allogeneic haematopoietic stem cell transplantation.

Results: HM patients displayed delayed antibody seroconversion and 37.5% failed to seroconvert. Baseline proteomic and cellular immune profiles revealed T cell associated chemokines CXCL13 and CRTAM were differentially expressed, with increased levels seen in vaccine responders. Vaccine response was also associated with a reduced frequency of circulating monocytes, greater numbers of B cells and a trend toward greater numbers of CD4+ helper cell phenotypes including T peripheral helper cells pre-vaccination. *In vitro* generation of COVID--specific T cells from a subset of participants showed increased cytotoxic CD4+ and CD8+ T cell activity in seroconverters and dysfunctional COVID specific T cell responses in non-seroconverters.

Conclusions: These results demonstrate that in addition to expected decreased humoral immune responses to vaccination, a proportion of HM patients have impaired T cell immunity, and circulating serum CXCL13 and CRTAM may predict for successful seroconversion, permitting identification of a group of at-risk patients who would benefit from alternative COVID prophylaxis strategies.

EARLY INFECTIOUS COMPLICATIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION: MICROBIOLOGICAL PROFILE AND ANTIMICROBIAL RESISTANCE PATTERNS

*Stefania Pantoja[1], Paula Perez[1], Juliana Pardo Aljure[2], **Manuela Estrada-Schweineberg**[1], Juliana Castro[2], Federico Ramos-Marquez[1], Juan Camilo Vasquez[1], Dana Taub Sánchez[2], Gabriel Ayala-Carrascal[3], Alejandra Melo[2], Mateo Gutierrez[2], Andrés Guerra[2], Laura Ortiz[1], Ana Maria Molano[1], Karen Chaves[1], Carmenza Camargo[1], Claudia Agudelo López[1], Guillermo Quintero[1], Beatriz Wills[1]*
[1]Fundación Santa Fé de Bogotá, Bogotá, Colombia, [2]Universidad de los Andes, Bogotá, Colombia, [3]Universidad Nacional de Colombia, Bogotá, Colombia

Background: Early infectious complications remain a major source of morbidity after hematopoietic stem cell transplantation (HSCT), with antimicrobial resistance posing an increasing challenge in the early post-transplant period.

Methods: This single institution study retrospectively analyzed early infectious complications during the index post-transplant hospitalization focusing on microbiological isolates, antimicrobial resistance patterns, and catheter-associated infections.

Results:

A total of (n = 112) patients were included in the analysis. Neutropenic fever occurred in (n=96, 85.7%) of patients, of which 74 (77.08%) underwent auto-HSCT, whereas 22 (22.92%) received an allogeneic transplant. In this cohort (n = 96), multiple myeloma was the most frequent diagnosis, accounting for 40 cases (41.67%). This was followed by mantle cell lymphoma with 11 cases (11.46%), acute myeloid leukemia with 9 cases (9.38%), and acute lymphoblastic leukemia, including precursor B-cell and other variants, with 8 cases (8.33%).

Microbiological documentation was obtained in 16 (16.67%) patients. Among documented isolates, Gram-negative bacteria predominated, accounting for approximately 60% of positive cultures, followed by Gram-positive bacteria (6.8%). The most frequently isolated pathogens were Escherichia coli (3.9%), Pseudomonas aeruginosa (1.9%), and Staphylococcus epidermidis (4,82%). Carbapenemase-producing organisms were identified in approximately 2–3% of isolates.

Among 22 infectious episodes with sufficient clinical information to assign an infection source, a focus was identified in 45.5%, most frequently catheter-related infections (27.3%) and gastrointestinal infections (18.2%), while primary bacteremia without an identifiable focus accounted for 45.5% of cases. The remaining episodes corresponded to other or unspecified infection sources. The median time from onset of fever to initiation of antibiotic therapy was 20 minutes (IQR 15–30), reflecting early antimicrobial treatment in most episodes. Kaplan–Meier analysis showed a median time to neutropenic fever of 14.9 days (SD=4.88).

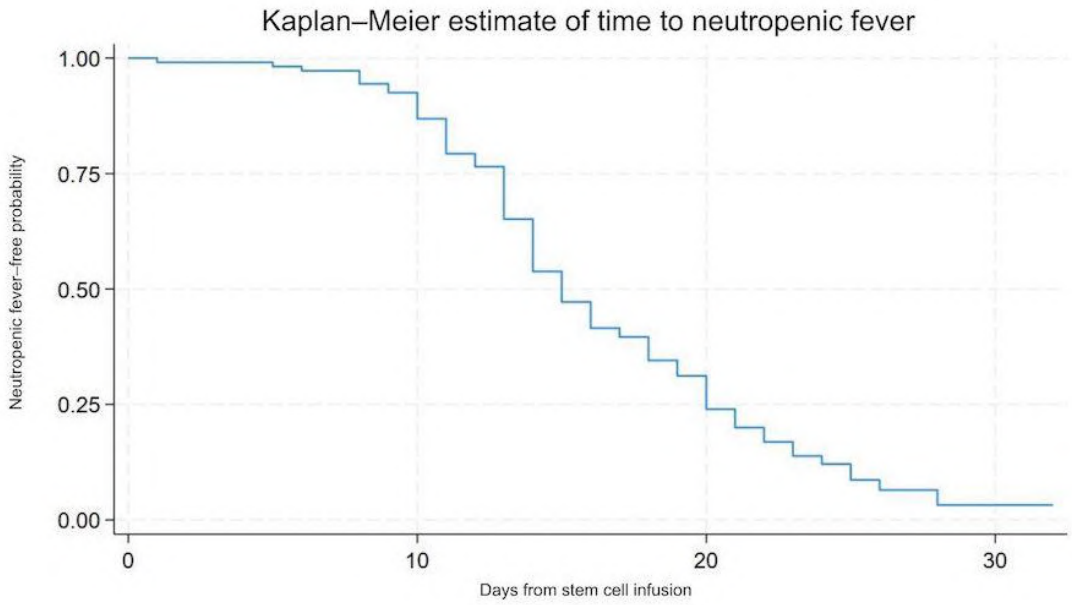

Table 1. Microbiological findings and infectious foci in early post-transplant infections

Category	Variable	Frequency / %
Microbiological documentation	n	16 (23.3%)
	Escherichia coli	4 (3.9%)
	Pseudomonas aeruginosa	2 (1.9%)
	Staphylococcus epidermidis	5 (4.8%)
	Staphylococcus hominis	1 (0,9%)
	Klebsiella pneumoniae	1 (0,9%)
	Serratia marcescens	1 (0,9%)
	Enterobacter cloacae	1 (0,9%)

Table 1. Microbiological findings and infectious foci in early post-transplant infections

Combined infections	Escherichia coli + Pseudomonas aeruginosa	1 (0,9%)
	Klebsiella pneumoniae + Streptococcus agalactiae	1 (0,9%)
Resistant microorganisms	Escherichia coli IRT	1 (0,9%)
	Multiresistant KPC + Staphylococcus epidermidis	1 (0,9%)
	Multiresistant KPC	1 (0,9%)
Infectious focus	n	22
	Catheter-associated infection	6 (27.3%)
	Gastrointestinal infection	4 (18.2%)
	Primary bacteremia (no identifiable focus)	10 (45.5%)
	Other / unspecified source	2 (9.1%)

Conclusions: Early post-transplant infections were frequent in this real-world cohort, with a high incidence of neutropenic fever occurring early after transplantation. Microbiological documentation was obtained in a minority of cases, predominantly involving Gram-negative pathogens, with a low but relevant proportion of carbapenemase-producing organisms. Catheter-associated infections and primary bacteremia without an identifiable focus accounted for most documented infectious episodes, highlighting the heterogeneity of early infectious complications following hematopoietic stem cell transplantation.

ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION IN PATIENTS WITH HIGH-RISK ACUTE LEUKEMIAS AND HIV INFECTION

*Marina Popova[1], Yulia Rogacheva[1], Andrey Chekalov[1], **Aleksandr Siniaev**[1], Alyona Shakirova[1], Vladislav Sergeev[1], Kirill Lepik[1], Ilya Zyuzgin[2], Yulia Vlasova[1], Anna Smirnova[1], Sergey Bondarenko[1], Ivan Moiseev[1], Alexander Kulagin[1]*
[1]RM Gorbacheva Research Institute, Pavlov University, St. Petersburg, Russian Federation (the), [2]Leningrad Regional Clinical Hospital, NMRC of Oncology named after N.N.Petrov of MoH of Russia, St. Petersburg, Russian Federation (the)

Background: Allogeneic hematopoietic cell transplantation (allo-HCT) serves as a curative therapy for acute leukemias and holds potential for curing HIV infection. Five patients achieved HIV cure through allo-HCT from donors with homozygous CCR5 gene mutation. In 2024-2025, two cases of HIV cure resulted from allo-HCT from donors without homozygous mutation (Sáez-Cirión, A., et al. 2024; Gaebler, C., et al. 2025), that's raising questions about cure mechanisms while risking unwarranted optimism. Experience with allo-HCT in HIV patients remains limited to case reports and series; this study presents the largest to our knowledge single-center experience in patients with HIV and acute leukemias.

Methods: From 2010 to 2025 at the RM Gorbacheva Research Institute 14 allo-HCTs were performed in 10 adult HIV-infected patients (median age of 36 years (25-59)) with high-risk acute leukemia. Indications included acute myeloid leukemia (AML) in 6 (60%), including 2 secondary AML, acute lymphoblastic leukemia (ALL) in 3 (30%), including one T-ALL and mixed-phenotype acute leukemia in 1 (10%). Three patients (30%) lacked remission at allo-HCT; hepatitis C co-infection occurred in 5 (50%). Median follow-up was 5 months (1-191), and 79 months (7-191) for survivors. Allo-HCT characteristics appear in Table 1. The study reports key allo-HCT outcomes, including one antiretroviral therapy (ART) discontinuation case.

Table 1. Characteristics of Allo-HCT in patients with high-risk acute leukemias and HIV

First allo-HCT	n=10
Donor type: MUD / MMUD / MRD / haploidentical	4 / 3 / 2 / 1
Donor CCR5 mutation status: Wild type / wt	4
Donor CCR5 mutation status: CCR5 heterozygote	3
Donor CCR5 mutation status: Unknown	3
Conditioning regimen: FluBu10 / FluBu8 / FluMel140	6 / 3 / 1
GVHD prophylaxis with ATG-based + CsA + MMF ± Maraviroc	2
GVHD prophylaxis with PTCy-based + Tacro + MMF ± Maraviroc/Ruxo	6
GVHD prophylaxis with No ATG/PTCy + CsA + Mtx/Tacro + MMF	2
Second allo-HCT	3

Third allo-HCT	1

Results: Median HIV-infection duration at allo-HCT was 89 (25-59) months. Nine patients received ART with suppressed viral load; median CD4 count was 281 cells/µl (77-1178). Graft failure occurred in 2 patients (20%) after first allo-HCT but succeeded engraftment after second. Acute GVHD affected 2 patients (20%, grades 2-3: skin, GI); localized chronic GVHD occurred in 1 (10%). One-year non-relapse mortality was 30% (95% CI 7.1-57.8%). Five patients either relapsed or showed disease progression (50%). Overall 10-year survival reached 50% (95% CI 18.4-75.3%). One patient post-allo-HCT from heterozygous CCR5 donor and Maraviroc GVHD prophylaxis discontinued ART after 8 years and HIV antibody loss (immunoblot); HIV rebound registered in 2 months and leukemia relapse in 6 months. Second remission was achieved and second allo-HCT (also from heterozygous CCR5 donor) have been performed, but patient died after anti-CD123 CAR-T and third allo-HCT without remission.

Conclusions: Allo-HCT outcomes in high-risk acute leukemias with HIV comparable with general patient cohorts. ART discontinuation, even post-allo-HCT from heterozygous CCR5 donors associated with risks of HIV rebound and leukemia relapse.

Disclosure: All authors are nothing to disclosure.

Background: CMV reactivation is a major cause of morbidity and mortality following allogeneic hematopoietic stem-cell transplantation (allo-HSCT). While Letermovir prophylaxis has significantly reduced CMV incidence, real-world outcomes in generic bioequivalent formulations remain under-reported, especially from resource limited settings. This multicenter study evaluated utilization patterns and CMV outcomes following generic Letermovir prophylaxis in India.

Methods: A retrospective multicenter cohort consisting of 156 allo-HSCT recipients receiving Letermovir prophylaxis was evaluated. Primary endpoints were incidence and timing of CMV reactivation and patterns of Letermovir utilization. Secondary endpoints included safety and discontinuation by Day+100. Statistical analysis included Kaplan–Meier survival for time to CMV reactivation and subgroup analyses by HSCT donor type and CMV risk in HSCT patients.

Results: The study analysed 156 patients who received Bioequivalent Generic Letermovir Prophylaxis post-hematopoietic stem cell transplantation (HSCT) of which 101 were pediatric patients and 55 were adult patients. Hemoglobinopathies (Transfusion dependent thalassemia and sickle cell disease) (54.5%) were the most common indication in Pediatric patients and AML (49.1%) was the most common Indication in adults. Most patients received primary prophylaxis (96.15%), with doses predominantly 240 mg (37.18%) and 120 mg (35.90%) in pediatric cohort. Sixty-one (39.1%) patients received cut or crushed tablets as only available SKU of Generic Letermovir is 240 and 480 mg tablets. A majority were high-risk for CMV (58.97%) as per established criteria.

Demographic Parameters: (n=156)	Adult Patients (n=55)	Paediatric Patients (n=101)
Age (Years) (Mean ± SD)	39.40 ± 15.7	7.49 ± 4
Weight (Kgs) (Mean ± SD)	64.83 ± 11.73	22 ± 10.77
HLA compatibility	Frequency	Percentage (%)
Haploidentical TCR	53	33.97%
HLA-matched Related	49	31.41%
Haploidentical TCD	39	25%
HLA-matched Unrelated	15	9.61%
Risk of CMV: High Risk	92	58.97
Risk of CMV: Low Risk	64	41.03%

Table 1: Demography and Clinical Parameters

Median duration of Letermovir use was 73 days (IQR 54.25–99), and incidence of CMV reactivation was 15.38%. None of the patients developed CMV disease. As on 06-12-2025, Kaplan–Meier analysis showed a mean CMV-infection-free survival of 173.2 days (95% CI: 160.2–186.1), with no statistically significant differences between CMV risk categories or donor types (Figure 1). Adverse events were rare (nausea 1.92%, vomiting 1.92%), and Letermovir discontinuation due to toxicity was infrequent (1.28%). Most patients discontinued prophylaxis after completion of the planned 100 days duration (76.28%).

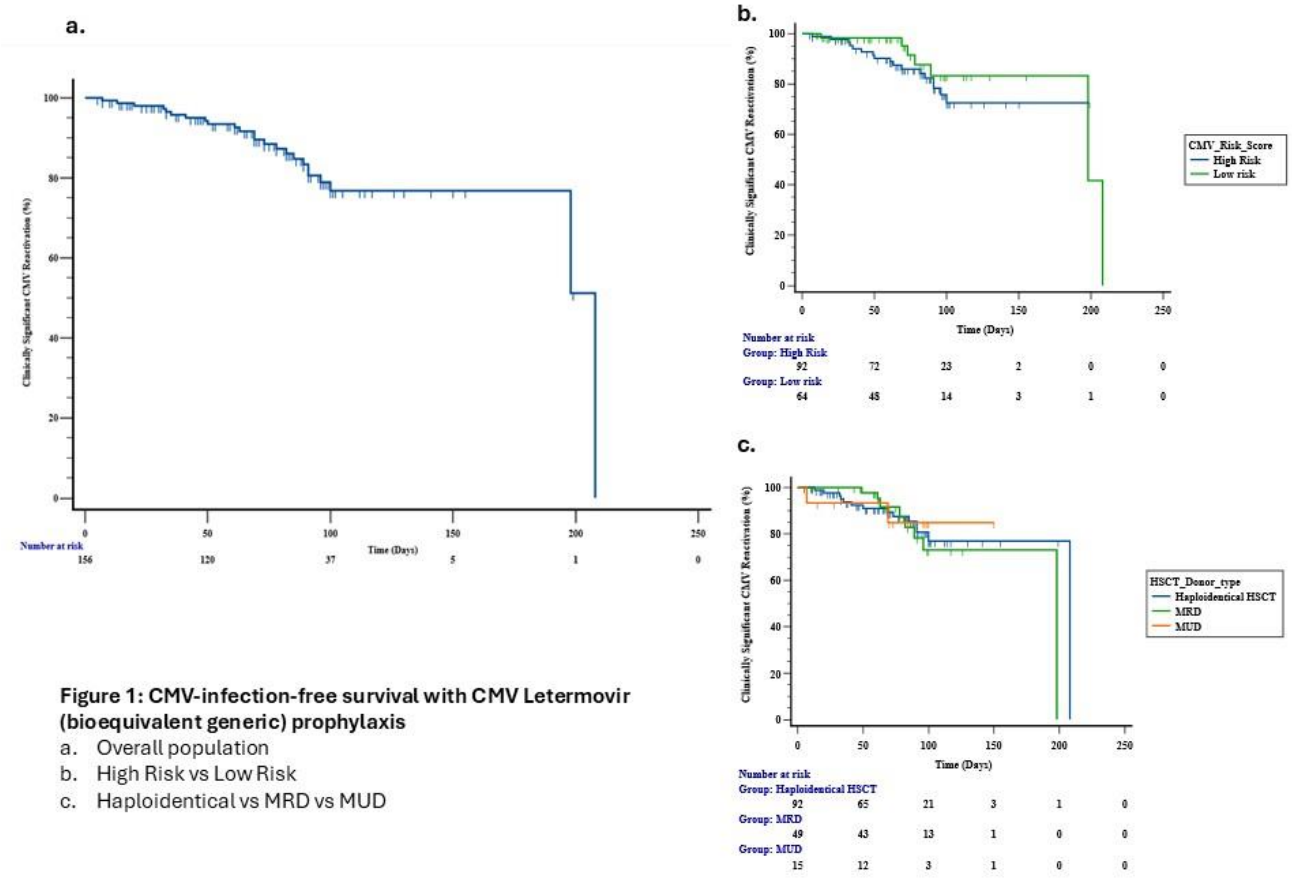

Figure 1: CMV-infection-free survival with CMV Letermovir (bioequivalent generic) prophylaxis

a. Overall population
b. High Risk vs Low Risk
c. Haploidentical vs MRD vs MUD

Conclusions: Real-world use of bioequivalent generic Letermovir demonstrates high tolerability, favourable CMV-infection-free survival, low breakthrough infection rates, and excellent adherence across varied transplant settings in India. These findings support its continued integration into routine CMV prophylaxis strategies for allo-HSCT recipients.

DECOLONIZATION OF MULTIDRUG-RESISTANT BACTERIA BY FECAL MICROBIOTA TRANSPLANTATION IN A PATIENT BEFORE ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

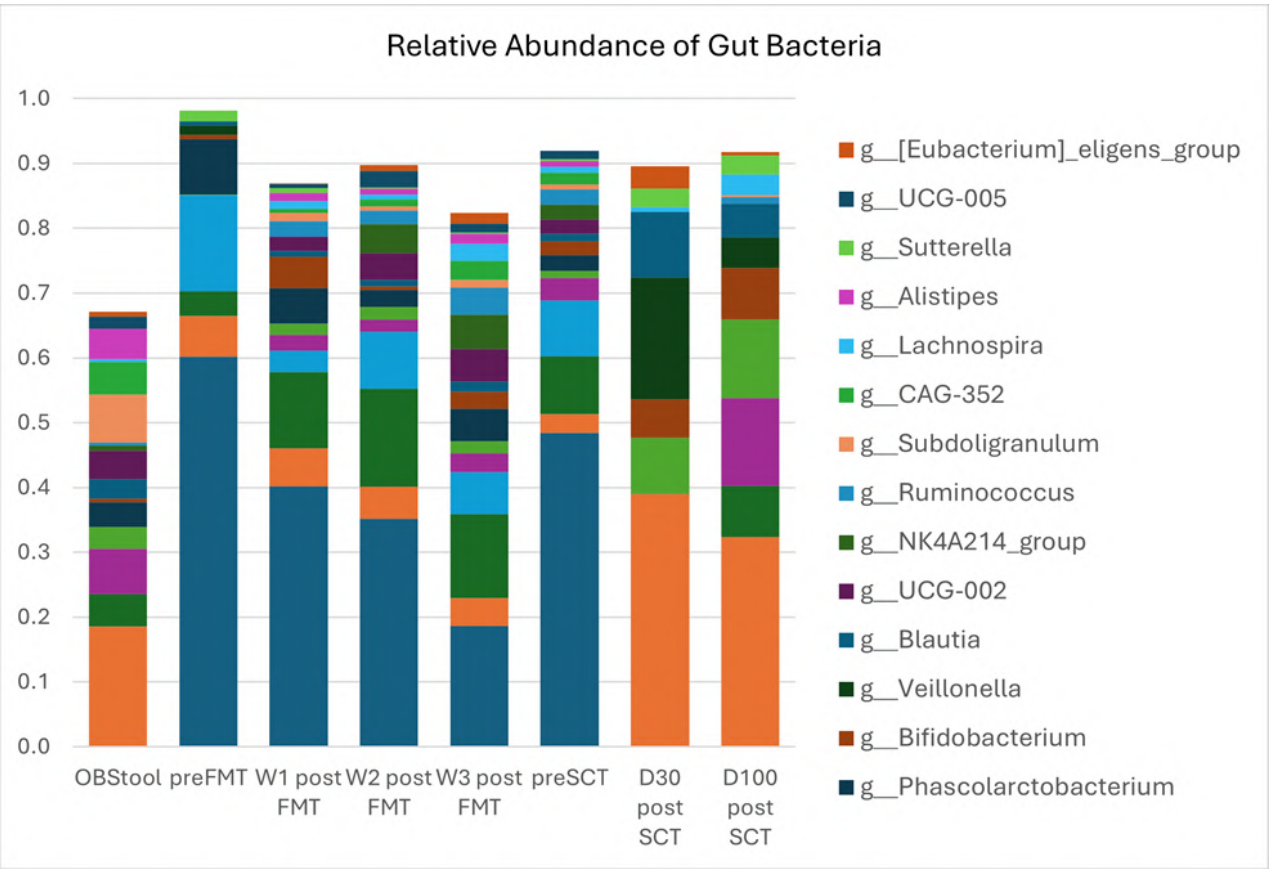
Deepa Nanayakkara[1], *Anthony Stein*[1], *David Engelthaler*[2], *Bernard Tegtmeier*[1], *Trilokesh Kidambi*[1], *Sanjeet Dadwal*[1]
[1]*City of Hope Comprehensive Cancer Center, Duarte, United States of America (the),*
[2]*Translational Genomics Research Institute, Phoenix, United States of America (the)*

Background: The gut microbiome is adversely affected by chemotherapy and antibiotics in patients undergoing hematopoietic stem cell transplantation (HSCT). Due to limited antibiotic options, multidrug-resistant organism (MDRO) infections are associated with high non-relapse mortality after HSCT. A few small cohort studies have reported successful fecal microbiota transplantation (FMT) to decolonize MDROs in immunosuppressed patients.

Methods: We describe a case report of a 63-year-old Indian male with acute myelogenous leukemia who developed infection with MDR *Klebsiella pneumoniae* and *Pseudomonas aeruginosa* post-consolidation chemotherapy. FMT was performed pre-HCT with the intent to decolonize the gut from these MDROs. This single patient study was approved by the institutional (City of Hope) IRB. Stool was tested for blaNDM and blaOXA-48 resistance genes using a commercial assay. Stool bacterial biodiversity was analyzed using 16s ribosomal DNA sequencing. Both testing was performed once prior to FMT, weekly after FMT until HSCT, and on day 30 and day 100 post-HSCT.

Results: The patient came to our center for treatment of AML, after undergoing induction chemotherapy in India. His course was complicated by Klebsiella pneumoniae carbapenemase (KPC)-producing *Klebsiella pneumoniae* bacteremia that was effectively treated with colistin. After receiving consolidation chemotherapy at our institution, he developed KPC-producing *Klebsiella pneumoniae* bacteremia and New Delhi metallo-beta-lactamase (NDM) and carbapenemase producing *Pseudomonas aeruginosa* bacteremia complicated by right thigh myositis, fasciitis, femoral osteomyelitis and abscess. He was successfully treated with cefiderocol and high-dose extended infusion of meropenem in conjunction with debridement of right femoral osteomyelitis/abscess. He completed 6-weeks of antibacterial therapy from surgical debridement. Upon clinical improvement and allowing for a 10-day washout period from stopping antibacterials, the patient underwent FMT on compassionate grounds. The stool product from OpenBiome stool bank was delivered via colonoscopy. Six weeks post-FMT, he underwent matched unrelated donor allogeneic HSCT using total marrow and lymphoid irradiation and cyclophosphamide conditioning and tacrolimus for graft-versus-host-disease (GvHD) prophylaxis. Cefiderocol and high-dose extended infusion of meropenem were given for neutropenic fever.
FMT was well-tolerated with mild self-resolving diarrhea soon after the procedure. No delayed adverse events were observed. Pre-FMT stool detected blaNDM and blaOXA-48 genes. Post-FMT stool pre-HSCT showed persistence of both resistance genes. On post-HSCT stool analysis, blaNDM gene on day 30 and day 100 and blaOXA-48 gene on day 100 were no longer identified consistent with eradication of MDROs. 16s ribosomal DNA sequencing of

stool showed decrease in *Prevotella* and an increase in *Faecalibacterium* and *Lachnospiraceae* between post-FMT and pre-HSCT time period. Improved stool alpha diversity was noted at day 30 and day 100 post-HSCT with an increased density of *Bacteroides*, *Veillonella*, *Blautia*, and *Bifidobacterium* species, comparable to donor stool. There was no delay in engraftment, no infectious complications post-HSCT, and no acute or chronic GvHD. The patient is doing well for 5 years post-HSCT.



Conclusions: FMT for MDRO-decolonization pre-HSCT was successful, safe, and effective in this patient with one of the longest follow-up periods reported. Given limited therapeutic options to combat MDRO infections, safety and efficacy of gut microbial restoration with FMT in patients undergoing HSCT needs to be actively explored.

ANTIBACTERIAL PROPHYLAXIS IN AUTOLOGOUS STEM CELL TRANSPLANTATION: CEFPODOXIME VERSUS FLUOROQUINOLONES

Taner Tan[1], Sidar Copur[1], Oğuz Usta[1], Erdem Çığ[1], Efe Semercioglu[1], Ahmet Umur Topcu[1], Ümit Barbaros Üre[2], ***Sinem Civriz Bozdag***[1]
[1]Koç University, Istanbul, Turkey, [2]Koç University Hospital, Istanbul, Turkey

Background: Patients undergoing autologous stem cell transplantation (ASCT) are at high risk for infectious complications due to profound neutropenia. Fluoroquinolones are commonly used for antibacterial prophylaxis; however, concerns regarding toxicity, drug–drug interactions, and antimicrobial resistance have increased interest in alternative agents. Oral third-generation cephalosporins such as cefpodoxime may offer a safer option. We aimed to compare cefpodoxime with fluoroquinolone-based prophylaxis in ASCT recipients using a non-inferiority design.

Methods: This retrospective, single-center cohort study included adult patients who underwent ASCT for hematologic malignancies between January 2022 and November 2025. Patients received oral cefpodoxime or fluoroquinolone-based prophylaxis (levofloxacin or moxifloxacin) according to institutional practice. Primary outcomes were duration of hospitalization and time to first febrile episode. Secondary outcomes included rates of bacteremia, site-specific infections, neutrophil and platelet engraftment times, duration of systemic antibiotic therapy, and all-cause mortality. Non-inferiority was assessed using bootstrapped mean differences (MD) adjusted for age and sex. Predefined non-inferiority margins were 1.0 days for time-dependent outcomes and 10% for infectious complications.

Results: A total of 149 ASCT recipients were included (99 cefpodoxime, 50 fluoroquinolone). Median age was 53 years, and 52% were female, with no significant baseline differences between groups. Median hospitalization duration was 21.0 days in the cefpodoxime group and 22.0 days in the fluoroquinolone group; the age- and sex-adjusted MD was −0.47 days (95% CI −1.86 to 0.92), establishing non-inferiority. Median time to first febrile episode was 3.0 versus 4.5 days, respectively, with an adjusted MD of 0.54 days (95% CI −1.73 to 0.65). Adjusted MDs for neutrophil and platelet engraftment were −0.29 days (95% CI −0.77 to 0.18) and −0.75 days (95% CI −2.25 to 0.75), respectively, meeting non-inferiority criteria. Rates of bacteremia, urinary tract, respiratory tract, and Clostridioides difficile infections were similar between two groups, with non-inferiority demonstrated for all except urinary tract infections. All cause mortality did not differ. Non-inferiority was not conclusively established for total antibiotic duration.

Conclusions: Cefpodoxime was non-inferior to fluoroquinolone-based prophylaxis for key clinical outcomes in ASCT recipients. Given increasing safety and resistance concerns related to fluoroquinolones, cefpodoxime represents a reasonable alternative in selected patients. Prospective randomized studies are warranted to confirm these findings.

Disclosure: Nothing to declare.

DIAGNOSTIC VALUE OF CMV PCR ON GASTROINTESTINAL BIOPSIES IN ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS

Sabrine Khirallah[1], Insaf Ben Yaiche[1], Siwar Frigui[1], Haithem Cherif[1], Rihab Ouerghi[1], Dorra Belloumi[1], Rimel Kanoun[1], Anna Chabaane[1], Lamia Torjmane[1], Yosra Chebbi[1], Wafa Achour[1], Tarek Ben Othman[1], ***Nour Ben Abdeljelil***[1]
[1]*National Bone Marrow Transplantation Center, Tunis, Tunisia*

Background: Cytomegalovirus (CMV) gastrointestinal (GI) disease remains a significant complication after allogeneic hematopoietic stem cell transplantation (allo-HSCT). Diagnosis is traditionally based on histopathology and plasma CMV PCR, but the sensitivity of these approaches may be limited.
The present study aimed to evaluate the additional diagnostic value of CMV PCR performed directly on GI biopsy specimens in detecting CMV GI disease post-allo-HSCT.

Methods: A retrospective descriptive study included allo-HSCT recipients from HLA-matched sibling or haploidentical donors (January 2021 - May 2025) who underwent GI biopsy for suspected CMV GI disease. All donors and recipients were screened for CMV serology prior allo-HSCT. Monitoring CMV was assessed for all patients by quantitative RT-PCR (qPCR) in plasma (Cobas AmpliPrep/COBAS TaqMan), from engraftment until 100 days after allo-HSCT, with 61 copies/mL as the limit of detection.
Patients with suspected CMV GI disease underwent simultaneous GI biopsy sampling for both histopathological assessment and quantitative CMV PCR testing performed on the same specimen using real-time PCR (Geneproof) with limit of detection around 123 UI/ml. Concurrent plasma CMV PCR was also performed in this setting.
The histological diagnosis of CMV GI disease was based on the existence of intranuclear and/or cytoplasmic viral inclusions. Preemptive treatment was initiated when plasma qPCR ≥150 copies/mL and curative antiviral therapy was initiated upon confirmation of CMV GI disease.

Results: Thirty-nine GI biopsy were performed in 25 patients, with a median age of 30 years (range, 7 – 50 y) and sex ratio of 2.6. Undelaying diseases included AML (n=8), ALL (n=9) and others (n=8). Before transplant, 35% of patients were in CR1 and 84% had positive CMV serostatus. A total of 20% of patients received TBI-based conditioning regimen. Stem cell source was bone marrow in 84% of patients. A GVHD was observed in 92% of patients and occurred before CMV infections (reactivation/suspected CMV GI disease) in 22 cases (88%).
Histological CMV GI disease was observed in 4/39 biopsies. Tissue CMV PCR was positive in 2/4 cases (both with negative CMV viremia). Among the 35 patients without histologic CMV GI disease, tissue CMV PCR was positive in 12 cases: 11 cases showed graft-versus-host disease (GVHD; 5 with low CMV plasma viral load <150 copies), and 1 case had chemical gastritis (negative CMV viremia). Tissue CMV PCR was negative in 23 cases, including 18 with GVHD (2 with low CMV plasma viral load), 2 with gastritis/colitis, and 3 non-contributive samples (all negative CMV viremia). These results demonstrate that tissue CMV PCR can detect viral presence even in biopsies without histologic confirmation of CMV.

Conclusions: CMV PCR on GI biopsy specimens provides complementary diagnostic information beyond histopathology and plasma PCR. Incorporating tissue PCR into the diagnostic workflow may enhance detection of CMV GI infection and guide timely antiviral therapy in allo-HSCT recipients.

Disclosure: Nothing to declare.

P160

ACICLOVIR-RESISTANT HERPES SIMPLEX VIRUS IN PEDIATRIC PATIENTS UNDERGOING ALLOGENEIC HAEMATOPOIETIC STEM CELL TRANSPLANT: A CASE SERIES

Jenna Nunn[1], *Ahmed Ahmed*[1], *Srividhya Senthil*[1], *Oana Mirci-Danicar*[1], *Denise Bonney*[1], *Claire Horgan*[1], *Omima Mustafa*[1], *Robert Wynn*[1], *Malcolm Guiver*[1], *Ramya Nataraj*[1]
[1]*Manchester University Foundation Trust, Manchester, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Herpes simplex virus (HSV) reactivation is a significant risk in haematopoietic stem cell transplant (HSCT) recipients and anti-viral resistance poses many clinical challenges.

Methods: We present a case series of nine pediatric patients with aciclovir-resistant HSV infection post allogeneic HSCT.

Results: Indications for HSCT included primary immunodeficiency, sickle cell disease, myelodysplastic syndrome (MDS) and relapsed/refractory leukaemia. T cell depletion was used in 5 patients (55%). Graft versus host disease occurred concomitantly in four patients (44%). All patients received aciclovir prophylaxis and were on immunosuppression at the time of HSV infection. TK mutations were the most common resistance mechanism (n= 7, 77%). Infections manifested as mucocutaneous disease, pneumonitis, keratitis, enterocolitis, and viraemia. Secondary complications included transplant-associated thrombotic microangiopathy (n=3, 33%), idiopathic pulmonary syndrome (n=3, 33%) and graft failure (n=2, 22%). All patients were treated with second-line antivirals (foscarnet and/or cidofovir), and three patients were treated with third-line antivirals (pritelivir). Treatment was complicated by nephrotoxicity (n=4, 44%). Adjunct treatments used included intravenous immunoglobulin (n=3, 33%) and donor lymphocyte infusion (n=1, 11%). Poor outcomes were seen across the cohort including death related to HSV infection and its complications (n=4, 44%).

Conclusions: Aciclovir-resistant HSV infection in pediatric HSCT recipients is associated with high morbidity and mortality, limited therapeutic options, and significant treatment-related toxicity. Early recognition, resistance testing, timely initiation of second-line therapy and weaning of immunosuppression are critical for disease control. Emerging therapies, such as helicase-primase inhibitors and adoptive T-cell therapy, hold promise but remain limited by access and pediatric data.

Clinical Trial Registry: n/a

A BUNDLED INTERVENTION TO REDUCE RISK OF CATHETER CENTRAL LINE ASSOCIATED BLOODSTREAM INFECTIONS (CLABSIS) FOLLOWING ALLOGENEIC STEM CELL TRANSPLANTATION

*Bruna Puglisi[1], Russel E. Lewis[2], Gabriella De Cicco[1], **Dario Schiavo**[1], Umberto Pizzano[1], Elena Bincoletto[1], Ivano Seccafien[1], Damiano Rondelli[3], Marta Stanzani[1]*
[1]Hematopoietic Stem Cell Transplant and Cell Therapy Program, Hematology Unit, Departement of Internal Medicine, Treviso, Italy, [2]Infectious Diseases, Departement of Molecular Medicine, Padova, Italy, [3]Division of Hematology/Oncology, University of Illinois at Chicago-UI Health, Chicago, United States of America (the)

Background: Catheter central line-associated bloodstream infections (CLABSIs) represent a major complication in allogeneic hematopoietic stem cell transplantation (allo-HSCT), with reported cumulative incidence rates varying widely from 9% to 66%. However, standardized care bundles have reported 60-70% reductions in CRBSI rates across multiple intervention studies, demonstrating that these infections are largely preventable.

Methods: We conducted a retrospective analysis CLABSIs of adult patients undergoing allogeneic HSCT between January 2024 and September 2025 at our newly established allo-HSCT program in Treviso, Italy. CLABSIs were classified according to EBMT ID Working party criteria. All patients received triple-lumen CVCs with a comprehensive CRBSI prevention bundle incorporating standard elements (hand hygiene, maximal sterile barriers, skin antisepsis, prompt catheter removal criteria). Intravenous infusions were administered through a 5-way RAMP manifold system (Fig 1a). This manifold, connected to the CVC via a 2-meter extension line and replaced every 72 hours, allowed centralized infusion management with dedicated lumens for Tacrolimus and Mycophenolate Mofetil (MMF), while the third lumen delivered all other therapies through the manifold system positioned distant from the insertion site of the patient.

Results: A total of 39 patients were included in the analysis. The median follow-up was 6 months. The median patient age was 60 years (range, 19–73). Donors were matched related (12.8%), matched unrelated (33.4%), mismatched unrelated (12.8%) or haploidentical (41%). Conditioning regimens were myeloablative, reduced intensity, or non-myeloablative in 43,5%, 36%, and 20,5% of patients, respectively. GvHD prophylaxis consisted of post-transplant cyclophosphamide, Tacrolimus, and MMF in 79.4% of patients.
Fluoroquinolone prophylaxis was not administered during the aplastic phase, as the policy of the centre. 77% of patients were colonized with antibiotic-resistant bacteria, as determined by rectal swab screening, at the time of admission.
During the hospitalisation, 84.6% of patients experienced one or more febrile episodes, where in 38.5% of these cases a microbiologically documented infection was identified.

Among these, one definite case of CLASBSI caused by *Staphylococcus epidermidis* and two probable CLABSI caused by *Staphylococcus aureus* BSI were identified. The incidence density of definite or probable CLABSI was 2.11 per 1000 patient days (95% CI 0.44-6.18). This incidence density is low relatively to previous literature reports (Fig 1 b).The median time to engraftment was 22 days, and the median length of hospitalization was 33 days. 1-year overall survival (OS) was 73.9% (95% CI: 58.6-93.2%) and 1-year non-relapse mortality (NRM) was 12.8%.

Figure 1) a. 5-way RAMP manifold system, b. CLABSI Incidence Rate (per 1000 catheter-days).

a.

Conclusions: Our newly established allogeneic HSCT program achieved a low incidence of CLABSIs through implementation of a comprehensive prevention bundle combined with a 5-way RAMP manifold system positioned distant from the CVC insertion site and changed every 72 hours. These results demonstrate that new transplant programs can achieve benchmark CLABSI prevention outcomes from inception through rigorous implementation of evidence-based strategies and innovative catheter management approaches.

Disclosure: Nothing to declare

P163

THE RELEVANCE OF PREVIOUSLY KNOWN BACTERIAL COLONIZATION IN DETERMINING THE ETIOLOGY OF BLOODSTREAM INFECTION IN HEMATO-ONCOLOGY PATIENTS: A TIMEFRAME ANALYSIS

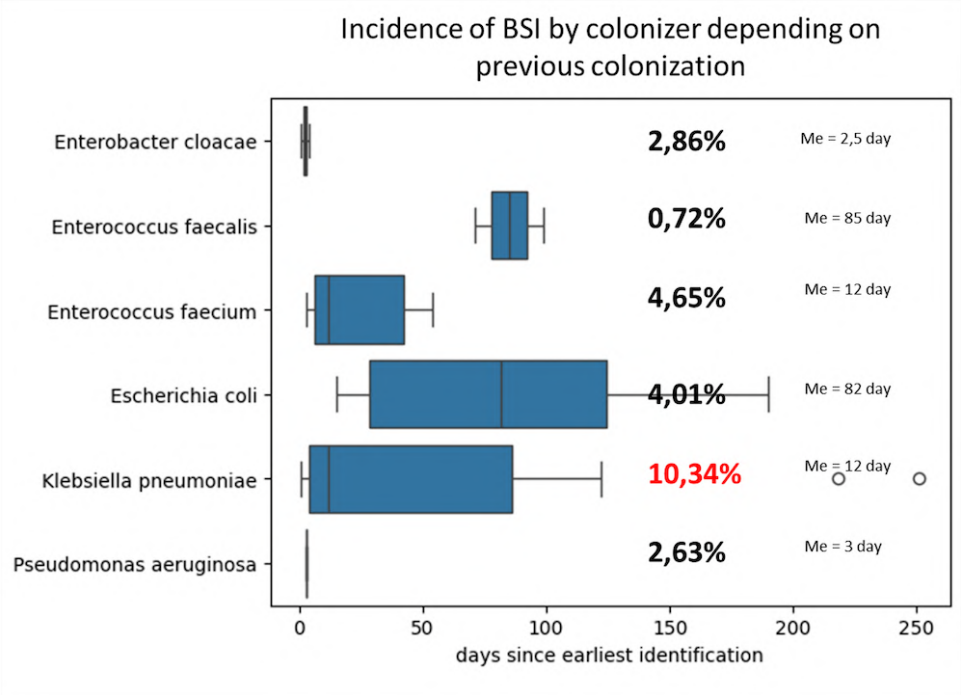
Ilya Potapov[1], *Iurii Osipov*[1], *Vladimir Ivanov*[1], *Dmitry Ovchinnikov*[1], *Galina Salogub*[1]
[1]*Almazov National Medical Research Centre, Saint Petersburg, Russian Federation (the)*

Background: Systematic microbial surveillance is currently recognized as a standard approach to guide treatment in high-risk hemato-oncology patients. Its clinical efficacy, however, is hampered by a lack of empirically defined protocols regarding monitoring frequency, optimal anatomical sampling sites, and the actionable significance of pre-existing colonization. This study aimed to delineate the timeframe of persistent colonization relevant for progression to bloodstream infection (BSI).

Methods: A retrospective analysis was performed using electronic health record (EHR) data from 373 patients of a high risk group defined by prolonged periods of Grade 4 neutropenia (>10 days) admitted to a hemato-oncology unit at a multi-specialty tertiary hospital between 01.01.2025 and 01.12.2025. During hospitalization, each patient underwent twice-weekly surveillance sampling from four non-sterile loci: rectal, buccal, and pharyngeal swabs, and a urine sample. In the event of a febrile episode, blood cultures were also obtained. The total number of bacteriological tests performed was 12,817 (urine - 3,143, buccal / pharyngeal swabs - 2,753, rectal swab - 2,582). All available microbiological data were analyzed to identify the most frequently detected bacterial species across the sampled non-sterile sites. For each confirmed bloodstream infection (BSI) episode, the first detection of the causative organism in any non-sterile site within the preceding 365 days was defined as the reference point for colonization.

Results: During the monitoring, Ac. baumannii was detected in 3.75% of patients (n=14), E. coli in 86.86% (n=324), Kl. pneumoniae in 46.65% (n=174), Enterobacter spp. in 18.77% (n=70), Enterococcus faecalis in 73.99% (n=276), Enterococcus faecium in 46.11% (n=172), Ps. aeruginosa in 10.19% (n=38), Stenotrophamonas maltophilia in 5.36% (n=20). Microorganisms of the Enterobacterales genus, as well as Enterococcus faecalis and faecium were significantly more often detected in rectal swab cultures, while Ac. baumannii and Stenotrophamonas maltophilia were more frequently detected in buccal / pharyngeal swabs, while the detection rate of Ps. aeruginosa was approximately the same for all of the loci (Table 1). A total of 41 cases of bloodstream infection were recorded during the observation period (including 3 cases of polymicrobial BSI). In patients with verified BSI, an identical pathogen was detected during the previous 2.5 to 85 days during microbiological monitoring (pathogen-specific parameters are presented in Fig). The most prominent causal inference between colonization and a BSI event appears to be observed for Kl. Pneumoniae, which may be associated with the spread of hypervirulent strains.

	Buccal swab	Rectal swab	Urine
Acinetobacter baumannii	57,14%	14,29%	21,43%
Enterobacter spp.	24,29%	68,57%	12,86%
Enterococcus faecalis	12,68%	85,14%	58,33%
Enterococcus faecium	20,35%	91,28%	30,81%
Escherichia coli	5,86%	97,53%	40,43%
Klebsiella pneumoniae	28,18%	86,21%	45,98%
Pseudomonas aeruginosa	42,11%	47,37%	31,58%
Stenotrophomonas maltophilia	45,00%	35,00%	15,00%



Conclusions: Microbiological examination of the rectal swab is the most informative method for detecting Enterobacterales. However, it should be noted that the reduction in the number

of analyzed infection loci may be due to the possibility of "missing" NGBN, which necessitates the continued need for microbiological examination of other loci. The data obtained suggest that prior colonization within the previous 2.5 to 85 days may be clinically significant, particularly in cases of Kl. pneumoniae detection (Me = 12 days), which has the highest rate of bloodstream infection detection. Further work should be aimed at determining the optimal frequency of microbiological monitoring, characterizing the virulence of identified microbial pathogens, and further improving approaches to antimicrobial therapy.

Disclosure: The authors have no potential conflict of interest to disclose.

P164

CLINICAL IMPACT OF HERPES ZOSTER INFECTION IN PATIENTS WITH PLASMA CELL DISORDERS: A RETROSPECTIVE STUDY

*Zehra Akşit Bozkina[1], **Ajda Güneş**[1], Nur Soyer[1], Meltem Taşbakan[2], Mahmut Töbü[1], Filiz Vural[1]*
[1]Faculty of Medicine, Ege University, Hematology, Izmir, Turkey, [2]Faculty of Medicine, Ege University, Infectious Diseases and Clinical Microbiology, Izmir, Turkey

Background: Multiple myeloma (MM) is a malignant plasma cell disorder that leads to bone destruction and bone marrow failure. It most commonly affects individuals between 65 and 74 years of age, with a median age at diagnosis of 69 years. Suppression of normal immunoglobulin production by the abnormal plasma cell clone results in impaired humoral immunity. The underlying immune dysfunction in plasma cell disorders predisposes patients to opportunistic infections such as herpes zoster (HZ). Approximately 10–60% of MM patients develop HZ infection, particularly after treatment with proteasome inhibitors or monoclonal antibodies if antiviral prophylaxis is not administered.

Methods: Between January 2008 and February 2025, a total of 353 patients diagnosed with multiple myeloma, amyloidosis, Waldenström macroglobulinemia, or solitary plasmacytoma in our clinic were screened. Among them, 34 patients who developed herpes zoster (HZ) infection were included in the study. The institutional database was reviewed in May 2025 to identify eligible cases for analysis.

Results:

Among the patients, 76.4% had MM alone, 14.7% had amyloidosis, one had plasma cell leukemia, one had solitary plasmacytoma, and one had Waldenström macroglobulinemia (WM). The baseline characteristics of the study population are summarized in Table 1. The median age at the time of HZ infection was 60 years. Overall, 55.8% of patients had IgG-type MM and 11.7% had IgA-type MM. Regarding comorbidities, two patients had a history of solid malignancy prior to diagnosis, and two developed acute myeloid leukemia (AML) during follow-up. At the time of HZ infection, 12.9% of cases had hypogammaglobulinemia (< 4 g/L). No HZ-related mortality was observed.Two patients who were receiving primary antiviral prophylaxis developed HZ within the first four months of prophylaxis initiation. Among patients on prophylaxis, 79% received acyclovir and 21% received valacyclovir. At the last follow-up, only 26.3% of patients were still receiving antiviral prophylaxis. Acyclovir

doses ranged from 200 mg (in patients with renal impairment) to 400–800 mg, while valacyclovir was administered in varying daily doses between 500 mg and 4000 mg.Postherpetic neuralgia (PHN) developed in 54.8% of patients. Hospitalization due to HZ infection occurred in only two cases. The median time between HZ infection and initiation of prophylactic antiviral therapy was 2.5 months. The median interval between disease diagnosis and the onset of HZ infection was 9.98 months, whereas in patients who developed HZ after autologous stem cell transplantation (ASCT), the median interval was 13.08 months. Overall, 35.3% of the patients died during follow-up, with a median overall survival of 129 months. The survival curve of the study cohort is shown in Figure 1.

Characteristic	**Total (n=34)**

Conclusions: The interplay between immune deficiency, recurrent infections, drug resistance, and disease progression underscores the need to further investigate prophylactic and immunotherapeutic strategies in MM. As MM requires long-term management, minimizing toxicity and improving quality of life should remain the main goals. The retrospective, single-center design caused missing data. Although HZ vaccines show high efficacy and safety, limited national access prevented vaccine data inclusion. Future prospective studies comparing prophylactic and vaccination approaches will help reduce morbidity and improve outcomes in MM patients.

P165

ACYCLOVIR PROPHYLAXIS FOR VARICELLA ZOSTER VIRUS REACTIVATION IN HEMATOPOIETIC CELL TRANSPLANTATION RECIPIENTS: WHAT IS THE TRULY EFFECTIVE LOW DOSE?

Ayşe Hilal Eroğlu Küçükdiler[1], *Sencer Küçük*[1], *Atakan Turgutkaya*[1], *Ali Zahit Bolaman*[1], *İrfan Yavaşoğlu*[1]
[1]*Aydın Adnan Menderes University, Aydın, Turkey*

Background: Autologous hematopoietic stem cell transplantation (auto-HCT) continues to have an impact on the treatment of patients with lymphoma and myeloma. *Varicella zoster* virus (VZV) reactivation is a known complication after auto-HCT. Currently, while guidelines strongly recommend the vaccination, it is an open question which acyclovir dose is beneficial. In this study, we evaluate the incidence of VZV reactivation with different doses of acyclovir prophylaxis in autograft recipients.

Methods: We retrospectively reviewed the clinical charts of 100 consecutive patients who underwent their first auto-HSCT at our institution from September 2021 and May 2025. Adult patients (>18 years) with follow-up for at least 6 months after transplantation were included in this study. SPSS 21 (Chicago, IL, USA) program was used for statistical analyses.

Results: The median age of the patients was 56.4 (19 -74). Forty-six were women, and 54 were men. Fifty-seven patients had MM, 25 had NHL, 16 had HL, 1 had AML, and 1 had APL. The median post-transplant neutrophil engraftment day was 14.5 days(min 10 – max 28).

The median follow-up period after auto-HCT was 23.6 (6-53) months. Four different doses of acyclovir were used for prophylaxis: 800 mg BID two days a week in three patients, 800 mg daily in 11 patients, 800 mg/day two days a week in 83 patients, and 200 mg three times daily in three patients. All patients who received prophylaxis for more than three months after auto-HCT were given acyclovir 800 mg/day twice a week. VZV reactivation developed in four patients whose characteristics are summarized in Table 1. Four patients had a history of shingles before auto-HCT, and none showed reactivation after transplantation. Thirty-six patients continued acyclovir prophylaxis without interruption. All of these patients were diagnosed with multiple myeloma and were receiving proteasome inhibitor therapy. Prophylaxis was discontinued in 64 patients; the median post-transplant prophylaxis duration was four months (min 3 months – max 12 months), and VZV reactivation was observed in only one of them.

Conclusions: The efficacy and safety of acyclovir/valacyclovir prophylaxis for VZV after transplantation are well established, although there is poor consensus on the dose and duration of prophylaxis. Current guidelines recommend acyclovir prophylaxis without a definite dosage. The meta-analysis of six studies with 3420 patients published by Seo et al. in 2017, the overall incidence of herpes zoster in the prophylaxis group is 7.8%. In the subgroup analysis of this study, the incidence was 15.44% in those who received prophylaxis for less than 1 year, while it was 2.1% in those who received it for at least 1 year. Another study in 2015, Kawamura et al., showed that the cumulative incidence of VZV disease after auto-HCT was 14.8% at 1 year, and after the cessation of acyclovir was 19.2%. In our study, the cumulative incidence of VZV reactivation was 4%, and the reactivation rate under prophylaxis was 8.3%, which is similar to the literature. Given the uncertain information in the literature regarding prophylactic dosage, our results are noteworthy, with similar reactivation rates and a tolerable, yet effective, lower dose.

Table 1: The characteristics of patients with VZV reactivation

Case	Age / Sex	Disease	Conditioning regimen	Neutrophil engraftment day	VZV reactivation after auto-HCT (months)	Acyclovir dose
1	58 / F	HL	BEAM	12	4	800 mg/day two days a week
2	66/ F	MM	Melphalan	16	10	800 mg/day two days a week
3	53/ F	NHL	Treosulphan-Fludarabine	11	5 (two months after cessation of	600mg/day everyday

					acyclovir prophylaxis)	
4	46/ F	MM	Melphalan	28	10	800 mg/day two days a week

PERSISTING FEVER AFTER ALLOGENEIC STEM CELL TRANSPLANTATION: A CASE REPORT OF A RARE INFECTION WITH LOMENTOSPORA PROLIFICANS

Janne Frömmichen[1], *Miriam Mozaffari Jovein*[1], *Theo Dähne*[2], *Ralph Wäsch*[1], *Robert Zeiser*[1], *Claudia Wehr*[1]
[1]*Department of Hematology, Oncology and Stem Cell Transplantation, Medical Center, Faculty of Medicine, University of Freiburg, Freiburg im Breisgau, Germany,* [2]*Institute of Virology, Medical Center, Faculty of Medicine, University of Freiburg, Freiburg im Breisgau, Germany*

Background: Primary antifungal prophylaxis substantially reduces the overall incidence of invasive fungal infections in immunocompromised patients but is increasingly associated with breakthrough infections caused by rare, intrinsically resistant molds, such as Lomentospora prolificans. Management of invasive Lomentospora infections remains challenging due to delayed diagnosis and limited therapeutic options, resulting in mortality rates approaching 90%.

Methods: This case report describes a fatal Lomentospora prolificans infection following allogeneic hematopoietic cell transplantation (allo-HSCT) and provides a critical appraisal of the clinical measures taken and omitted, with the aim of informing future management.

Results: A 70-year-old patient proceeded to allo-HSCT due to high risk chronic myelomonocytic leukemia (CMML), characterized by ASXL1, NRAS, RUNX1, SETBP1, and SRSF2 variants, leukocytosis above 13,000/µl and more than 5% bone marrow blasts (CPSS-Mol score = 5). Cytoreductive therapy with hydroxyurea was initiated immediately after diagnosis, with no other prior antineoplastic treatment administered. Conditioning with fludarabine, thiotepa, and melphalan was started 7 months after the initial diagnosis. No neutropenic episodes were reported before transplantation. The patient received an HLA-identical unrelated male donor peripheral blood stem cell graft, with graft-versus-host disease prophylaxis comprising cyclosporine, mycophenolate mofetil, and anti-thymocyte globulin (ATG). Pre-transplant routine chest CT showed no pulmonary infiltrates or signs of fungal infection. Antifungal prophylaxis with fluconazole was started at hospital admission. On day −3, the patient developed febrile neutropenia and broad-spectrum antibiotic treatment (piperacillin/tazobactam) was initiated. Recurrent fever on day +1 led to escalation to meropenem and a switch from fluconazole to posaconazole; blood cultures

remained negative.
Under these measures, the fever persisted. On day +10, the clinical condition worsened with development of tachyarrhythmia absoluta. On day +11, increasing somnolence, pathological breathing pattern, and new oxygen requirement prompted sampling of peripheral and central blood cultures and empiric addition of linezolid and tigecycline. Repeated CT revealed new pulmonary infiltrates and the patient was transferred to the intensive care unit (ICU). As the CT suggested an invasive mold infection, Isavuconazole was started immediately.
Septic shock and progressive respiratory failure led to death on day +13. Post-mortem microbiological examination confirmed Lomentospora prolificans in blood cultures obtained on day +11. Neutrophil engraftment was not achieved prior to the patient's death.

Conclusions: Only a small number of Lomentospora prolificans cases have been reported. In this case, we describe a patient with disseminated infection, most likely originating from a pulmonary focus. The diagnosis was established post mortem, highlighting the diagnostic challenges due to the need for fungal isolation, absence of specific biomarkers and the aggressive disease course. Earlier chest imaging and consideration of bronchoalveolar lavage (BAL) might have allowed earlier detection and intervention. However, BAL is not established as routine procedure in neutropenic patients after allo-HSCT at our institution. Given the organism's intrinsic resistance to most standard antifungals, current recommendations include combination therapy with voriconazole and terbinafine as first-line treatment, combined with surgical debridement and correction of neutropenia whenever feasible. Therefore, in transplant recipients with persistent fever despite adequate prophylaxis and empiric therapy, breakthrough infection with resistant molds such as Lomentospora prolificans should be actively considered.

PULMONARY COMPLICATION AFTER ALLO-HCT WITH EBV DETECTION IN BALF – A STUDY ON BEHALF OF THE PALG

Agnieszka Piekarska[1], *Karolina Beldzinska-Gadek*[1], *Agnieszka Tomaszewska*[2], *Joanna Drozd-Sokolowska*[2], *Malgorzata Sobczyk-Kruszelincka*[3], *Alicja Sadowska-Klasa*[1], *Jan Maciej Zaucha*[1], *Lidia Gil*[4]
[1]*University Clinical Centre, Medical University of Gdansk, Gdansk, Poland,* [2]*Medical University of Warsaw, Warsaw, Poland,* [3]*Maria Sklodowska-Curie National Research Institute of Oncology Gliwice Branch, Gliwice, Poland,* [4]*Poznan University of Medical Sciences, Poznan, Poland*

Background: Detection of cytomegalovirus (CMV) DNA in bronchoalveolar lavage fluid (BALf) in patients with lower respiratory tract infection (LRTI) may be associated with probable CMV disease. The available literature is very inconclusive on the clinical significance and management of Ebstein-Barr virus (EBV) identification in BALf. There is increasing data

on the association between viral LRTI and further development of lung graft-versus-host disease (GVHD) with bronchiolitis obliterans syndrome (BOS) phenotype. However, *shedding of Herpesviridae* of unknown significance is often observed in LRT across various conditions.

Methods: We surveyed transplant centers affiliated with the Polish Adult Leukemia Group (PALG) to identify centers that test for EBV in BALf in patients with pulmonary complications after allogeneic hematopoietic cell transplantation (allo-HCT). The data were then retrospectively collected from 3 transplant centers.

Results: In 16 patients diagnosed with LRTI or unexplained deterioration on pulmonary function tests, EBV DNA was detected. Most patients underwent allo-HCT for acute leukemia using myeloablative conditioning regimens (12/16; 75%), and 13/16 received a T-cell-depleting component (anti-thymocyte globulin or post-transplant cyclophosphamide) as part of their immunosuppression protocol. Haploidentical donors were used in 4/16 (25%). Median EBV load in BALf was 2593 IU/mL (138-151 000) and in 4/16 (25%) patients, EBV-DNA was simultaneously present in serum with a median load of 5438 IU/mL (133-25523). Eleven patients (69%) received rituximab at a dose of 375mg/m2 weekly with a median of 3 doses (1-4). In 11/16 (69%) patients, other co-pathogens were identified in BALf, including at least two co-pathogens in 4/11 (36%).
During the post-EBV detection period, 8/16 (50%) patients developed or experienced progression of chronic GVHD (a moderate/severe form), including 4/16 (25%) with non-infectious pulmonary complication: lung GVHD in two patients (bronchiolitis obliterans syndrome; BOS) and non-BOS restrictive pulmonary pathology in the other two. Seven (43.8%) patients died, and only one death was directly related to EBV (EBV-HLH), while two deaths were caused by pulmonary infectious complications during other LRTI episodes. Patients were divided into two groups: a sole EBV and a mixed EBV group if other clinically significant co-pathogens were identified in BALf. The detailed characteristics of the groups are presented in Table 1. In the sole EBV group, a viral load >10,000 was more common: 3/5 (60%) versus 4/11 (36%) in the mixed group. The outcomes of the groups were similar regarding pulmonary complications, including lung-GVHD. Deaths related to infections were only reported in the mixed group.

Table 1. Patient characteristics in the sole EBL group versus the mixed group (with clinically-relevant co-pathogens identified in BALf)

Abbreviations:
AA, aplastic anemia; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; ATG, anti-thymocyte globulin; BAL, bronchoalveolar lavage; BALf, BAL fluid; BOS, bronchiolitis obliterans syndrome; CLL, chronic lymphocytic leukemia; CMV, cytomegalovirus; EBV, Ebstein Barr virus; GVHD, graft-versus-host disease; Haplo, haploidentical donor; HL, Hodgkin lymphoma; NHL, non-Hodgkin lymphoma; MAC, myeloablative conditioning; MDS, myelodysplastic neoplasm; MM, multiple myeloma; MPN, myeloproliferative neoplasm; MSD, matched sibling donor; MUD, matched unrelated donor; mMUD, mis-matched unrelated donor; NMA, non-myeloablative conditioning; PTCy, post-transplant cyclophosphamide; RIC, reduced intensity conditioning; RTC, reduced toxicity conditioning

Conclusions: Clinical practice regarding the management of EBV DNA detection in BALf varies among PALG transplant centers. However, in most patients with EBV DNA detected, rituximab was prescribed despite a lack of recommendations.
In patients with a multifactorial etiology of LRTI, EBV DNA detection may reflect viral shedding. However, some patients with isolated EBV DNA in BALf developed immune-mediated sequelae leading to pulmonary complications.
Therefore, well-designed prospective studies are needed to determine a potential link of EBV with pulmonary post-transplant complications and the role of rituximab in management.

VERY EARLY-ONSET PULMONARY TUBERCULOSIS FOLLOWING ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION: A CASE REPORT

Duha Yahya[1], Hajira Karim[2], Bahadır Ceylan[2], Abdullah Kansu[2], Hüseyin Saffet Beköz[2], Süreyya Yiğit Kaya[2], ***Leylagül Kaynar***[2]
[1]Başakşehir Çam ve Sakura City Hospital, Istanbul, Turkey, [2]Istanbul Medipol University, Istanbul, Turkey

Background: Post-transplant infections are common after allogeneic hematopoietic stem cell transplantation (HSCT), but tuberculosis (TB) is a rare opportunistic pathogen in this setting. Most reported cases of post-HSCT TB occur several months after transplant, typically 2–6 months, when prolonged immunosuppression and graft-vs-host disease (GVHD) prophylaxis heighten susceptibility. TB presenting within the first few weeks post-transplant is exceedingly rare and diagnostically challenging. This case is noteworthy for an exceptionally early onset of pulmonary TB (Day +15 post-HSCT), underscoring the need for clinicians to maintain a high index of suspicion for TB even during the immediate post-transplant aplastic phase.

Methods: Ethics committee approval (E-10840098-202.3.02-7688) was obtained from the Istanbul Medipol University Ethics Committee. Patient information was obtained from the electronic system and patient files.

Results: A 23-year-old male with T-acute lymphoblastic leukemia (T-ALL) underwent allogeneic HSCT from an HLA-matched sibling donor. Pre-transplant screening for latent TB with an interferon-gamma release assay (QuantiFERON) was negative. On post-transplant Day +8, during bone marrow aplasia, he developed high-grade febrile neutropenia unresponsive to broad-spectrum antibiotics and later antifungal therapy. By Day +14, he exhibited progressive dyspnea and imaging revealed new patchy right upper lobe infiltrates on chest CT, raising suspicion of an atypical or opportunistic pneumonia (Figure 1).

On Day +15, bronchoalveolar lavage (BAL) was performed. Conventional microbiology was unrevealing: the acid-fast bacilli smear was negative and mycobacterial cultures later showed no growth. However, a rapid PCR-based assay on the BAL fluid detected Mycobacterium tuberculosis, confirming the diagnosis of pulmonary TB. Standard four-drug anti-TB therapy (isoniazid, rifampicin, pyrazinamide, ethambutol) was initiated immediately. The patient's fever defervesced by Day +17 with marked clinical improvement and concurrent neutrophil/platelet engraftment. His course was complicated by Grade III acute cutaneous GVHD, which emerged during TB treatment and required corticosteroids, ruxolitinib and extracorporeal photopheresis for control. Notably, rifampicin's cytochrome P450 induction necessitated close monitoring and adjustment of his calcineurin inhibitor

(cyclosporine) doses to maintain adequate immunosuppression. The patient completed a full course of anti-TB therapy without significant toxicity and achieved durable resolution of TB. At last follow-up, he completed TB therapy without relapse of tuberculosis, GVHD flare, or underlying malignancy.

Conclusions: In conclusion, we report a rare very early-onset pulmonary TB occurring on Day +15 after an allogeneic HSCT for T-ALL. This case demonstrates that tuberculosis, though uncommon, can emerge even in the immediate post-transplant period. Clinicians should not dismiss TB as a cause of fever and pulmonary infiltrates during the aplastic phase, especially in patients from TB-endemic areas. Early diagnostic intervention (including bronchoscopy and molecular testing) facilitated prompt anti-TB treatment in our patient, resulting in defervescence and favorable outcomes despite concurrent GVHD. This experience reinforces the need for heightened awareness of TB in post-transplant patients and rapid diagnostic strategies to improve patient outcomes.

Disclosure: Nothing to declare.

P169

REAL-WORLD UTILIZATION AND EFFICACY OF LETERMOVIR PROPHYLAXIS IN ADULT ALLOGENEIC HAEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS: SUBGROUP ANALYSIS DEFENDER STUDY

Nataraj KS[1], *Sameer Ramesh Melinkeri*[2], *Gaurav Kharya*[3], *Nidhi Jain*[4], *Kasi Viswanathan*[5], *Rajat Bhattacharyya*[6], *Santanu Sen*[7], *Megala Chandrashekar*[1], *Yesheswini N. Naik*[1], *Shilpa Hm*[1], *Suyash Bharat*[8]
[1]*HCG Cancer Centre, Bangalore, India,* [2]*Deenanath Mangeshkar Hospital & Research Center, Pune, India,* [3]*Indraprastha Apollo Hospital, New Delhi, India,* [4]*Zydus Cancer Hospital, Ahmedabad, India,* [5]*Meenakshi Mission Hospital & Research Centre, Madurai, India,* [6]*Apollo Multispeciality Hospital, Kolkata, India,* [7]*Kokilaben Dhirubhai Ambani Hospital and Medical Research Institute, Mumbai, India,* [8]*Zydus Lifesciences Ltd, Ahmedabad, India*

Background: Cytomegalovirus (CMV) reactivation remains a significant cause of morbidity and mortality in adult allogeneic haematopoietic stem cell transplantation (allo-HSCT) recipients, with limited real-world data on generic bioequivalent letermovir formulations in routine clinical practice.

Methods: This retrospective observational study evaluated bioequivalent generic Letermovir (Anvimo) utilization patterns and outcomes in 55 adult allo-HSCT recipients who received letermovir for CMV prophylaxis. Data were extracted from electronic medical records of patients who received letermovir for CMV prophylaxis between January 2025 and December 2025. Primary outcomes included CMV reactivation rates and utilization patterns. Secondary outcomes assessed adverse events, drug interactions, discontinuation rates, and mortality. Statistical analysis included descriptive statistics, Chi-square tests for categorical variables, and Kaplan-Meier analysis for time to CMV reactivation.

Results: The mean age of study participants was 39.40±15.7 years and the mean weight was 64.83±11.73 kg. Median duration of letermovir therapy was 91 days (range 45-100). Patients underwent transplantation for various haematological malignancies (AML 34.55%, ALL 20.00%, MDS 14.55%, others 30.90%) with diverse HLA compatibility (haploidentical TCR 45.45%, HLA matched related 34.55%, haploidentical TCD 10.91%, matched unrelated 9.09%). Conditioning regimens included myeloablative (52.73%), reduced intensity (45.45%), and non-myeloablative (1.82%). CMV serostatus distribution was D+/R+ (58.18%), D-/R- (40.00%), and D-/R+ (1.82%), with 45.45% classified as high-risk. Letermovir was administered at 240 mg (45.45%) or 480 mg (54.55%) doses, primarily as primary prophylaxis (98.18%). GVHD prophylaxis included post-transplant cyclophosphamide (63.64%), tacrolimus (45.45%), cyclosporine (41.82%), and mycophenolate mofetil (38.18%). CMV reactivation occurred in 14 patients (25.45%), with 9 (16.36%) progressing to clinically significant reactivation while on Letermovir prophylaxis, rest had reactivation post planned primary prophylaxis with Letermovir. Kaplan-Meier analysis showed mean time to clinically significant CMV reactivation of 177.8 days (95% CI: 158.6-197.0) and median of 198 days (95% CI: 198.0-208.0), with CMV-free survival of 82.5% at day 100. Dose modification was required in 41.82%. Pre-emptive therapy was given to 25.45%: ganciclovir (14.55%), valganciclovir (7.27%), cidofovir (3.64%). Early discontinuation occurred in

25.45% due to CMV reactivation (14.55%), death (5.45%), adverse events (3.64%), or physician decision (1.82%); 74.55% completed planned duration. Adverse events were minimal (vomiting 5.45%). At day 100, 48 patients (87.27%) were alive, 1 (1.82%) alive with relapse, and 6 (10.91%) deceased. Acute GVHD developed in 32.73% (grade 1: 5.45%, grade 2: 12.73%, grade 4: 3.64%, grade unspecified: 10.91%).

Conclusions: Bioequivalent Generic Letermovir (Anvimo) prophylaxis in adult allo-HSCT recipients demonstrated favourable real-world effectiveness with low rates of CMV reactivation and clinically significant reactivation. The 100-day survival rate and low adverse event profile support the safety and tolerability of letermovir in routine clinical practice.

Disclosure: Nothing to declare

P170

POSTINFLAMMATORY HYPERPIGMENTATION AND ATROPHIC SCARS AFTER HERPES ZOSTER IN ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANT PATIENT: CLINICAL CASE REPORT AND COSMETOLOGY TREATMENT OPTIONS

Anna Dmitrova[1], *Milana Dadaeva*[1]
[1]*MaVie Clinique, Moscow, Russian Federation (the)*

Background: Infectious complications in patients after allogeneic hematopoietic stem cell transplantation (allo-HSCT) are the most frequent life-threatening issues that cause organ damage, pancytopenia, adverse outcomes and reduced quality of life.
Despite antiviral prophylaxis herpes zoster (HZ) is a common complication after allo-HSCT resulting from the reactivation of varicella-zoster virus from its latent state. Some patients suffer from post-infectious skin complications such as postinflammatory hyperpigmentation (PIH), scars and postherpetic neuralgia.
We report a clinical case of late-onset PIH and atrophic scars after HZ in patient after allo-HSCT and its treatment with cosmetology techniques that interrupted due to leukemia relapse.

Methods: 32-years old patient diagnosed with B-cell acute lymphoblastic leukemia (B-ALL) and treated with allo-HCST from haploidentical donor in 2024 in National Medical Research Center for hematology in Russia. On +180 day after allo-HSCT she developed painful localized rash (vesicles) and deep blisters affecting the thoracic dermatome and the lower third of the face. She diagnosed with HZ and treated with antiviral agents. Recovery completed within 4 weeks. Deep blisters healed with atrophic scars. The area of the skin eruption of herpes zoster became discolored.
On +1 year after allo-HSCT patient started treatment in aesthetic medicine clinic with hematologists and dermatologists. The patient was in complete remission after allo-HSCT and there were no clinical features of chronic graft-versus-host disease. Physical examination revealed PIH on the skin of the right side of the neck, right ear and the lower third of the face. In the area of the previous blisters of the HZ infection presented depigmented atrophic

scars with prominent arborizing vessels.
In scar and PIH treatment protocols we included 3 procedures of radiofrequency microneedling treatment within 3 months. Then to target hyperpigmentation and to improve the texture of the damaged skin we performed 2 procedures of broadband light therapy and 2 procedures of 1927 nm laser within 2 months. On +1.5 year after allo-HSCT we interrupted the treatment in cosmetology due to patients' leukemia relapse.

Results:

Table 1. Global Aesthetic Improvement Scale (GAIS)

Score	Description
1	Very much improved
2	Much improved
3	Improved
4	No change
5	Worse
6	Much worse

Follow-up of 5 months revealed visible improvements of PIH area like brightening of the dark spots, reducing the appearance of the arborized vessels on dermoscopy and improving scar appearance. The preliminary results of unfinished treatment are presented on the image 1 and include before/after and 3D skin imaging system photos. To evaluate the results, we utilized the Global Aesthetic Improvement Scale (GAIS) and the patients score was 3 point (improved: marked improvement in appearance from the initial condition but not completely optimal).

Conclusions: PIH and skin eruptions like scarring after HZ are not associated with the life-threatening conditions but significantly reduce the quality of patients' life. The management of PIH and scars in immunocompromised patients after allo-HSCT has no specific unified protocols but early inclusion of cosmetology treatment options should be considered more. To continue the unfinished treatment plans like collagen and hyaluronic acid filler injections, laser resurfacing of the scars the patient should firstly be treated for relapsed B-ALL.

Disclosure: Nothing to declare.

P171

HRCT LUNG FINDINGS OF HUMAN METAPNEUMOVIRUS (HMPV) IN PATIENTS WITH HAEMATOLOGICAL MALGNANCIES POST BMT: THE GREAT MIMICKER

Amrita Guha[1]
[1]*Homi Bhabha National University, Advanced Centre for Treatment, Research and Education in Cancer (ACTREC), Homi Bhaba National Institute, Navi Mumbai, India*

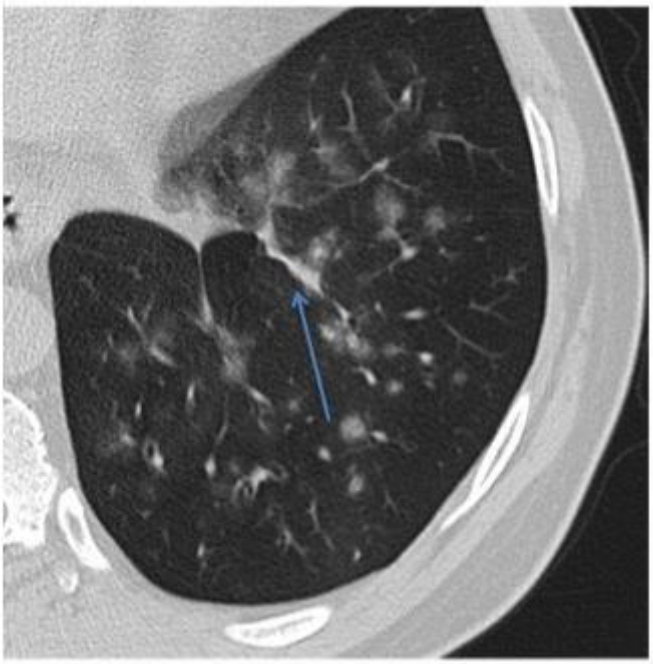
Background: Human metapneumovirus usually involves upper respiratory tract, however there are increasing cases of lower respiratory tract infection being reported, particularly in patients post BMT. Through this exhibit we aim to showcase our experience with different presentations of HMPV and its differentials.

1. To illustrate the different presentations of HMPV in lung parenchyma on CT.
2. Patterned approach to imaging clues for differential diagnosis.

Methods: We analyzed electronic medical records for microbiologically confirmed HMPV cases in patients with haematological malignancies post BMT. Inclusion criteria required a good quality HRCT scan performed within one week of confirmation. Nine patients meeting the criteria were retrospectively identified. Patient demographics, underlying malignancies, and specific HRCT patterns were recorded and analyzed by an expert radiologist.

Results: The cohort consisted of 9 patients (mean age 44.2 years, range 25–61 years), with a female predominance (67%). Radiological abnormalities were present in 7 out of 9 patients (78%). The most frequent radiological pattern was Nodules with Ground-Glass Opacities (GGOs), seen in 4 cases (44%). Other patterns included Centrilobular Nodules (2 cases), Consolidation with GGOs (2 cases), Interstitial Thickening (1 case), Bronchiolitis (1 case), and Pleural Effusion (1 case). Importantly, none of the patients demonstrated cavitation, the

halo sign, or lymphadenopathy. Two patients (22%) had no significant imaging findings.



Conclusions: HMPV infection in patients with hematological malignancies post transplant often manifests on HRCT as nodular GGOs, centrilobular nodules, or consolidation, mimicking other viral, bacterial, and opportunistic fungal infections. The absence of features like cavitation can provide subtle clues, but HMPV remains a "great mimicker" and should be included in the differential diagnosis of pneumonitis in this high-risk population.

ASTROVIRUS ENCEPHALITIS STATUS POST STEM CELL TRANSPLANT

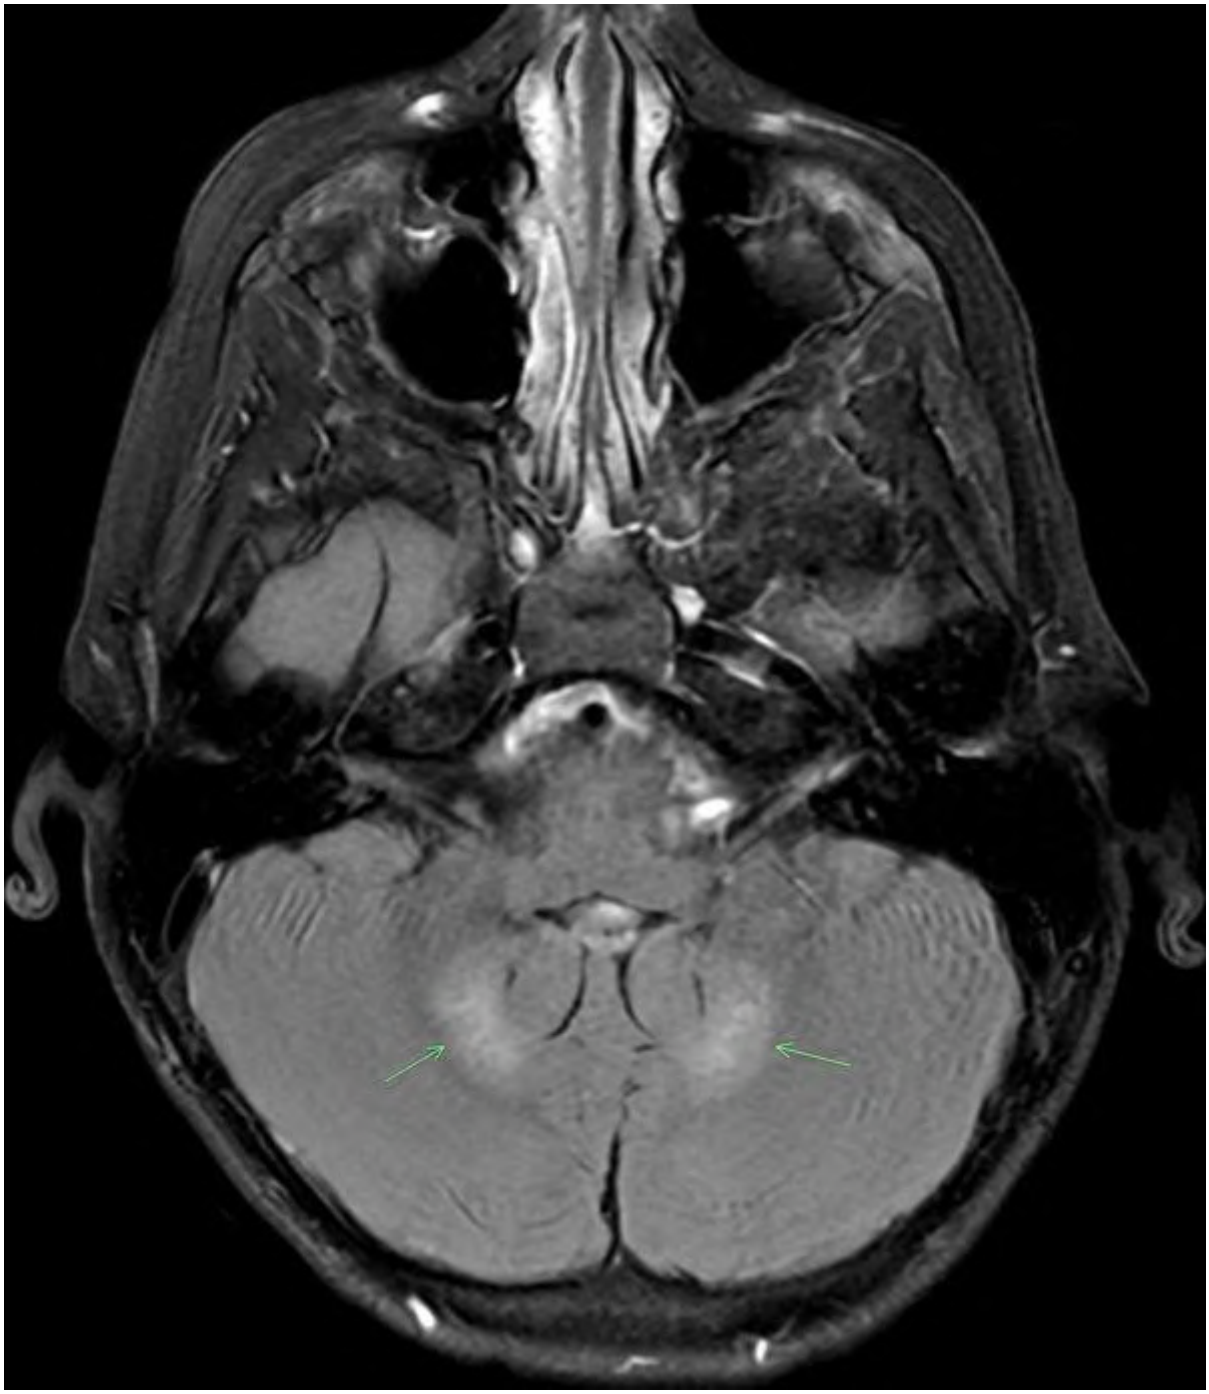
Alan Siegel[1], Catherine Bollard[1], Benjamin Hanisch[1], Michael Keller[1], Roger Packer[1], Gilbert Vezina[1], ***David Jacobsohn***[1]
[1]*Children's National Hospital, Washington, United States of America (the)*

Background: Human astrovirus is classically an enteric pathogen but has emerged as a cause of severe central nervous system (CNS) disease in immunocompromised patients. Neurovirulent strains such as HAstV-VA1 are typically undetectable by standard CSF assays, contributing to diagnostic delay. Since 2010, metagenomic next-generation sequencing (mNGS) has been critical in diagnosing astrovirus encephalitis, although no standard treatment exists and reported mortality is high. We describe a child with relapsed Infantile B-

cell acute lymphoblastic leukemia (B-ALL) who developed progressive encephalopathy following haploidentical peripheral blood stem cell transplant (PBSCT) and was ultimately diagnosed with astrovirus encephalitis using mNGS.

Methods: We describe a 4-year-old boy with relapsed KMT2A-rearranged B-ALL who underwent haploidentical A/B T-cell–depleted PBSCT after bridging chemotherapy. Preparative regimen was TBI (1200 cGY), cyclophosphamide, thiotepa, and distal rabbit ATG without GVHD prophylaxis. Post-transplant complications included cytokine release syndrome, and CMV-, BK-, and adeno-viremia without GVHD.
Around day +90 post-PBSCT, the patient had increased somnolence and behavioral changes without focal deficits and was hospitalized for acute altered mental status on day +91. A complete metabolic and infectious workup and MRI/MRA were non-diagnostic. EEG showed non-specific diffuse cerebral dysfunction. After transient clinical improvement, he experienced progressive decline and was readmitted on day +102 with severe encephalopathy, mutism, bowel incontinence, decreased mobility, and upper-extremity abnormal movements.
Repeat CSF studies included cell count, protein/glucose, bacterial culture, meningoencephalitis panel, HSV PCR, adenovirus PCR, BK virus, autoimmune encephalitis panel, and mNGS. MRI with contrast was repeated. Therapies included empiric cidofovir for adenovirus viremia, and therapeutic plasma exchange (TPE) for a possible immune-mediated process.

Results:



Conventional CSF studies, PCR-based viral assays, and autoimmune testing were negative. Repeat MRI demonstrated enhancement of bilateral oculomotor, trigeminal, and facial–vestibulocochlear nerve complexes, as well as T2 hyperintensity of the dentate nuclei (Image 1) and right thalamus, consistent with infectious or inflammatory meningoencephalitis.

mNGS of CSF subsequently identified human astrovirus VA1, establishing the diagnosis. Antiviral treatments included: administrations of high-dose IVIG, ribavirin, nitazoxanide and remdesivir. Following this multi-treatment approach, neurologic deterioration stabilized and autonomic instability improved. Follow-up CSF mNGS was negative; however, clearance is difficult to interpret due to low sensitivity. The patient remains hospitalized at day+146 undergoing supportive care and continued antiviral therapy including multivirus specific T cells.

Conclusions: Astrovirus encephalitis is a rare but important cause of neurologic decline after HSCT, particularly in patients with T-cell dysfunction. Diagnosis often requires mNGS, as routine CSF testing may be negative. Early consideration of atypical neurotropic viruses is essential when evaluating unexplained encephalopathy in post-transplant patients due to the high morbidity and mortality. Combination antiviral may stabilize disease, although optimal treatment remains undefined. This case underscores the critical role of mNGS in timely diagnosis and highlights the ongoing need for evidence-based therapeutic strategies for astrovirus CNS infection in PBSCT recipients.

P173

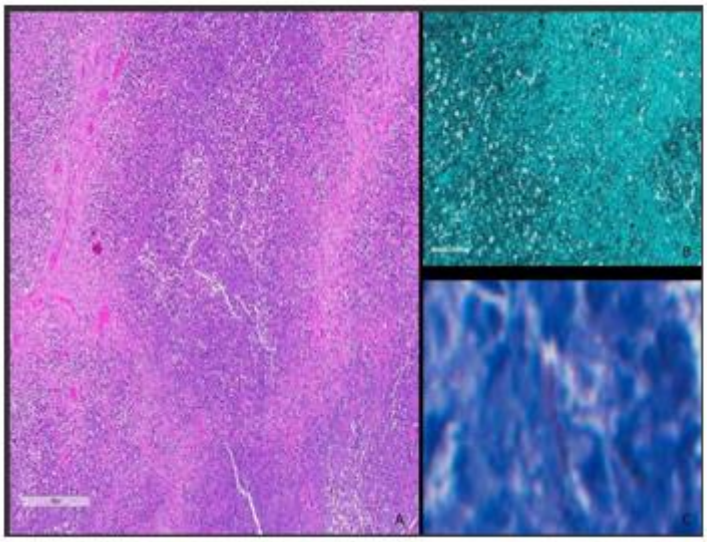
NOCARDIOSIS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION: DIAGNOSTIC PITFALLS, THERAPEUTIC CHALLENGES, AND DIVERGENT CLINICAL OUTCOMES—A DECADE-LONG CASE SERIES

Shahbaz Memon[1,2,3], *Mohammed Essa*[1,2,3], *Maysam Ali A Alamri*[2], *Layan Omar A Alhudaif*[2], *Mohsen Al Zahrani*[1,2,3], *Bader Ahmari*[1,2,3], *Saeed Alshieban*[1,2,3], *Hala Alsamani Hassan Saad*[1]
[1]*Ministry of National Guard and Health Affairs, Riyadh, Saudi Arabia,* [2]*King Saud Bin Abdulaziz University for Health Sciences, Riyadh, Saudi Arabia,* [3]*King Abdullah International Medical Research Center, Riyadh, Saudi Arabia*

Background: Nocardiosis is a known but rare infection in stem cell transplant patients, caused by multiple Nocardia species. It has been estimated to occur in 0.3-1.7% of allogeneic hematopoietic stem cell transplant (HSCT) recipients. It is considered an opportunistic infection, and a significant risk factor is being immunocompromised. This report describes a heterogeneous group of three cases of nocardiosis over 10 years, one pediatric and two adult cases, with divergent clinical presentations, distinct Nocardia species, and contrasting treatment outcomes.

Methods: A retrospective observational study was conducted at the department of Pediatric and Adult Bone Marrow Transplant Unit between 2015 and 2024. Here we describe a case series describing three patients who developed nocardiosis post-hematopoietic stem cell transplantation: an adult male with disseminated pulmonary disease, a middle-aged woman with isolated CNS involvement, and a pediatric patient with multisystem dissemination.

Results: The patients, ranging from age 7 to 53 years of age, post stem cell transplant, in pediatric and adult stem cell transplant units, encountered Nocardiosis infection post SCT in BMT units.
-Patient 1: An adult with a T cell background, unfortunately, had graft failure, had very low counts, leading to severe Nocardiosis and PICU admission, followed by respiratory failure and death.
-Patient 2: A 44-year-old woman with refractory myeloma had an autologous stem cell transplant and later on an allogeneic stem cell transplant with myeloablative conditioning chemotherapy. The pt. had complicated CNS Nocardiosis post second SCT, confirmed with brain biopsy, successfully treated with almost one year of antibiotic therapy.
-Patient 3: A 7-year-old girl with Familial Haemophagocytic lymphohistiocytosis (HLH). She went through for the second SCT due to graft failure post-first SCT. She was later complicated with disseminated nocardiosis involving the lungs, brain, and skin, successfully cured with 18 months of antibiotic therapy.



Histological findings of brain lesion biopsy. There are multiple foci of suppurative inflammation and micro-abscess formation (A, H&E stain, 10X). GMS stain highlights numerous branching filamentous micro-organisms (B, GMS stain, 40X). Fite stain highlights filamentous rod of *Nocardia* (C, Fite stain, 60X).

Clinical details of three Nocardiosis cases after hematopoietic stem cell transplant.

	Case 1	Case 2	Case 3
Age/gender	53 years male	44 years old female	7 years
Primary diagnosis	T cell acute lymphoblastic leukemia/lymphoma	Refractory multiple myeloma	Familial Hemophagocytic Lymphohistiocytosis.
immune status	Allogenic HSCT with graft failure	Autologous and allogenic HSCT	Allogenic SCT two times

Nocardia species	Nocardia cyriacigeorgica	Nocardia Farcinica	Nocardia cyriacigeorgica
site of infection	Pulmonary (Disseminated).	CNS	Disseminated (CNS, lungs, skin)
Diagnostic methods	Blood cultures	Imagings+biospy	Imagings+biospy
anti-microbial therapy	Imipenem, amikacin, trimethoprim-sulfamethoxazole	Imipenem, moxifloxacin and trimethoprim-sulfamethoxazole	Ceftriaxone, amikacin, moxifloxacin and trimethoprim-sulfamethoxazole
Duration of therapy	10 days	12 months	18 months
Outcome	Died	survived	survived

Conclusions: This case series contributes to the growing body of evidence surrounding nocardiosis in HSCT recipients. Given the high mortality associated with it, clinicians should maintain a high index of suspicion in severe immunocompromised or heavily chemotherapy-treated patients presenting with unexplained pulmonary, skin, or neurological symptoms. Early recognition, appropriate diagnostic strategies, a multidisciplinary approach, and prompt initiation of antibiotic therapy are essential for optimizing outcomes and improving survival in high-risk populations.

LATE CYTOMEGALOVIRUS INFECTION IN ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANT RECIPIENTS AFTER COMPLETING LETERMOVIR PRIMARY PROPHYLAXIS – A SINGLE-CENTER PRELIMINARY ANALYSIS

Agnieszka Tomaszewska[1], *Kacprzyk Piotr*[1], *Ewa Karakulska-Prystupiuk*[1], *Joanna Drozd-Sokołowska*[1], *Błażej Izdebski*[2], *Piotr Boguradzki*[1], *Kamila Skwierawska*[2], *Katarzyna Pruszczyk-Matusiak*[2], *Grzegorz Basak*[1]
[1]*Medical University of Warsaw, Warsaw, Poland,* [2]*University Clinical Center of the Medical University of Warsaw, Warsaw, Poland*

Background: Cytomegalovirus (CMV) remains the most important viral pathogen in patients after allogeneic hematopoietic cell transplantation (allo-HCT). Letermovir (LTV) prophylaxis against CMV infection during the first 100 days after allo-HCT is a standard of care in

seropositive recipients. The published data regarding late CMV infection after completing LTV prophylaxis are non-exhaustive and inconclusive.

Methods: We evaluated frequency and main risk factors of any late CMV infection (CMV DNAemia and clinically significant infection-csCMVi) in 81 consecutive allo-HCT conducted in Department of Hematology, Transplantation and Internal Medicine of Medical University of Warsaw between October 2022 and March 2025 in 76 seropositive recipients who received letermovir prophylaxis until the day +100 (5 patients underwent the second allo-HCT, 4 due to relapse of underlying disease).

Results: We identified 35 (43%) CMV late infections in our cohort of transplants but the most cases demonstrated low viral load and were self-limiting. Only 6 (6/35-17%; 6/81–7%) infections were csCMVi and required antiviral therapy. Most recipients underwent allo-HCT due to acute leukaemia (AML–50, ALL–9) with use of myeloablative conditioning regimens in 59 (72%) procedures and in 73/81 (90%) transplants T-cell-depleting component (anti-thymocyte globulin or post-transplant cyclophosphamide) was applied. The median recipient age was 53 (18-72) and median donor age was 29 (18-59). Used donors were matched sibling (MSD) in 12 procedures, matched unrelated (MUD) in 56, mismatched unrelated (mMUD) in 7 and haploidentical in 6, respectively. 29 donors were CMV seronegative – in 15 patients with seronegative donor CMV late infection was diagnosed and 4 was csCMVi. CMV "blips" were diagnosed in 10 patients during LTV prophylaxis and in 5 of these patients any CMV late infection occurred but only in 1 recipient csCMVi. Median immunoglobulin G (IgG) concentration in patients with CMV late infection was 637 mg/dL (117-1829 mg/dL; normal value-700-1600 mg/dL) in comparison to 754 mg/dL (361-1587 mg/dL) in those without late infection. During follow-up, 11 recipients developed acute GvHD and 17 chronic GVHD requiring additional immunosuppressive treatment, 13 patients received ruxolitinib as a second line therapy of GvHD. In 10 of 13 (77%) patients on ruxolitinib therapy any CMV late infection was diagnosed but only in 1 was csCMVi. In 17/35 (47%) recipients with any CMV infection other viral co-pathogens were detected: EBV in 12, BKV in 3, HHV-6 in 1 and AdV in 1, respectively. Relapse of underlying disease was diagnosed in 15/76 (20%) recipients after allo-HCT and in 8 (53%) of them CMV DNA was detected.13/76 (17%) patients died and no one death was directly related to CMV late infection, but 6 (46%) recipients who died presented any CMV late infection during observation.

Conclusions: Primary anti-CMV prophylaxis with LTV substantially reduced occurrence of csCMVi within the first 100 days after allo-HCT. However, any late CMV infection after completing LTV prophylaxis (beyond day +100) is diagnosed in a significant group of recipients (43% in our cohort). Selected risk factors for this complication could be characterized but further studies are needed to determine if and in whom extending the duration of primary LTV prophylaxis is beneficial.

Disclosure: Nothing to declare.

P176

TRIAL IN PROGRESS: A PHASE 2, SINGLE-ARM, MULTICENTER STUDY OF MARIBAVIR FOR CYTOMEGALOVIRUS INFECTION IN PATIENTS WITH LYMPHOID MALIGNANCIES UNDERGOING BISPECIFIC ANTIBODIES (MALMBA)

Soyean Kwon[1], *Chan Mi Lee*[2], *Youngil Koh*[2], *Dong-Yeop Shin*[2], *Junshik Hong*[2], *Hyungwoo Cho*[3], *Sung-Yeon Cho*[4], *Jamin Byun*[2]
[1]*Boramae Hospital, Seoul, Korea (the Republic of),* [2]*Seoul National University Hospital, Seoul, Korea (the Republic of),* [3]*Asan Medical Center, Seoul, Korea (the Republic of),* [4]*Seoul St. Mary's Hospital, Seoul, Korea (the Republic of)*

Background: Maribavir is an oral, highly selective antiviral agent that inhibits the CMV UL97 kinase, thereby interfering with viral DNA maturation and nuclear egress. Unlike conventional CMV agents such as ganciclovir, cidofovir, and foscarnet—often restricted by myelosuppression or renal toxicity—maribavir provides robust antiviral activity without hematologic toxicity, supporting its use in immunocompromised populations.
Bispecific antibodies (BsAbs) have emerged as an important therapeutic class in multiple myeloma (MM) and B-cell lymphomas, but their use is associated with increased infectious risk due to immunoglobulin suppression, B-cell depletion, cytopenias, and impaired cellular immunity. In MM, clinically significant CMV reactivation or infection has been reported in up to 33% of BsAb recipients, with susceptibility potentially amplified in regions with high CMV seroprevalence. In B-cell lymphomas, CMV is often mentioned as one of the etiologies of fatal infection.

Methods: This is an open-label, single arm, multicenter study conducted in Korea and registered on clinicaltrials.gov as NCT07014319.
Eligible participants are adults with lymphoid malignancies who are receiving approved or investigational BsAbs and develop clinically significant CMV infection, defined as CMV end-organ disease or plasma CMV DNA ≥500 IU/mL in two consecutive assessments accompanied by investigator determination that treatment is indicated. Patients must have adequate organ function and be able to undergo weekly virologic monitoring. Individuals with severe renal or hepatic dysfunction, uncontrolled active viral infections (HIV, replicative HBV, or HCV), pregnancy, or conditions that prevent maribavir administration will be excluded.
All participants will receive maribavir 400 mg orally twice daily from Week 1 until CMV DNA becomes unquantifiable or <500 IU/mL in the absence of CMV end-organ disease. CMV viral loads will be assessed weekly using quantitative plasma CMV DNA PCR, with additional diagnostic evaluation performed as clinically indicated for suspected CMV disease.
Primary endpoints comprise both efficacy and safety measures, including the proportion of patients achieving CMV DNA <500 IU/mL, time to reaching this threshold, and the characterization of maribavir safety based on the type, frequency, severity of adverse events and their relationship to maribavir. Secondary endpoints include the time to a >1 log10 reduction in CMV DNA from baseline, the proportion achieving such decline, and the rate of breakthrough CMV disease. CMV-specific cellular immune responses (CMV-CMI) to IE-1 and pp65 will be assessed as exploratory endpoints at screening and at end of treatment (EOT)

using a T-SPOT.CMV ELISpot assay, with interferon-γ–producing CD4+ and CD8+ T-cell spot counts quantified per 250,000 PBMCs.

Results: No data are available at this stage as the trial is ongoing.

Conclusions: No data are available at this stage as the trial is ongoing.

Clinical Trial Registry: NCT07014319

P177

OUTCOMES OF USING GENERIC LETERMOVIR FOR CMV PROPHYLAXIS IN HSCT: RETROSPECTIVE ANALYSIS

Anil Aribandi[1], *Chaitanya G B*[1], *Ranjit Kumar C.S*[1], *Bhavya Sri Vallamshetla*[1]
[1]*Sindhu Hospitals, Hyderabad, India*

Background: CMV infection remains a major cause of morbidity and mortality following allogeneic hematopoietic stem cell transplant (allo- HSCT). Antiviral prophylaxis with Ganciclovir or Valganciclovir is limited by myelosuppression. Letermovir is an effective alternative with minimal side effect profile.
We aimed to study the outcome of using generic Letermovir in allo-HSCT recipients as primary prophylaxis. Outcome was assessed based on the cumulative incidence of CMV reactivation in our study population at D+100 after HSCT.

Methods: This is a retrospective study of patients undergoing allogeneic HSCT (n=27) between March and November 2025 at Sindhu Hospitals, Hyderabad. All patients were initiated on Letermovir prophylaxis from Day+1 of transplantation and continued till D+100. Patients who died prior to engraftment were excluded. CMV viral load monitoring was done by quantitative PCR. Data was collected from electronic medical record. Statistical analyses were performed using SPSS software.

Results: Total 27 patients were enrolled in the study, including both children and adults. 14(51.8%) were children<18yrs and 13(48.1%) were adults>18yrs. There was a male predominance (M:F=18:9). Ages ranged from 10 months to 49 years. Both donor and recipient were 100% CMV IgG seropositive and CMV IgM negative. Varied spectrum of cases including Acute Leukemia (9), CML(2), Relapsed ALCL (1), Thalassemia major-Class III (6), Sickle Beta thalassemia (1), Sickle cell anaemia (1), IBMFS (2), Enzyme deficiency (1), Osteopetrosis (1), CGD (1), MPS (1) and SAA (1) were part of the study. Haploidentical HSCT predominated(n=22). Graft sources were bone marrow (3), peripheral blood stem cells (22), and combined (2). In small children, the drug was given crushed via nasogastric tube(n=5). Letermovir was dosed as per standard guidelines. CMV reactivation occurred in 8 patients(29 %). CMV copy numbers ranged from 687 to 31,00,000copies/mL, observed between days+12 and+68 post- transplant. Upon reactivation, patients were treated with anitivirals

as per guidelines. Only one mortality was noted, unrelated to CMV. There was no CMV disease or CMV related deaths in the study.

Conclusions: Cumulative incidence of CMV reactivation was marginally higher in our study compared to Western data. All patients responded well to first line Pre-emptive therapy. Time of onset of CMV reactivation was early.

Disclosure: Nothing to declare.

P178

MYCOBACTERIUM ABSCESSUS AS A COMPLICATION OF IMMUNOSUPPRESSION AFTER ALLOGENEIC STEM CELL TRANSPLANTATION FOR CONGENITAL NEUTROPENIA

Ruben Van Paemel[1], *Yoni Aelvoet*[1], *Cedric Bosteels*[1], *Frances Claus*[1], *Nathalie Herman*[1], *Sophie Van Lancker*[1], *Jef Willems*[1], *Jakko van Ingen*[2], *Heidi Schaballie*[1], *Jerina Boelens*[1], *Pieter De Cock*[1], *Petra Schelstraete*[1], *Victoria Bordon*[1]
[1]*Ghent University Hospital, Ghent, Belgium,* [2]*Radboud University Medical Centre, Nijmegen, Netherlands (the)*

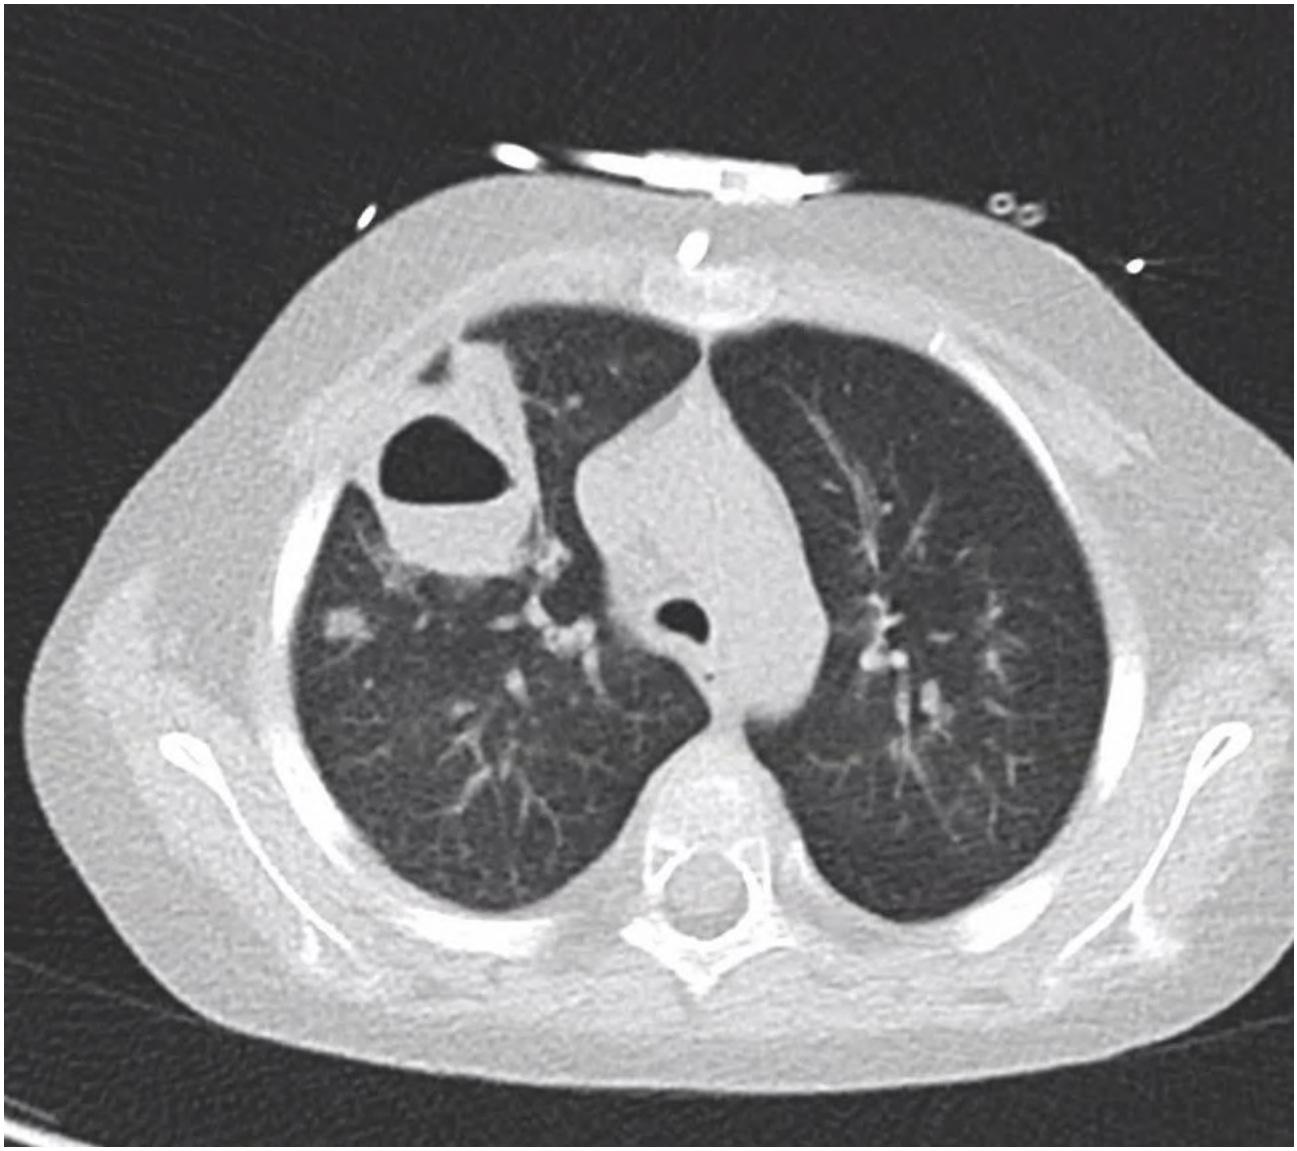
Background: *Mycobacterium abscessus* (Mabs) is a rapidly growing nontuberculous mycobacterium (NTM), commonly found in soil and water. It has an intrinsic resistance to numerous antimicrobial classes. Furthermore, it can form biofilms and survive within macrophages and thus is one of the most difficult NTMs to eradicate. These biological defenses severely limit therapeutic options and complicate standardized treatment, especially in pediatric patients.
Pulmonary disease is the most common presentation. Disseminated infection, while rare, is associated with high morbidity and mortality, particularly in patients with impaired innate and adaptive immunity. It often requires prolonged multidrug therapy and careful monitoring for drug toxicity.
Among the most vulnerable groups are patients undergoing allogeneic stem cell transplantation (allo-SCT). Prolonged neutropenia, delayed T-cell reconstitution, intensive immunosuppression, impaired mucosal barriers and frequent exposure to broad-spectrum antimicrobials create an optimal environment for opportunistic pathogens such as MAbs. Post-transplant complications, such as GvHD, viral reactivation, and fungal infection, further obscure early diagnosis, as their symptoms commonly overlap with those of NTM disease.

Methods: Here we describe a patient case of a 3-year-old boy with congenital neutropenia, due to a homozygous *CSF3R* mutation, who underwent allo-SCT with a 10/10 MUD. Diagnostic evaluation included review of microbiologic data, bronchoalveolar lavage (BAL) studies, radiographic imaging, and serial blood cultures. Clinical decision-making was undertaken by an antibiotic stewardship team to establish the diagnosis of invasive Mabs infection and to guide therapeutic management.

Results: Following early post-transplant complications, including pneumonia, CMV reactivation, and cutaneous GvHD, the patient developed progressive respiratory symptoms by day +78. These were initially attributed to pulmonary GvHD or bronchiolitis obliterans. Despite treatment with systemic corticosteroids, ruxolitinib, ibrutinib, antiviral agents, and antifungal therapy for a probable invasive pulmonary aspergillosis infection, respiratory status continued to decline.

By day +190, the patient presented with septic shock, for which invasive mechanical ventilation (IMV), fluid expansion and vasopressor therapy were required. After shock reversal and weaning off IMV he was eventually discharged home. Worsening oxygenation prompted repeat CT imaging on day +210, revealing a new 30-mm cavitary lung lesion (see figure). BAL and blood cultures were positive for *M. abscessus massiliense*, confirming invasive pulmonary disease with bacteremia.

Treatment consisted of intravenous amikacin, tigecycline, imipenem, and TDM guided azithromycin and clofazimine, in addition to ongoing antifungal therapy. Subsequently the patient showed gradual clinical improvement, with resolution of oxygen dependence and decreasing inflammatory markers. Intravenous therapy was stopped after 3 months, clofazimine and azithromycin are being continued, with a planned treatment duration of one year. During treatment he developed a severe drug-induced hepatitis. Immunosuppression was cautiously tapered, though ruxolitinib was later re-introduced for bronchiolitis obliterans. Follow-up BAL and blood cultures remained negative for Mabs.



Conclusions: This case illustrates how Mabs can emerge insidiously in pediatric alloSCT recipients, mimicking more common post-transplant complications and progressing rapidly to severe invasive infection. The patient's gradual recovery underscores the importance of early recognition, aggressive multidrug therapy, and careful reassessment of immunosuppression and toxicity. More broadly, this case highlights the urgent need for consensus-driven guidelines for managing NTM infections in immunocompromised children.

Disclosure: Nothing to declare.

P179

GRAFT REJECTION AND POOR GRAFT FUNCTION AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION IN PEDIATRICS: BEWARE OF PARVOVIRUS INFECTIONS

Mayara Satsuki Kunii[1], *Ana Carolina Ribeiro Correa*[1], *Aline Ferrari Martins*[1], *Erica Almeida Viana*[1], *Camila Margarida Maria Soares de Sousa*[1], *Olga Margareth Felix*[1], *Nathalia Goncalves Rissardi*[1], *Cintia Monteiro Lustosa*[1], *Adriane da Silva Santos Ibanez*[1], *Raisa Machado Amaral*[1], *Ana Claudia Ramos Donatelli*[1], *Maria Gabriela Matos*[1], *Roseane Vasconcelos Gouveia*[1], *Valeria Cortez Ginani*[1], *Luciana dos Santos Domingues*[1], *Lais Lima Quintino*[1], *Yohanna Bastani de Mattos*[1], *Fernanda de Oliveira Mota*[1], *Maria Estela Shiroma*[1], *Lahis Cardoso de Castro*[1], *Maria de Los Angeles Duran Salas*[1], *Adriana Seber*[1]
[1]*Grupo de Apoio ao Adolescente e a Criança com Cancer, Sao Paulo, Brazil*

Background: Human parvovirus B19 (Parvo) is a DNA virus. The infection has a very wide clinical presentation varying from asymptomatic, fever, erythema, arthralgia, erythroid aplasia) to severe manifestations as myocarditis, glomerulonephritis, hepatitis, vasculitis, myositis and nervous system involvement. Parvo has been detected after allogeneic hematopoietic stem cell transplantation (HCT) in association with engraftment failure and pure red cell aplasia.

Methods: We have recently included marrow Parvo PCR in the work up of poor graft function or delayed engraftment and were surprised by positive results in four patients that are rescribed in this paper.

Results: Case 1. A 4-year-old patient who underwent HLA-identical related HCT for sickle cell anemia conditioned with ATG, busulfan, and cyclophosphamide. Due to delayed engraftment,, a PCR for parvovirus was performed in the bone marrow sample and it was positive.. The patient received immunoglobulin 0.4g/kg for 5 days (IVIG) and engrafted soon thereafter.
Case 2. A 3-year-old patient who underwent unrelated HCT with HLA-B allelic mismatch for B-cell acute lymphoblastic leukemia (ALL) in second remission, conditioned with TBI 1,200cGy and etoposide 60mg/kg. Six months after the HCT, the patient presented with pancytopenia and the marrow aspirate tested positive for Parvo and improved after IVIG. Seven months post HCT, the patient had bloody diarrhea neutropenia and anemia. He tested positive for Parvo again, was retreated with IVIG and resolved all symptoms.
Case 3. A 14-year-old patient underwent Haploidentical HCT for ALL with TBI and etoposide. He had primary graft failure. The D+30 marrow was negative for minimal residual disease, had 53% donor chimerism and tested positive for Parvo PCR. Despite IVIG He remained pancytopenic and underwent a second haploidentical HCT with fludarabine, cyclophosphamide and TBI 200Gy but developed sinusoidal obstructive syndrome and died of pulmonary hemorrhage.
Case 4. A 16-year-old patient had haploidentical HCT for Ph+ ALL conditioned with TBI and Etoposide. Despite neutrophilic engraftment he remained platelet transfusion dependent,had several infections and thrombotic microangiopathy. Five months post-HCT, ParvoPCR was detected in the bone marrow. He received IVIG but has notfully recovered yet.

Conclusions: Parvo infections may have a role in poor graft function and graft failure and sis currently being prospectively studied in our patients.

Disclosure: Nothing to declare.

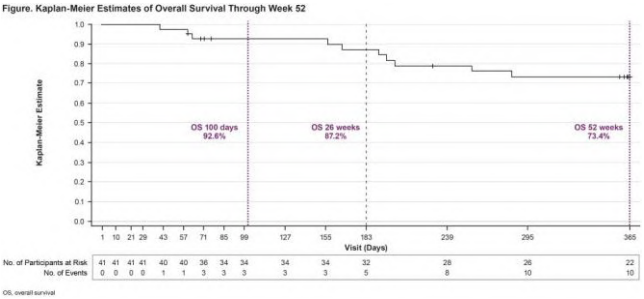
Background: Ravulizumab, a complement C5 monoclonal antibody, demonstrated efficacy and safety over a 26-week treatment period in pediatric hematopoietic stem cell transplantation–associated thrombotic microangiopathy (HSCT-TMA). Here, data up to 52 weeks are reported.

Methods: ALXN1210-TMA-314 (NCT04557735) is a phase 3, open-label, single-arm, multicenter study. Eligible patients were aged 28 days to <18 years, weighed ≥5 kg, received HSCT within the prior 12 months, and had HSCT-TMA persisting for ≥72 hours despite trigger management. Protocol inclusion criteria included proteinuria of ≥1 mg/mg. Patients received body weight–based ravulizumab plus best supportive care for 26 weeks, followed by a 26-week follow-up period with only best supportive care. The primary endpoint was protocol-defined complete TMA response (≥50% reduction in urine protein/creatinine ratio [UPCR], ≥50% improvement in platelets, and lactate dehydrogenase [LDH]

normalization with absence of schistocytes) during the 26-week treatment period. Key secondary endpoints included individual TMA response components, overall survival (OS; at day 100, week 26, and week 52), and safety (incidence of treatment-emergent adverse events [TEAEs] and serious TEAEs). Quality of life, measured by Pediatric Quality of Life Inventory (PedsQL), was assessed.

Results: Of 41 enrolled patients (mean age, 7.6 years; 51% female; 54% White), 28 (68.3%) completed the 26-week treatment period, and 24 (45.5%) completed the 52-week study. At week 26, protocol-defined TMA response occurred in 29 (70.7%) patients meeting ≥1 criterion, of which 7 (17.1%) met protocol-defined complete TMA response, and 22 (53.7%) met protocol-defined partial TMA response. Mean UPCR improved from 5.5 mg/mg at baseline (n=41) to 0.93 mg/mg at week 26 (n=21) and 0.27 mg/mg at week 52 (n=21). Mean platelets were 46,976/mm^3 at baseline (n=41; reference range lower limit of normal = 163,000/mm^3), increased to 169,000/mm^3 at week 26 (n=25), and progressively improved to 216,000/mm^3 at week 52 (n=18). Age-normalized LDH decreased from 1.6 x upper limit of normal (ULN) at baseline (n=37) to <1.0 x ULN at week 26 (n=28), which was maintained through week 52 (n=24). At week 52, 79% of patients had normal LDH. Estimated OS was 92.6% at day 100, 87.2% at week 26, and 73.4% at week 52 (**Figure**). During the 26-week treatment period, all patients experienced ≥1 TEAE (n=860), 30/41 (73.2%) reported 94 serious TEAEs, and 3 (7.3%) had serious TEAEs assessed as related to ravulizumab. During the 26-week follow-up period, 24/29 (82.8%) patients experienced ≥1 TEAE (n=178), 15/29 (51.7%) reported 27 serious TEAEs, and 2 (6.9%) had serious TEAEs assessed as related to ravulizumab. No meningococcal infections were reported, and no unexpected or new safety signals were identified. Respective [VA1] mean (SD) patient-reported and parent-reported PedsQL total score increased from 52.6 (19.2) and 50.4 (20.6) at baseline (n=32 and n=31) to 60.3 (21.3) and 57.7 (21.5) at week 26 (n=25 and n=26) and 72.2 (18.5) and 67.9 (21.4) at week 52 (n=20 and n=18).

Figure. Kaplan-Meier Estimates of Overall Survival Through Week 52



Conclusions: In this global phase 3 trial in pediatric patients with HSCT-TMA, ravulizumab treatment resulted in clinically meaningful OS of 73.4% at 52 weeks and normalization of early laboratory markers of TMA beyond 26 weeks.

Background: Pediatric patients undergoing hematopoietic cell transplantation (HCT) are at disproportionately higher risk of developing endotheliopathies including sinusoidal obstructive syndrome (SOS), transplant-associated thrombotic microangiopathy (TMA), capillary leak syndrome (CLS) and diffuse alveolar hemorrhage (DAH), with the potential for progression to pediatric multi-organ dysfunction syndrome (p-MODS) and need for critical care support (CC).

Methods: POEM (NCT05090345) is a multi-center prospective registry/biorepository. Subjects are enrolled prior to HCT and followed to evaluate the proportion who develop endotheliopathies and/or p-MODS within 100 days of HCT. Plasma is collected at baseline, day 0, and weekly for four weeks and at the time of a qualifying event (endotheliopathy/p-MODS) within 100 days of HCT; samples are interrogated to determine the proportion who develop abnormal levels of circulating angiogenic factors.

The risk of p-MODS was assessed within 7 days of HCT and weekly for 4 weeks, to dynamically evaluate organ function across 8 systems: respiratory, cardiovascular, renal, hepatic, hematologic, neurologic, immune, and gastrointestinal. Each system was graded on a 0–5 scale based on clinical and laboratory parameters, with total pMODS calculated using the worst score per organ.

Results: At the time of interim analysis, 264 subjects have enrolled across 12 centers. This report includes outcomes of 239 subjects that are $\geq$ 100 days post-HCT. Overall incidence of endotheliopathies was 13.4%.
All subjects had similar baseline p-MODS scores. Subjects who developed endotheliopathies and/or required critical care support within 30 days of HCT, had a significantly different progressive rise (with median change by 2 points) in p-MODS score starting at week 1 compared to subjects who did not (Figure 1). The median time to diagnosis of endotheliopathies was 12 (range: 2 to 94) days post-HCT and median time to critical care admission was 13 (range: -7 to 94 days).
Comparison of circulating angiogenic factors identified several factors that were significantly lower at baseline in patients who developed SOS compared to controls: CD31 ($p< .0001$), VEGF-D ($p<.0005$), EMMPRIN ($p<.005$), and Lyve-1 ($p<.005$). In contrast, at the point of SOS diagnosis, only two factors were lower in patients with SOS, BMP-9 ($p < 0.005$) and VEGF-D ($p <0.05$), while HGF ($p<0.05$) was higher in patients with SOS, at the time of diagnosis compared to controls.

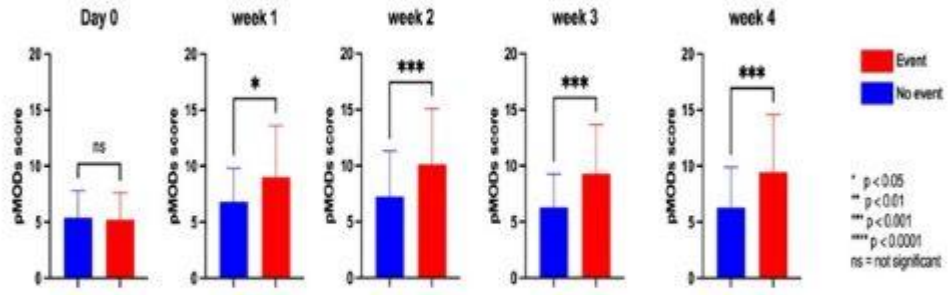

Figure 1A: Progressive rise in p-MODS scores from baseline to Week 4

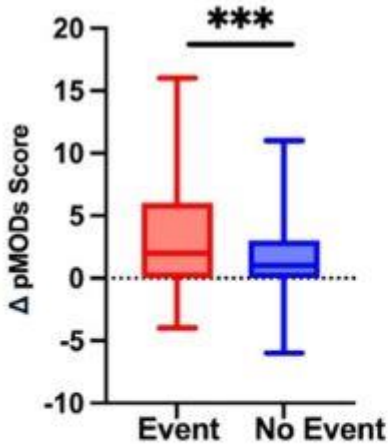

Figure 1B: Significant change in p-MODS score from baseline to Week 1 comparing subjects with events versus no events in the first 30 days post-HCT

Conclusions: Patients who develop SOS may have different circulating angiogenic factors at baseline. Angiogenic signatures may identify patients at highest risk for SOS prior to initiation of preparative regimen. A progressive rise in p-MODS score starting at week 1 post-HCT may further identify subjects at risk for endotheliopathies and clinical deterioration. Future work will validate these findings in a larger number of patients (total planned enrollment, n = 500) and will assess the predictive power of measuring CD31, VEGF-D, EMMPRIN, and Lyve-1 together at baseline in patients preparing for HCT. Characterization of circulating angiogenic factors in subjects with other endotheliopathies is planned. Sequential sample analysis and p-MODS score assessment may enhance sequential time adjusted risk propensity for endotheliopathy and critical care support.

Clinical Trial Registry: NCT05090345.

ORAL IPTACOPAN DEMONSTRATES EFFICACY AS SALVAGE THERAPY FOR HIGH-RISK TRANSPLANT-ASSOCIATED THROMBOTIC MICROANGIOPATHY: FIRST REAL-WORLD EXPERIENCE

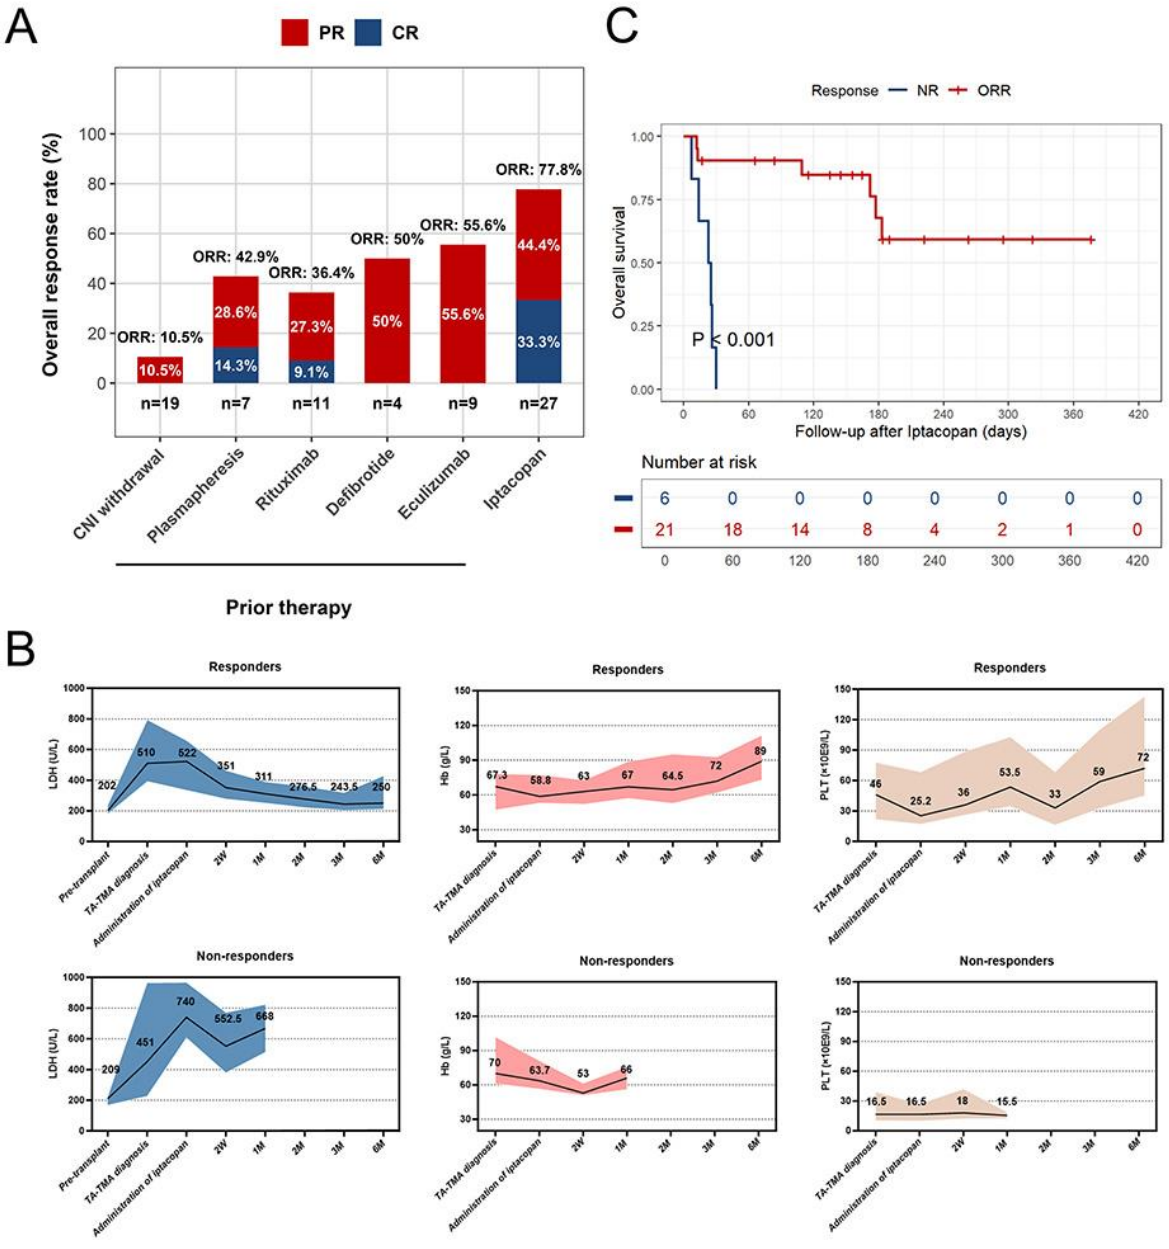
Fei Gao[1], *Qi Wen*[2], *Xiaofan Li*[3], *Jianping Zhang*[4], *Na Xu*[5], *Yuanyuan Zhang*[2], *Daoxing Deng*[2], *Yeqian Zhao*[1], *Jimin Shi*[1], *Yi Yu*[1], *Congxiao Zhang*[1], *Jun Kong*[1], *He Huang*[1], *Yang Cao*[6], *Weijie Cao*[7], *Xiaodong Mo*[2], *Yanmin Zhao*[1]
[1]*Bone Marrow Transplantation Center of The First Affiliated Hospital & Liangzhu Laboratory, Zhejiang University School of Medicine, Hangzhou, China,* [2]*Peking University People's Hospital, Peking University Institute of Hematology, National Clinical Research Center for Hematologic Disease, Beijing Key Laboratory of Hematopoietic Stem Cell Transplantation, Beijing, China,* [3]*Department of Hematology, Fujian Medical University Union Hospital, Fuzhou, China,* [4]*Department of Bone Marrow Transplantation, Hebei Yanda Lu Daopei Hospital, Yanda, China,* [5]*Department of Hematology, Nanfang Hospital, Southern Medical University, Guangzhou, China,* [6]*Department of Hematology, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China,* [7]*Department of Hematology, The First Affiliated Hospital of Zhengzhou University, Zhengzhou, Zhengzhou, China*

Background: Transplant-associated thrombotic microangiopathy (TA-TMA) is a lethal complication after hematopoietic stem cell transplantation (HSCT). Recent advances in complement inhibition have demonstrated promising therapeutic potential, as evidenced by eculizumab. Activated complement factor B product is significantly elevated in the early period of TA-TMA, thereby supporting the predominant pathogenic role of the alternative pathway. Iptacopan, an oral small-molecule complement factor B inhibitor, can efficiently block the formation of C3 convertase, inhibit C5 convertase, decrease the membrane attack complex formation, and reduce damage to the endothelial system.

Methods: TA-TMA diagnosis and treatment response were assessed according to Jodele et al. High-risk disease was defined by ≥ 1 of the following: concomitant infection, peak LDH ≥ 2 ULN, aGVHD, end-organ dysfunction, rUPCR ≥ 1 mg/mg, and sC5b-9 plasma levels ≥ 250 ng/mL. Iptacopan was to be administered orally at 200 mg twice daily, with discontinuation considered upon resolution of hematologic TA-TMA and stabilization or improvement of MODS, or at the treating physician's discretion. All patients received antibacterial prophylaxis against Neisseria meningitidis and antifungal prophylaxis during iptacopan treatment.

Results: In this retrospective study, a total of 27 TA-TMA patients from 7 Chinese institutions received iptacopan therapy between July 2024 and May 2025. TA-TMA was diagnosed at a median of 81 days (IQR 25–227) post-HSCT. Organ involvement included intestine (n=12), kidney (n=6), and CNS (n=5). Elevated urinary protein excretion and elevated sC5b-9 level were both present in 14 patients, respectively. The median LDH level was 2.2 times the ULN (IQR 1.5–3.1). Specifically, 14 patients (51.9%) had grade II–IV

acute GVHD. Infections were documented in 22 patients (81.5%). Prior salvage therapies were extensive, including calcineurin inhibitor withdrawal (n=19), rituximab (n=11), and eculizumab (n=9), plasma exchange (n=7), and defibrotide (n=4). (Figure 1A) Most had refractory disease (48.1%) or a prior response followed by TMA progression/flare (29.6%). The median time to initial response was 12 days, and the median duration of iptacopan treatment was 27 days. Iptacopan yielded an overall response rate (ORR) of 77.8% (9 complete, 12 partial). Iptacopan resulted in marked reduction of LDH from baseline at 1 month (median 561 IU/L vs 353 IU/L, $p<0.001$). Responders achieved independence from red blood cell transfusion at a median of 47 (IQR 30–84) and from platelet transfusion at 63 (IQR 14–97) days. (Figure 1B) Notably, ORR did not differ significantly between eculizumab-pretreated (66.7%) and treatment-naïve (83.3%) patients ($p=0.36$). The most frequent adverse events were infectious complications (n=11). Contributing causes of death were TMA/MODS (n=5), GVHD (n=2), viral pneumonia (n=2), fungal pneumonia (n=2), and intracerebral hemorrhage (n=1). No relapse of underlying diseases was observed after iptacopan. At the last follow-up, the 6-month OS after TMA diagnosis was 62.7%, with 72.4% of responders (15/21) remaining alive. Survival was significantly higher in responders (67.9%) than non-responders (0%) at 6 months post-iptacopan ($p<0.001$). (Figure 1C)



Conclusions: In conclusion, the oral complement inhibitor iptacopan demonstrated significant clinical efficacy as salvage therapy in high-risk TA-TMA patients, irrespective of prior eculizumab exposure.

BASELINE LIVER ELASTOGRAPHY PREDICTS THE RISK OF SOS/VOD IN PATIENTS UNDERGOING ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Lorenzo Lazzari[1], *Anna Francesio*[1,2], *Alessandro Bruno*[1], *Simona Piemontese*[1], *Andrea Acerbis*[1], *Fabio Giglio*[1], *Raffaella Greco*[1], *Andrea Assanelli*[1], *Maria Teresa Lupo-Stanghellini*[1], *Fabio Ciceri*[1,2], *Annalisa Ruggeri*[1]
[1]*IRCCS San Raffaele Scientific Institute, Milano, Italy,* [2]*Vita-Salute San Raffaele University, Milano, Italy*

Background: Sinusoidal obstruction syndrome/veno-occlusive disease (SOS/VOD) is a potentially severe complication of allogeneic hematopoietic stem cell transplantation (alloHCT). Liver stiffness measurement techniques, such as transient elastography (TE), are non-invasive tools potentially useful for the diagnosis of SOS/VOD. Early identification of patients at risk is critical due to the high morbidity and mortality associated with SOS/VOD.

Methods: We conducted a retrospective observational cohort study using prospectively collected data. Between June 2018 and October 2025, 643 adult patients underwent alloHCT at our Center. Of these, 446 patients had at least one evaluable pre-transplant TE assessment and were included in the analysis. TE was routinely performed for all transplant candidates using FibroScan (Echosens, Paris, France) after a minimum of 4 hours of fasting, obtaining at least 10 valid measurements and an interquartile range/median ratio ≤30%. SOS/VOD was diagnosed and graded according to the latest EBMT criteria. Primary endpoint of the study was the incidence of SOS/VOD, while secondary endpoint was non-relapse mortality (NRM).

Results: Patients and transplant characteristics are displayed in *Table 1*. Median follow-up for survivors was 23 months (range, 1-86). The cumulative incidence of SOS/VOD at 100 days was 4.7% (95%CI, 3%-7%) and that of NRM at 1 year was 14.4% (95%CI, 11.3%-18%). Twenty-one patients developed SOS/VOD (5 moderate, 14 severe, 2 very-severe) after a median time of 13 days (range, 1-82) from alloHCT; 28% were late-onset cases. Seven of these patients (of 10 exposed overall) had received inotuzumab ozogamicin before alloHCT, and 8 patients died from transplant-related complications (6 SOS/VOD, 1 fungal and 1 bacterial infection). Defibrotide was administered in 16 SOS/VOD cases.

	TE ≤7.9 kPa (*N*=366)	**TE >7.9 kPa (*N*=80)**	***P***

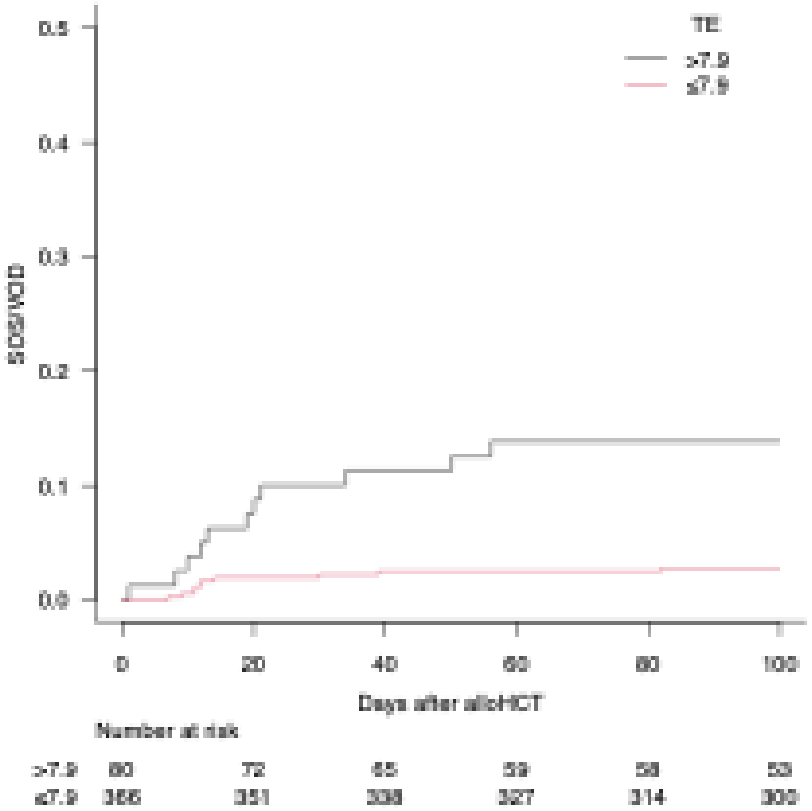
Donor type, number (%) MRD MUD CBU Haploidentical	 43 (12%) 208 (57%) 22 (6%) 93 (25%)	 9 (11%) 50 (63%) 3 (4%) 18 (22%)	0.9
TCI, number (%) Low Intermediate High	 47 (13%) 201 (55%) 118 (32%)	 20 (25%) 44 (55%) 16 (20%)	<0.01
Prior inotuzumab, number (%)	4 (1%)	6 (7%)	<0.01
GvHD prophylaxis, number (%) PTCy-based ATG-based Other	 333 (91%) 11 (3%) 22 (6%)	 74 (92%) 3 (4%) 3 (4%)	0.5

Patients who developed SOS/VOD had significantly higher baseline TE values compared with those who did not (10.3 ±7.4 kPa versus 6.2 ±4.3kPa; p<0.001). A time-to-event ROC curve for baseline TE identified 7.9 kPa as the optimal threshold (sensitivity 0.53, specificity 0.83; AUC 0.691), consistent with established cutoffs for differentiating a fibrotic liver from a normal one. Using this threshold, patients with elevated baseline TE had a significantly higher cumulative incidence of SOS/VOD (13.8% versus 2.8% at 100 days; p<0.001; *Figure 1*) and NRM (19.8% versus 13.3% at 1 year, p=0.04). Conditioning intensity, disease-risk index, HCT-CI, number of previous transplants, and donor type showed no significant association with SOS/VOD incidence. A linear regression confirmed that baseline TE was a significant positive predictor of SOS/VOD (β=0.8%, 95%CI 0.4%-1.2%; t=3.86, p<0.001).



Conclusions: Baseline TE measurement may serve as a non-invasive tool to identify alloHCT recipients at increased risk of SOS/VOD. Patients with elevated TE, especially those previously exposed to hepatotoxic agents such as inotuzumab ozogamicin, may benefit from targeted preventive strategies to mitigate NRM.

Clinical Trial Registry: Not applicable.

OS04-07

POOR GRAFT FUNCTION AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION (HSCT) IS ASSOCIATED WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE USE AND DELAYED B AND T-CELL IMMUNE RECOVERY

Davide Murgia[1,2], *Alessandra Algarotti*[1], *Chiara Pavoni*[1], *Benedetta Rambaldi*[1], *Giuliana Rizzuto*[1], *Antonio Scannella*[1,2], *Maria Chiara Finazzi*[1], *Elena Oldani*[1], *Orietta Spinelli*[1], *Cristian Meli*[1], *Alessandro Rambaldi*[1,2], *Federico Lussana*[1,2], *Anna Grassi*[1]
[1]*ASST Papa Giovanni XXIII, Bergamo, Italy,* [2]*University of Milan, Milan, Italy*

Background: Poor graft function (PGF) is a serious early complication of HSCT, characterized by persistent cytopenias despite achieving full-donor chimerism. Its study has long been limited by heterogeneous diagnostic criteria, leading to variable incidence and outcomes. In 2024, an internationally harmonized definition was introduced to standardize classification and enhance comparability across studies.

Methods: This study aims to assess the incidence, risk factors, and clinical outcomes of PGF defined by the 2024 harmonizing criteria, in a cohort of patients undergoing HSCT at our Center between 2015–2025. PGF incidence was calculated using cumulative incidence functions treating death as a competing risk. Predictors of PGF were evaluated using logistic regression. The impact of PGF as a time-dependent variable on NRM was assessed with Simon–Makuch curves and the Fine–Gray model.

Results: We identified 655 adult patients who underwent HSCT. Of these, 46 patients (7%) met the harmonizing criteria for PGF. The median time to diagnosis was 86 days post-transplant. One-third of patients showed pancytopenia, and two-thirds bone marrow hypocellularity. Baseline characteristics are summarized in Table 1.

Characteristics	**All, N=655**	**PGF, N=46**	**Non-PGF, N=609**
Age at HSCT, median (range)	54 (17-72)	58 (19-69)	53 (17-72)
Female	267 (40.8%)	19 (41.3%)	248 (40.7%)
Male	388 (59.2%)	27 (58.7%)	361 (59.3%)
Indication for HSCT			
AML	301 (46%)	8 (17.4%)	293 (48.1%)
ALL	108 (16.5%)	9 (19.6%)	99 (16.3%)
Myelofibrosis	76 (11.6%)	12 (26.1%)	64 (10.5%)

MDS	70 (10.7%)	9 (19.6%)	61 (10%)
Lymphoma	54 (8.2%)	3 (6.5%)	51 (8.4%)
Other	46 (7%)	5 (10,9%)	41 (6,8%)
ABO Compatible	287 (44.3%)	18 (39.1%)	269 (44.7%)
ABO Major incompatible	194 (29.9%)	20 (43.5%)	174 (28.9%)
ABO Minor incompatible	167 (25.8%)	8 (17.4%)	159 (26.4%)
Graft: <5x10^6 CD34+ cells/kg	291 (50.8%)	28 (70.0%)	263 (49.3%)
PTCy	138 (21.1%)	15 (32.6%)	123 (20.2%)
ATG/ATLG	422 (64.4%)	29 (63%)	393 (64.5%)

Table 1: Baseline characteristics

In the multivariable analysis, myelofibrosis (OR 7.25, 95%CI: 2.86–19.01, p <.0001), myelodysplasia (OR 4.91, 95%CI: 1.72–13.82, p= 0.0024), major ABO-incompatibility (OR 2.32, 95%CI: 1.15–4.71, p=0.0187), CD34+ cell dose $<5\times10^6$ cells/kg (OR 2.34, 95%CI: 1.16–5.00, p=0.0222) and post-transplant cyclophosphamide (PTCy) (OR 2.39, 95%CI: 1.11–4.99, p=0.0221) were independently associated with PGF.
PGF patients showed significantly higher 5-year NRM rate (25% vs 15% non-PGF, p=0.0401), with infections accounting for 67% of the NRM vs 27% in non-PGF. This paralleled a marked delay in immune reconstitution: PGF patients showed reduced CD3+, CD4+, CD8+ and CD16+ cell counts during the first year post-transplant (Fig. 1A-D), irrespective of PTCy or anti-thymocyte globulin (ATG) exposure. ROC analysis identified CD3+ count <178/µL at day +30 as the optimal early predictor for developing PGF. B-cell recovery was also impaired, with higher rates of hypogammaglobulinaemia (OR 2.41, 95%CI: 1.07–5.69, p=0.0362), and lower CD19+ counts throughout the first year after transplantation (Fig 1E).

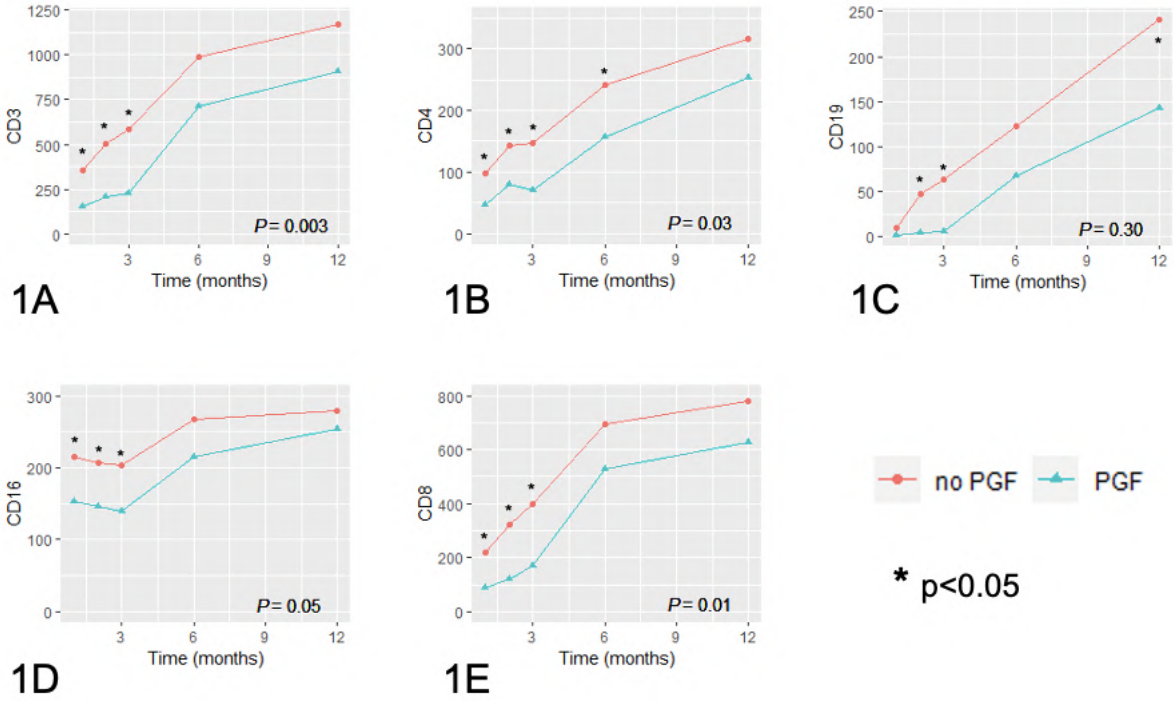

Figure 1: Immune reconstitution during the first year after HSCT in patients with and without PGF.

Among PGF patients, 23 received Eltrombopag, which resulted in platelet, erythroid and neutrophil response rates of 65%, 58% and 50%, respectively. The drug was well tolerated, with only 6 cases of transient transaminitis up to grade 3 CTCAE v5 and no thrombotic events. Moreover, 7 patients received a stem-cell boost (2 cases with CD34+ selection), resulting in the resolution of PGF in 71% of cases. Finally, acute GvHD (up to overall grade 4) occurred in 2 patients after unmanipulated boost infusion.

Conclusions: This single-center retrospective study, one of the first applying the 2024 harmonizing definition, shows that PGF is associated with higher NRM and delayed T- and B-cell immune recovery, with infections as the main cause of NRM. In high-risk diseases, such as myelofibrosis or myelodysplasia, additional risk factors (major ABO incompatibility, low CD34+ dose, PTCy) warrant careful evaluation. Both Eltrombopag and stem cell boosts were effective for managing PGF.

Disclosure: Nothing to declare.

OS04-08

RISK FACTORS FOR HEPATIC VENO-OCCLUSIVE DISEASE AFTER ALLO-HSCT IN ACUTE LEUKEMIA PATIENTS TREATED WITH ANTIBODY-DRUG CONJUGATES

Zhemal Rakhmanova[1], *Polina Kozhokar*[1], *Kseniia Afanaseva*[1], *Elena Semenova*[1], *Ivan Moiseev*[1], *Ludmila Zubarovskaya*[1]
[1]*RM Gorbacheva Research Institute, Pavlov University, Saint-Petersburg, Russian Federation (the)*

Background: Hepatic veno-occlusive disease (VOD), also known as sinusoidal obstruction syndrome (SOS), remains a severe early complication of allogeneic hematopoietic stem cell transplantation (allo-HSCT) associated with high mortality. An elevated risk of VOD has been observed in patients previously treated with targeted agents, particularly antibody-drug conjugates (ADCs). This study aimed to identify clinical and therapeutic factors associated with an increased risk of VOD in patients with acute leukemia undergoing allo-HSCT after prior ADC therapy.

Methods: We retrospectively analyzed 121 patients (median age: 19 years; range: 1-56 years; 57 pediatric patients <18 years) with acute leukemia who underwent allo-HSCT at CIC725 between 2017 and 2025 following ADC-based therapy. ADC exposure included gemtuzumab ozogamicin in acute myeloid leukemia (n=36., median doses: 3; range: 1-3) and inotuzumab ozogamicin in acute lymphoblastic leukemia (n=85, median doses: 3; range: 1-11), Patients transplanted outside first or second complete clinical and hematological remission comprised 60% (advanced disease). In the study group 30 patients had EASIX score>3. Transplant characteristics are summarized in Table 1.

Table 1. Characteristics of allo-HSCT

Characteristic	n(%)
Conditioning regimen	
Myeloablative (MAC)	66 (54,55%)
-based on busulfan 10-14 mg/kg -based on total body irradiation -based on treosulfan 42 mg/m^2	58 (47,93%) 1 (0,83%) 7 (5,79%)
Reduced-intensity (RIC)	55 (45,45%)
-based on melphalan 140 mg/m^2 -based on busulfan 8 mg/kg -based on treosulfan 36 mg/m^2 -other	45 (37,19%) 6 (4,96%) 2 (1,65%) 2 (1,65%)
Graft-versus-host disease (GVHD) prophylaxis	

Post-transplant cyclophosphamide	111 (91,74%)
Calcineurin inhibitors (tacrolimus)	72 (59,5%)
Other	10 (8,26%)
Donor type	
Matched related	13 (10,74%)
Unrelated	21 (17,36%)
Haploidentical	87 (71,9%)
Graft source	
Bone marrow	63 (52,07%)
Peripheral blood stem cells	58 (47,93%)
Number of allo-HSCT	
First allo-HSCT	101 (83,47%)
Second or subsequent allo-HSCT	20 (16,53%)

Results: VOD was diagnosed by EBMT criteria in 36 of 121 patients (30%). Median time to onset was 14 days post-transplant (range: 4–76 days). VOD severity: mild (n = 2, 1,65%), moderate (n = 13, 10,74%), severe (n = 6, 4,96%), and very severe (n = 15, 12,4%). Day-100 non-relapse mortality was significantly higher in the VOD group (42% vs. 5%; p < 0.001). Univariate analysis identified the following significant risk factors for VOD: advanced disease (38.4% vs. 17.5%, p = 0.02), use of calcineurin inhibitors vs calcineurin-free regimens (39% vs. 16.3% , p = 0.008), busulfan-based conditioning: in the pediatric subgroup (60% vs. 21.2%, p = 0.018); with no significant difference in adults (33% vs. 11%, p = 0.22), pretransplant EASIX(>3): 47.2% vs. 26.5% (p = 0.03).
Multivariate logistic regression was performed for the three significant univariate predictors: advanced disease, use of calcineurin inhibitors, and busulfan-based conditioning. In the multivariate model, only transplantation in advanced disease remained a statistically significant independent predictor of VOD (OR 3.14, 95% CI 1.29–8.35; p = 0.02), while calcineurin-containing regimens only showed a trend towards significance (OR 2.54, 95% CI 0.91–7.61; p = 0.08).

Conclusions: In patients with acute leukemia treated with ADCs prior to allo-HSCT, VOD occurred in 30% and was linked to high non-relapse mortality. Transplantation in advanced disease was the only independent risk factor. The study indentified a possible improvement with calcineurin-free regimens, but this should be confirmed by future studies.

Background: Cardiac events (CE) after allogeneic hematopoietic cell transplantation (allo-HCT) in patients with acute myeloid leukemia (AML) are potentially life-threatening complications. However, identifying patients at higher risk of CE remains challenging due to the heterogeneity of events and the limited availability of validated predictive models in allo-HCT settings.
The CARE-BMT (Vasbinder et al. 2023) score was developed to predict cardiotoxicity after HCT using clinical variables and laboratory biomarkers. Subsequently, given the growing use of post-transplant cyclophosphamide (PTCy) and its association with early CE, a refined CARE-BMT score incorporating the variable PTCy use (50 mg/kg/day for 2 days) was proposed (Torrent-Rodríguez et al. 2025).
This multicenter retrospective study aimed to externally validate the predictive performance of the CARE-BMT and modified CARE-BMT scores in a large AML cohort undergoing allo-HCT.

Methods: 809 adults with AML who underwent their first allo-HCT at the 11 participating transplant centers of the Spanish Hematopoietic Cell Transplant and Cell Therapy Group (GETH-TC) were included. CE incidence was the primary endpoint and was estimated considering relapse and death as competing risks. CE were defined and graded according to CTCAE criteria. Baseline demographics were retrospectively collected. Patients were stratified using both CARE-BMT versions and categorized into risk groups according to the respective definitions (**Figure 1).**

Results: Overall, the median age was 52 (range:17-75) years, 434 (53.6%) were males and 622 (76.9%) were previously treated with high-dose of antracycline-based therapies (dose>250mg/m^2), and 407 (49.7%) patients were transplanted using standard doses of PTCY for GVHD prevention.

Sixty (7.4%) patients had CE, yielding a cumulative incidence of 6.9% (95% CI 5.2–8.8). CE were heterogeneous with arrythmia and heart failure being the most prevalent ones. Patients with CE were older and more frequently had dyslipidemia (26.6% vs 11.1%) and previous CV disease (41.6% vs 7.3%). Moreover, occurrence of CE independently increased NRM risk (HR 3.20, P<0.001).

Using the original CARE-BMT score, 246 (30.4%) and 563 (69.6%) patients were classified into moderate and high-risk groups, respectively, with cumulative incidence of CE of 3.0% and 8.6% (P=0.004), respectively (HR 2.89, p=0.005) **(Figure 1)**. One-year OS was significantly higher in the intermediate-risk group compared with the high-risk group (73.2% vs. 62.2%; P=0.001), while NRM was significantly increased in the high-risk group (18.0% vs. 10.2%; P=0.009), with comparable relapse incidences between groups.

Subsequently, the refined CARE-BMT score with the variable PTCY-use, stratified patients into low (n=85), intermediate (n=558), and high-risk groups (n=166) with CE incidences of 2.4%, 6.1%, and 11.8%, respectively (p=0.011) **(Figure 1)**. High-risk patients had a >5-fold increased hazard of CE than low-risk patients (HR 5.37; p=0.024). Post-transplant outcomes showed that, one-year OS declined across risk categories (72.9%, 66.6%, and 58.4%), while NRM increased (10.5%, 15.7%, and 18.3%), with similar relapse incidence.

Figure 1. A. The CARE-BMT score and the modified score; B. Cumulative incidence of cardiac events according to CARE-BMT groups; C. Cumulative incidence of cardiac events according to modified score groups.

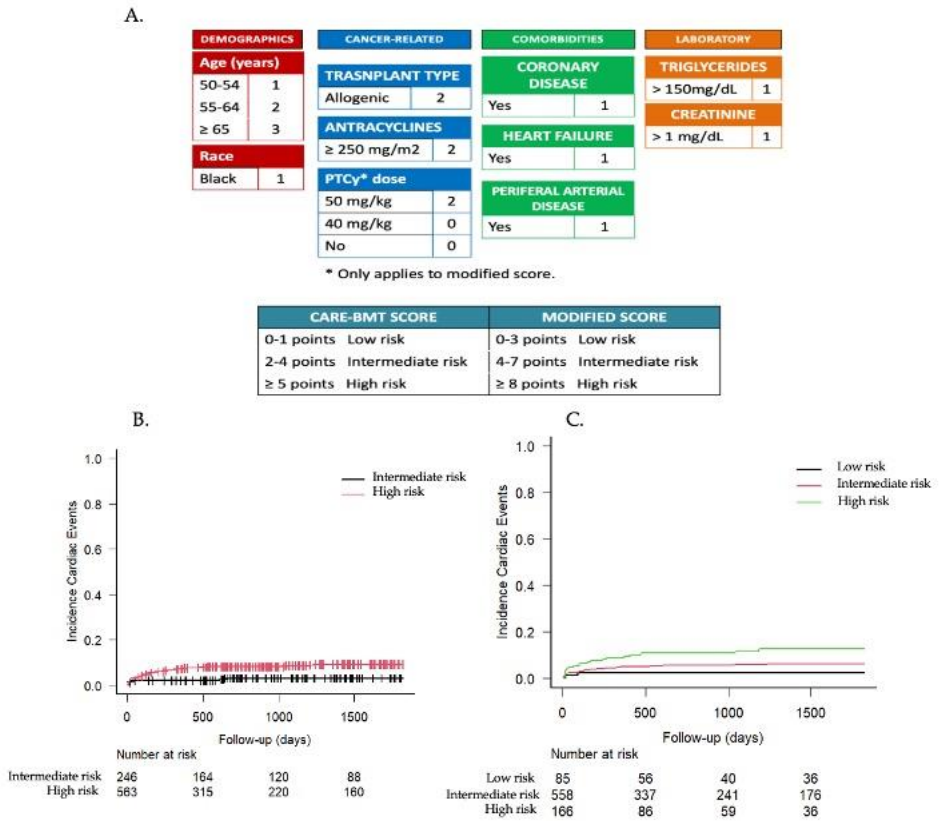

Table 1. Characteristics of the study population according to the CARE-BMT score and modified score.

Cardiac events, n patients (%) Arrythmia Pericardial condition HF Stroke/Ischemia Acute pulmonary edema Hypertensive crisis	 2 (2.4) 0 (0.0) 0 (0.0) 0 (0.0) 0 (0.0) 0 (0.0)	 13 (2.3) 6 (1.1) 12 (2.2) 6 (1.1) 0 (0.0) 1 (0.2)	 5 (3.0) 4 (2.4) 5 (3.0) 2 (1.2) 1 (0.6) 2 (1.2)	0.881 - - - - - -
Days to cardiac event, median (range)	53 (16-89)	125 (1-2158)	98 (9-1185)	0.043

Conclusions: CE occurred in 7% of patients and were strongly associated with increased NRM risk. Both CARE-BMT scores effectively identified patients at higher CE risk, with the

refined version providing superior discrimination. This easy-applicable tool may support tailored cardio-oncology evaluation, monitoring, and preventive strategies in AML patients undergoing allo-HCT.

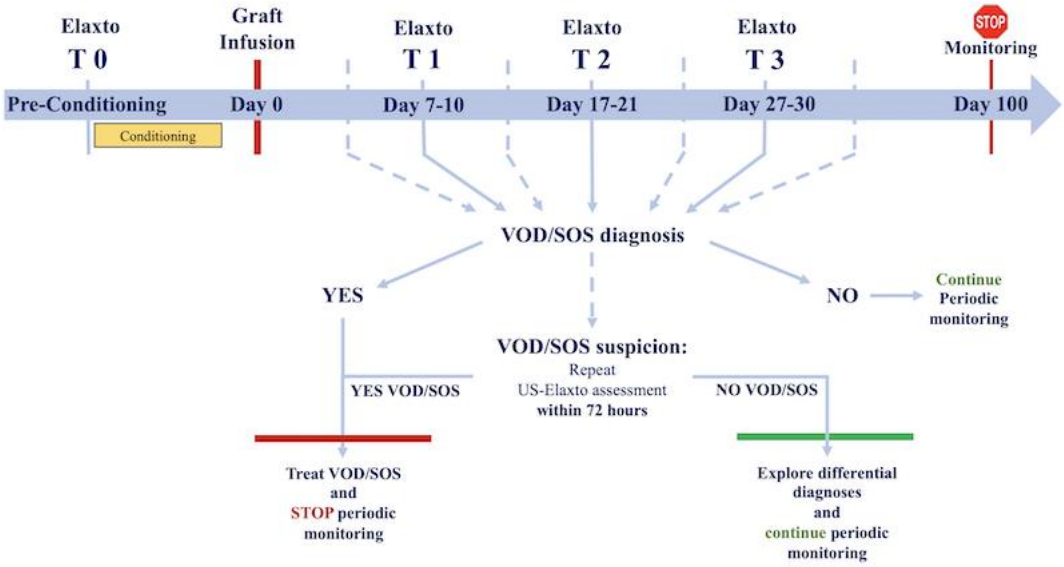
SYSTEMATIC LIVER STIFFNESS MEASUREMENT FOR DIAGNOSIS OF HEPATIC VENO-OCCLUSIVE DISEASE IN ADULT PATIENTS UNDERGOING ALLOGENEIC HAEMATOPOIETIC STEM CELL TRANSPLANTATION: A PROSPECTIVE REAL-WORLD SINGLE-CENTRE EXPERIENCE

Gianmario Pasqualone[1], *Arianna Brega*[2], *Benedetta Mariotti*[2], *Gottardo De Angelis*[2], *Giulia Ciangola*[2], *Antonio Colecchia*[3], *Federico Ravaioli*[4], *Camilla Page*[1], *Elisa Linnea Lindfors Rossi*[1], *Federica Frenza*[1], *Adriano Venditti*[1,2], *Raffaella Cerretti*[2]
[1]*University of Rome "Tor Vergata", Rome, Italy,* [2]*Fondazione Policlinico Tor Vergata, Rome, Italy,* [3]*University of Modena and Reggio Emilia, Modena, Italy,* [4]*University of Bologna, Bologna, Italy*

Background: Hepatic veno-occlusive disease/sinusoidal obstruction syndrome (VOD/SOS) is a severe post-HSCT complication with a high risk of mortality, that can exceed 80%. Early diagnosis and treatment of severe cases are decisive for patient outcome. The recent ELASTOVOD study showed that liver stiffness measurement (LSM) is a reliable, non-invasive diagnostic tool for VOD/SOS.

Methods:



LSM by point-shear-wave elastography (pSWE) and two-dimensional-shear-wave elastography (2D-SWE) were performed before conditioning (T0) and post-HSCT at regular intervals (Figure) in consecutive patients undergoing allo-HSCT at Fondazione Policlinico Tor Vergata (Rome, Italy) from August 2023 to October 2025. Revised 2023 EBMT criteria were applied for diagnosis and grading of VOD/SOS. According to ELASTOVOD study, LSMs were interpreted with diagnostic thresholds: ≤6 kPa to rule out VOD/SOS and ≥25 kPa to rule it in. The "grey zone" (>6 kPa and <25 kPa) was evaluated through the ELASTOVOD's stepwise diagnostic algorithm.

Results: A population of 94 patients (median age 59, range 20-74) underwent systematic LSM by pSWE and 2D-SWE (Table). Six patients were diagnosed with VOD/SOS (overall incidence: 6.7% [95%CI 2.5–14.1%]). The median time at diagnosis was 15.5 days (range 7-20), with all cases identified as "classical" VOD/SOS. Four of 6 patients (66%) were classified as "severe", 1 as "very severe", and 1 as "mild". The median number of VOD/SOS risk factors at HSCT was 4.5 (IQR 3-6) for patients who developed VOD/SOS, not significantly different from others (5, IQR 4-6, p=0.5967). No differences were observed in basal (T0) LSM between VOD/SOS patients and others (p=0.2685 by pSWE; p=0.3949 by 2D-SWE). The only patient who experienced "mild" VOD/SOS fully recovered with supportive measures alone. All other cases received defibrotide and showed a therapeutic response, but the "very severe" patient died of multi-organ-failure associated with septic shock. Liver stiffness–based diagnostic performance was comparable across techniques. Using predefined ELASTOVOD cut-offs, pSWE achieved a sensitivity of 83.3% (95%CI 35.9–99.6) and specificity of 97.6% (95%CI 91.6–99.7), with a positive predictive value (PPV) of 71.4% (95%CI 29–96.3), negative predictive value (NPV) of 98.8% (95%CI 93.2–100), and an AUROC of 0.900 (95% CI 0.740–1.00). For 2D-SWE, sensitivity was 66.7% (95% CI 22.3–95.7), specificity 100% (95% CI 95.7–100), PPV 100% (95% CI 39.8–100), NPV 97.6% (95% CI 91.8–99.7), and AUROC 0.830 (95% CI 0.630–1.00). Additionally, both pSWE and

2D-SWE demonstrated significant differences between LSMs of patients who experienced hepatic AE≥G3 and those with VOD/SOS (p=0.035 and p=0.019, respectively).

Descriptive characteristics of the overall population (n=94)

Gender	n (%)

Myeloablative Reduced-intensity	24 (25.6) 70 (74.4)
Conditioning regimen type	n (%)
TBI FLU-TREO TBF	3 (3.2) 20 (21.3) 71 (75.5)
Donor type	n (%)
HLA-Id Haplo UD	8 (8.5) 32 (34) 54 (57.5)
HCT-CI Score	n (%)

Descriptive characteristics of the overall population (n=94)

0 1-2 ≥3	26 (27.6) 42 (44.8) 26 (27.6)
Stem cell source	n (%)
BM PBSC	33 (35) 61 (65)

Abbreviations:
AML - acute myeloid leukemia; ALL - acute lymphoblastic leukemia; BM - bone marrow; FLU-TREO - treosulfan/fludarabine; Haplo - haploidentical related donor; HCT-CI - haematopoietic cell transplantation specific comorbidity index; HLA-Id - HLA identical sibling donor; HSCT - haematopoietic stem cell transplantation; MDS - myelodysplastic syndrome; MPN - myeloproliferative neoplasms; PBSC - peripheral blood stem cells; TBF - thiotepa/busulphan/fludarabine; TBI - total body irradiation; UD - unrelated donor.

Conclusions: In our single-centre experience, the ELASTOVOD cutoff for diagnosis (>25kPa) and exclusion (<6kPa) of VOD/SOS, together with the "stepwise algorithm" to assess LSM in the “grey zone”, were effective with excellent sensitivity and specificity for both pSWE and 2D-SWE. In addition, both pSWE and 2D-SWE values confirmed the ability of discriminating between VOD/SOS and non–VOD/SOS post-HSCT severe hepatopathies. Despite the limited number of VOD/SOS cases, our work confirms LSM as bedside non-invasive diagnostic tool and represents the first validation of the ELASTOVOD study.

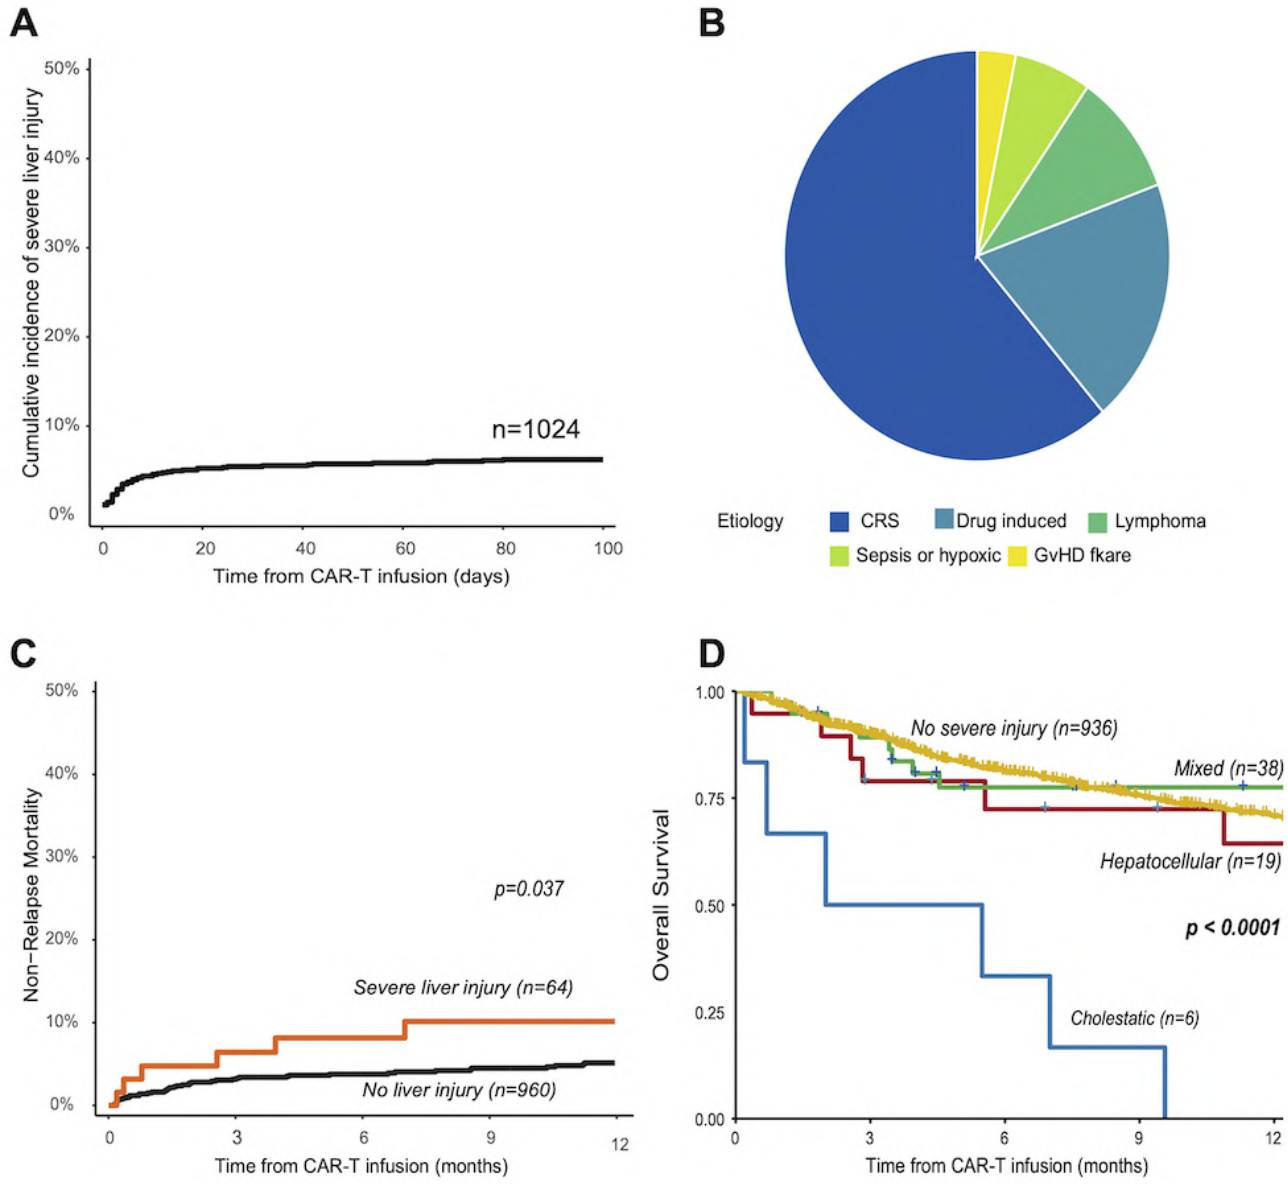
[1]*Memorial Sloan Kettering Cancer Center, New York, United States of America (the),* [2]*Universitat Autonoma de Barcelona, Barcelona, Spain,* [3]*LMU University Hospital, Munich, Germany,* [4]*Chaim Sheba Medical Center, Tel Aviv University, Tel Aviv, Israel,* [5]*University of Iceland, Reykjavik, Iceland,* [6]*Rambam Health Care Campus, Haifa, Israel,* [7]*Hadassah-Hebrew University Hospital, Jerusalem, Israel,* [8]*Soroka University Medical Center, Beer Sheva, Israel*

Background: CAR-T cell therapy is associated with a distinct toxicity profile, in which cytokine release syndrome (CRS), immune effector cell–associated neurotoxicity syndrome (ICANS), and cytopenias represent the most recognized complications. In contrast, hepatotoxicity remains poorly characterized, with limited data on its incidence, risk factors, and clinical implications. Our aim was to delineate severe liver injury phenotypes after CAR-T therapy and evaluate their clinical relevance.

Methods: We conducted a retrospective multicenter cohort study including adults with non-Hodgkin lymphoma treated with commercial CD-19 directed CAR-T products between 2016 and 2025 across five international centers (United States, Germany and Israel). Longitudinal liver laboratory data were extracted and analyzed through day 100 after infusion, relapse, or death. Severe liver injury was classified as hepatocellular (ALT or AST ≥5×ULN with R-ratio ≥5), cholestatic (ALP ≥5×ULN with R-ratio ≤2), or mixed (ALT/AST ≥3×ULN with 2<R<5). Patients meeting severe liver injury criteria at baseline were excluded. U.S. cases underwent adjudication, with ambiguous episodes reviewed jointly with senior hepatologists. Predictors of severe hepatotoxicity were assessed using uni- and multivariable logistic regression, and time-to-event outcomes were analyzed using standard survival methods.

Results:



Characteristic	Severe liver injury (n=64)	No severe liver injury (n=960)	P-value
Age in years, median (IQR)	63 (49-70)	66 (57-73)	0.019
Diagnosis, n (%)			

Large B-cell lymphoma	42 (66)	639 (67)	
Other lymphoma	22 (34)	321 (33)	
Prior allo-HCT, n (%)	7 (11)	21 (2)	0.001
Prior hepatic disease at baseline, n (%)	4 (7)	72 (9)	0.8
CAR-T product			<0.001
Axi-cel, n (%)	43 (67)	451 (47)	
Liso-cel/Tisa-cel/Brexu-cel, n/n/n (%)	8/5/8 (33)	239/205/65 (53)	

A total of 1,026 adults with non-Hodgkin lymphoma were included. Overall, 22,567 patient-days of longitudinal liver function testing were analyzed within the first 100 days. In the overall cohort, AST and ALT showed modest early fluctuations, whereas ALP remained relatively stable.

The cumulative incidence of severe liver injury was 6.3% during the first 100 days (Fig 1A). Injury patterns were mixed in 61%, hepatocellular in 30%, and cholestatic in 9%. Median time from infusion to onset and peak of liver injury was 4 days (IQR 2–12) and 7 days (IQR 4–21), respectively. CRS occurred in 94% of patients with liver injury vs in 79% of those without (p=0.005).

In adjudicated hepatology review (n=31), CRS-related inflammatory liver injury was the most likely primary etiology (61%), followed by idiosyncratic drug-induced injury (19%), hepatic lymphoma involvement (10%), infection-related or ischemic injury (7%), and hepatic GvHD flare (3%). Contributing mechanisms were frequently observed, and notably all adjudicated cholestatic injury cases (n=3) were attributed to lymphoma involvement of the liver (Fig 1B).

In a multivariable logistic regression, only CAR-T product and baseline LDH were independently associated with severe liver injury; liso-cel (vs. axi-cel) was protective (OR 0.35, 95% CI 0.15–0.72), while elevated pre-LD LDH increased risk (OR 2.25, 95% CI 1.11–4.66).

While overall survival (OS) was comparable between patients with and without severe liver injury (65% vs 71%, p=0.57), non-relapse mortality (NRM) was increased in the former (10% vs 5%, p=0.037, Fig 1C). Finally, within the liver injury patterns, cholestatic abnormalities, although uncommon, were strongly linked to inferior OS (p<0.0001), (Fig. 1D).

Conclusions: In this first comprehensive multicenter real-world study encompassing over 1,000 patients, approximately 6% of CD19 CAR-T recipients experienced severe liver injury. Importantly, NRM was doubled in this population, with particularly low OS in patients with

cholestatic injury. These findings emphasize that hepatic toxicity after CAR-T therapy is clinically meaningful and warrants focused evaluation and management.

Background: Poor graft function (PGF) is a life-threatening complication following haematopoietic stem cell transplantation (HSCT). The use of CD34+ selected stem cell boost

(SCB) from the original donor is increasing with promising results, but experience is still limited, particularly in children. In addition, data on the required CD34+ cell dose for complete haematological recovery after SCB infusion, as well as other risk factors associated with response and survival, are scarce. In a previous multicentre retrospective study, we found that only the infused CD34+ cell dose emerged as a significant factor for complete response (CR) (*Communication O149, EBMT 2025*). Since CD34+ cellularity appears to be one of the most important prognostic factors for achieving a CR, this study aims to determine the required CD34+ cell dose for this outcome.

Methods: For this national multicentre retrospective study, we included paediatric patients who had received a SCB for PGF following allogeneic HSCT. PGF was defined according to *Sureda A. et al. Bone Marrow Transplant 2024.*
Nine centres participated in two independent cohorts: the training cohort and the validation cohort.
CR in terms of trilineage hematopoietic recovery was studied in the training cohort, using competing risk approach with Fine & Gray model. Multivariable model was the result of a backward-forward stepwise procedure using Akaike's Information Criterion (AIC). The optimal CD34+ cell dose cut-off was determined in the training cohort using maximally selected rank statistics for time to CR. This threshold was subsequently applied to the validation cohort. Differences in outcomes were analysed using the Fine & Gray model for competing risks.

Results: The characteristics of the training and validation cohort are shown in table 1. The training cohort included 42 patients with a median age of 11.2 years, with malignant (n=23; 54.8%) or non-malignant (n=19; 45.2%) diseases. The validation cohort included 14 patients with a median age of 11.9 years, with malignant (n=9, 64.3%) or non-malignant disease (n=5, 35.7%). No statistically significant differences were found between the two patient cohorts.

Table 1. Characteristics of patients included in the training and validation cohorts

Variable	Training cohort (n=42)	Validation cohort (n=14)	p-value
INCLUSION PERIOD	2013 - 2023	2022 - 2025	___

CD34+ SCB INFUSION			
Time from HSCT to SCB infusion in days, median (IQR)	149 (105 - 308)	165 (115 - 247)	0.7051
CD34+ cell dose infused (x10^6/kg), median (IQR), range	7.3 (4.6 - 9.2) 1.03 - 20.09	4.72 (4.01 - 7.01) 1.20 - 15.0	0.0636
Time to response in days, median (IQR)	13 (6 - 20)	17 (10 - 34)	0.267
Time to complete response, median (IQR)	43 (26 - 98)	41 (23- 76)	0.6841

In the training cohort, both in the univariable and multivariable analyses CD34+ was significantly associated to complete response (HR 1.14, CI 95%: 1.02 – 1.26, P = 0.019). No other variable was significant in the univariable analysis or selected in the best multivariable model according to AIC.
Using maximally selected rank statistics, we explored best cut-off in the training cohort obtaining 4.65 x 10^6/kg as the best cutoff (Figure 1a, 1b). We furtherly validated this result using a second cohort in which cellularity greater than this value were more likely to respond

(p = 0.013) (Figure 1c).

Figure 1. Establishing and validating the optimal CD34+ cell dose threshold for effective SCB in children with PGF

Figure 1a. Maximally selected rank statistic in training cohort

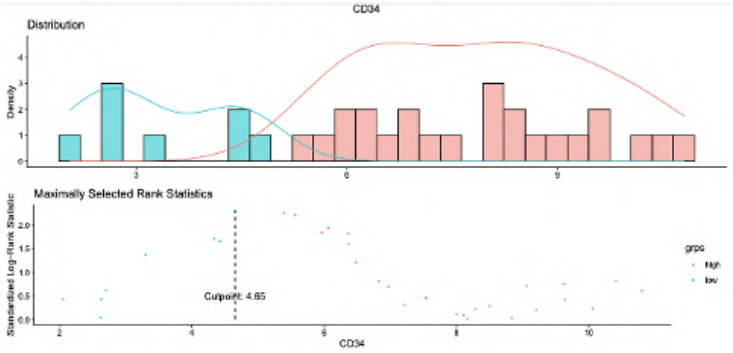

Figure 1b. Probability of CR in the training cohort

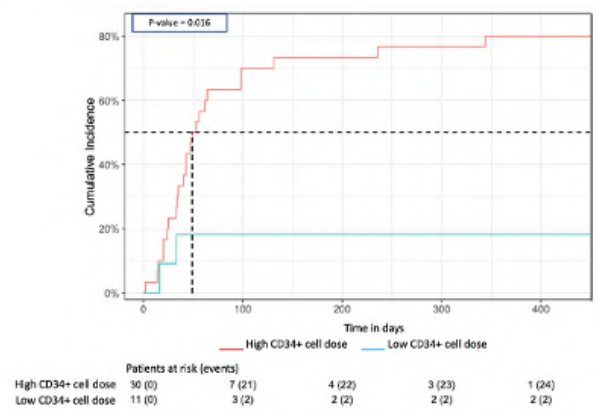

Figure 1c. Probability of CR in the validation cohort

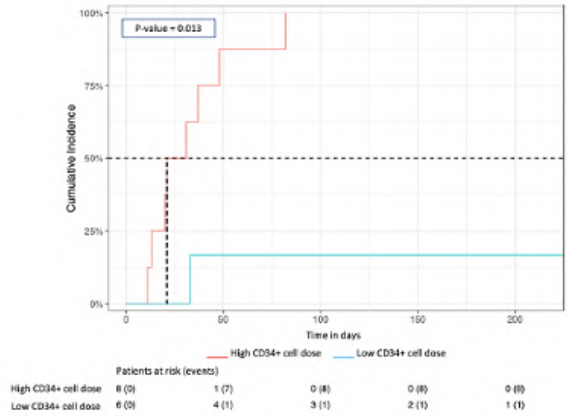

Conclusions: PGF is a severe complication after HSCT and in paediatric HSCT recipients with PGF, SCB can provide durable trilineage engraftment. In this study, we determined the CD34+ cell cut-off point necessary for a CR following a SCB. We also demonstrated that patients with a CD34+ cellularity greater than 4.65 x 10^6/kg are more likely to respond. However, these results need be validated in larger cohort of patients.

ENGRAFTMENT SYNDROME IN PEDIATRIC ALLOGENEIC HSCT: RISK FACTORS AND OUTCOMES

Anne B. Verbeek[1], *Lotte S.J. Verheijen*[1], *Erik G.J. von Asmuth*[1], *Gertjan Lugthart*[1], *Arjan C. Lankester*[1], *Emilie P. Buddingh*[1]
[1]*Leiden University Medical Center, Leiden, Netherlands (the)*

Background: In this cohort study, we evaluated the outcomes of engraftment syndrome (ES) and identified risk factors for the development of ES in pediatric allogeneic hematopoietic stem cell transplantation (HSCT) recipients.

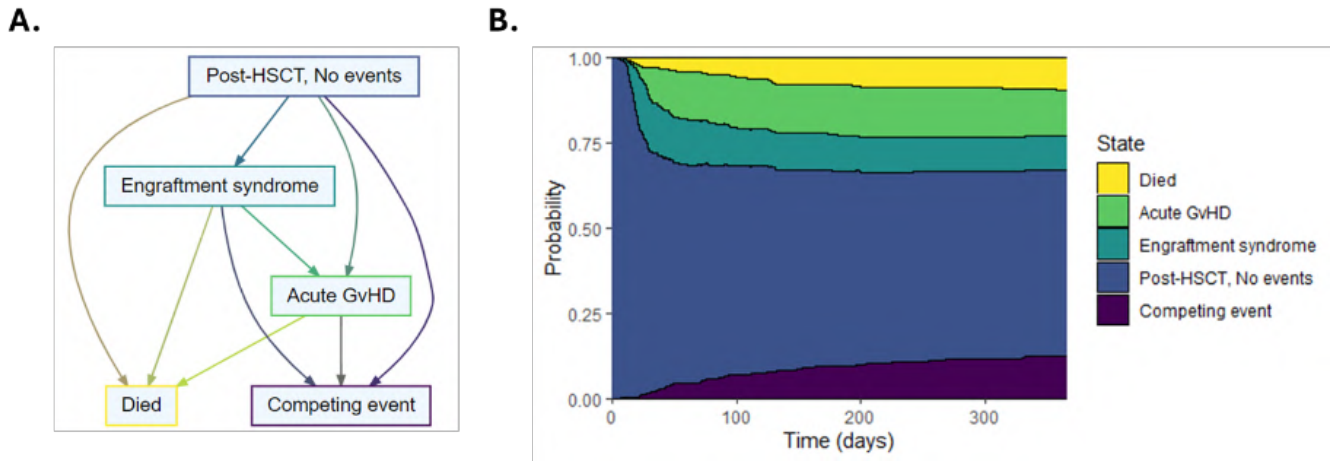
Methods: We included 384 pediatric HSCT recipients who were consecutively transplanted between 2010 and 2022 at our center. Clinical and laboratory data were collected retrospectively from electronic health records. ES was diagnosed using the Spitzer criteria. Twenty-eight inflammatory serum proteins were measured before HSCT using a Luminex immunoassay. Associations between ES and acute GvHD, non-relapse mortality (NRM) and overall survival (OS) were modeled using a Cox model with ES as a time-dependent covariate. Risk factors for ES and unfavorable outcome after ES were identified using a multi-state model, which allows the estimation of hazard ratios (HR) for different events after HSCT (Figure 1A). Multiple testing correction was performed on the Luminex data using the Benjamini-Hochberg procedure.

Results: Patient- and transplant characteristics are displayed in Table 1. The cumulative incidence of ES was 20% at day 50 post-HSCT (N = 75). The most common major criterium of ES was fever without infection (72/75, 96%), followed by rash (52/75, 69%) and pulmonary edema (37/75, 49%). Occurrence of ES was significantly associated with acute GvHD (HR 3.05, 95% CI 1.86-5.01, p <0.001) and OS (HR 1.98, 95% CI 1.14-3.44, p 0.016). We evaluated which of the individual major criteria of ES contributed most to an increased risk of acute GvHD and mortality. All criteria were significantly associated with acute GvHD, skin rash being the most important (HR 3.19, 95% CI 1.93-5.27, p <0.001). Only pulmonary edema was associated with NRM and OS (respectively HR 3.74, 1.88-7.44, p < 0.001 and HR 3.13, 1.80-5.43, p <0.001). CXCL16 serum levels at HSCT correlated most strongly with the development of ES out of all measured inflammatory serum proteins, however, these results were insignificant after multiple testing correction (HR 2.79, corrected p >0.05). Recipients of transplants from unrelated donors had an increased risk of developing ES, as compared to related donors (HR 2.37, 95% CI 1.36-4.12, p 0.002). Furthermore, patients transplanted for malignant diseases (HR 1.91, 95% CI 1.11-3.29, p 0.02) and inborn errors of immunity (HR 2.39, 95% CI 1.36-4.21, p 0.003) had an increased risk of developing ES, as compared to non-malignant hematological diseases.

Table 1. Patient and transplant characteristics	**N = 384**
Age (median, IQR)	8.2 (3.0-13.1)
Patient sex	
Male	235 (61%)
Female	149 (39%)

Table 1. Patient and transplant characteristics	N = 384
Diagnosis	
Hematologic malignancy	115 (30%)
Hemoglobinopathy and other non-malignant hematologic diseases	185 (48%)
Inborn error of immunity	81 (21%)
Other	3 (0.8%)
Donor type	
Matched unrelated	129 (34%)
Mismatched unrelated	112 (29%)
Matched related	105 (27%)
Mismatched related	38 (9.9)
Graft type	
Bone marrow	295 (77%)
Umbilical cord blood	50 (13%)
Peripheral blood stem cells	39 (10%)

Figure 1: Diagram of possible transitions within multistate model (A) and a graphical overview of proportions of patients in each state within the first year after HSCT (B).



Conclusions: These findings highlight the clinical burden of ES through its association with adverse outcomes after HSCT. Careful monitoring of these patients is warranted to recognize patients at risk for further complications, especially in patients suffering from pulmonary edema. Prospective studies are needed to optimize treatment strategies for ES, ultimately improving patient outcomes after HSCT.

Disclosure: Nothing to declare.

INCIDENCE OF VOD AND LONGITUDINAL DYNAMICS OF EASIX AND ENDOTHELIAL BIOMARKERS AFTER ALLO-HCT WITH PTCY

Blanca De Moner Rafel[1,2,3], *Laura Creus-Vilalta*[3], *María Suárez-Lledó*[4,3], *Julia Martinez-Sanchez*[1,3], *Ana Belen Moreno-Castaño*[1,3], *Cristina Moreno*[4], *Esther Carcelero*[5], *Arnau Trorent*[5,3], *Begoña Fernández*[4,3], *Laura Rosiñol*[4,3], *Enric Carreras*[6], *Francesc Fernández-Avilés*[4,3], *Carmen Martínez*[4,3], *Montserrat Rovira*[4,3], *Maribel Diaz-Ricart*[1,3], *María Queralt Salas*[4,3]

[1]*Hemostasis and Erythropathology Laboratory, Hematopathology, Department of Pathology, Biomedical Diagnostic Center, Hospital Clínic de Barcelona, Spain, Barcelona, Spain,* [2]*Josep Carreras Leukemia Research Institute, Barcelonaspains, Spain,* [3]*Universitat de Barcelona, Barcelona, Spain,* [4]*Hematopoietic Transplantation Unit, Hematology Department, Institute of Cancer and Blood Diseases (ICAMS), Hospital Clínic de Barcelona, Barcelona, Spain,* [5]*Pharmacy Service, Hospital Clínic Barcelona, Barcelona, Spain,* [6]*Fundació Josep Carreras Contra la Leucèmia, Barcelona, Spain*

Background: Veno-occlusive disease (VOD) is a severe complication after allo-HCT, linked to endothelial and hepatocyte injury. Post-transplant cyclophosphamide (PTCy) is widely used for GVHD prophylaxis, but its effect on VOD remains unclear. Emerging evidence suggests that biomarkers of endothelial stress and inflammation may improve early identification and

diagnosis of VOD, while providing mechanistic insights into endothelial dysfunction. Hence, integrating these biomarkers with clinical risk assessment in allo-HCT with PTCy could enhance VOD prevention, early intervention strategies, and optimize patient outcomes. This study characterizes the incidence and outcomes of VOD in adults undergoing allo-HCT with PTCy and evaluates the dynamics and predictive value of endothelial biomarkers.

Methods: The 374 consecutive adults who underwent allo-HCT with PTCy-based prophylaxis between 2014 and January 2025 were included. VOD was diagnosed according to modified Seattle, Baltimore, or EBMT criteria, depending on the timing. Clinical characteristics and outcomes of VOD patients were analyzed. Longitudinal EASIX scores were calculated for all patients during the first six months post-transplant. Complementary, in a subset of 109 patients transplanted between 2022 and January 2025, analyses of endothelial injury biomarkers (VWF, TM, VCAM-1, TNFRI) were performed using plasma samples longitudinally collected at HCT admission, day 0, +7, +14, and +21. Samples were cryopreserved and analyzed in October 2025.

Results: Baseline characteristics of patients are reported in **Table 1.** Overall, the median age was 53 years, 59.9% were male, and 5.3% were diagnosed with myeloproliferative neoplasms (MPN). All patients received PTCy, and donor types are detailed in **Table 1.** VOD occurred in 12 (3.2%) patients at a median of 12 days post-transplant, with a day +100 cumulative incidence of 2.7%. Patients with MPN were overrepresented among VOD cases (41.7% vs. 4.1% in non-VOD; P<0.001). All 8 (66.7%) moderate and severe cases received defibrotide, and one (8.3%) underwent TIPS placement. Complete response was achieved in 11 (91.7%) patients, while one (8.3%) died from unresponsive VOD. However, the two-year overall survival and non-relapse mortality in VOD patients were 33.3% and 31.2%, respectively, compared with 71.8% and 12.6% in non-VOD patients.
As illustrated in **Figure 1,** median EASIX scores were significantly higher in patients who developed VOD both pre-transplant (median EASIX-PRE 3.2 vs. 1.1, P<0.01) and during the early post-transplant period. Additionally, elevated pre-transplant log2-EASIX-PRE and independently predicted VOD in univariate analyses (HR 4.6; P=0.003).
Complementary biomarker analyses were conducted on samples from 109 patients, of whom 4 (3.7%) had VOD. Baseline characteristics are summarized in **Table 1.** At HCT admission, patients with VOD showed higher EASIX scores and elevated levels of endothelial activation markers (VCAM-1 and TNFRI). Furthermore, patients with VOD had increased levels of all endothelial activation biomarkers even before clinical diagnosis and during the early post-transplant period **(Figure 1).**

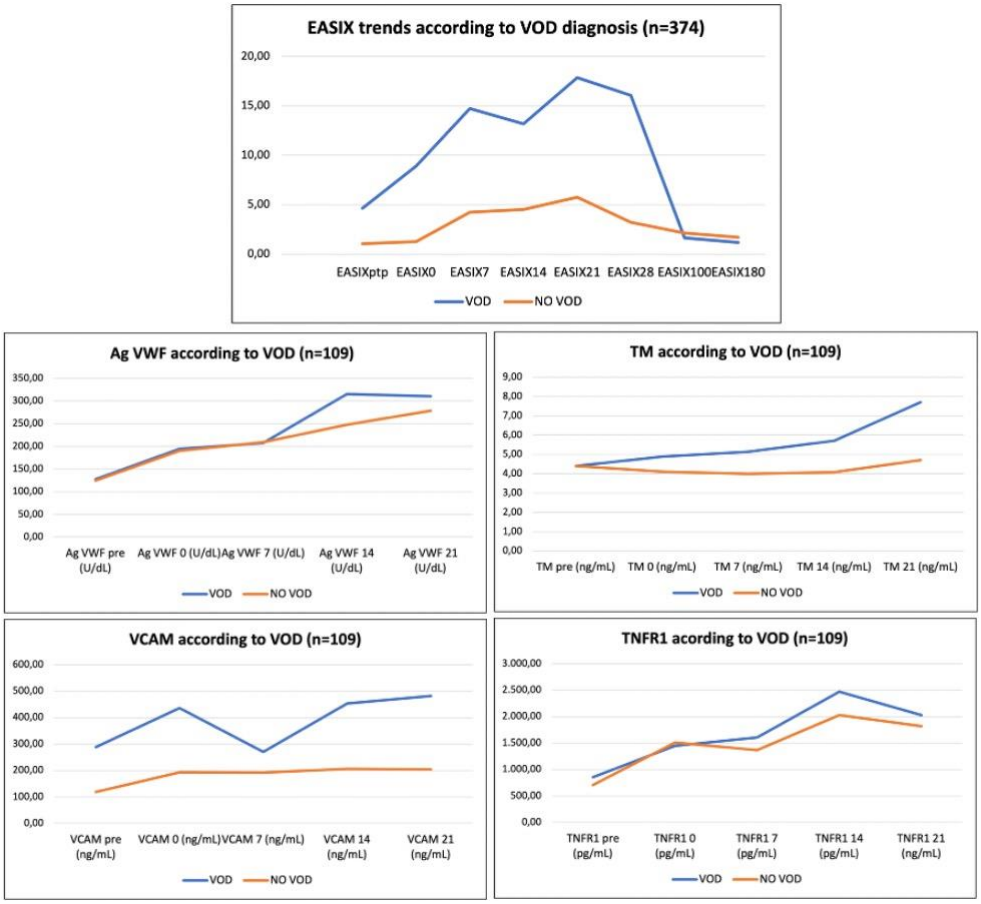
Figure 1. Median biomarker values according to VOD diagnosis



Conclusions: VOD remains a clinically significant complication after allo-HCT with PTCy, associated with relevant morbidity, organ dysfunction, and reduced survival. Complementary, findings support the central role of endothelial dysfunction in VOD pathophysiology and that biomarker monitoring may enable earlier patient risk stratification.

Disclosure: The research group has received partial financial support from JAZZ Pharmaceuticals to conduct the study. Otherwise, the authors declare that they have no relevant conflicts of interest.

SECOND ALLOGENEIC STEM CELL TRANSPLANTATION TO TREAT PRIMARY AND SECONDARY GRAFT FAILURE: A SINGLE CENTRE EXPERIENCE

*Julia Parra Serrano[1], **Ignacio Gómez-Centurión**[1,2], Rebeca Bailén[1,2], María José Llácer[1,2], Lucía Castilla[1,2], Cristina Muñoz[1,2], Santiago Sabell[1,2], Íñigo Gastaminza Láinez[1], Javier Bañón Soria[1], Pedro Antonio Rodriguez[1,2], Leticia Gómez[1,2], Javier Anguita[1,2], Ismael Buño[1,2], Carolina Martínez[1,2], Ramón García Sanz[1,2], Mi Kwon[1,2,3]*
[1]Department of Hematology, Hospital General Universitario Gregorio Marañón, Madrid, Spain, [2]Instituto de Investigación Sanitaria Gregorio Marañón, Madrid, Spain, [3]Department of Medicine, Complutense University of Madrid, Madrid, Spain

Background: Graft failure (GF) is an unusual but threatening complication after allo-HSCT, associated with several factors, including use of mismatched donors. Second allo-HSCT has been proposed as a safe and effective strategy to rescue these patients.
The objective of this study was to analyse characteristics and outcomes of patients treated with a second allo-HSCT to treat GF.

Methods: We retrospectively analyzed all patients who received a second allo-HSCT to treat GF in a single centre between 2014 and 2024.
Primary GF was defined as the absence of neutrophil engraftment by day +28 with mixed chimerism (MC) and secondary GF as initial engraftment and later development of severe cytopenia and MC. Complete chimerism (CC) was defined as the presence of a percentage of recipient cells below 1% in peripheral blood (PB) and 5% in T lymphocytes (TL). Relapse was ruled out in all cases with GF suspicion.

Results: A second allo-HSCT was used as salvage therapy following GF in 18 patients: 7 (39%) for primary GF and 11 (61%) secondary GF. Five patients were female (28%), median age was 33 (range 18-69) and the most common diagnosis were AML/MDS (n=7, 39%) and ALL (n=6, 33%). Donors used in the first procedure were: MRD (n=2,11%), MUD (n=1,5%), haploidentical (n=12,67%) and UCB (n=3,17%). Eleven patients (61%) had received a reduced intensity conditioning (RIC) regimen. At the time of GF diagnosis, median percentage of recipients' cells were 47% (range 5-100%) and 94% (range 25-100%) in PB and TL, respectively.
Main characteristics of second allo-HSCT are shown in Table 1. Second allo-HSCT was performed at a median of 42 days (range 34-68) and 94 days (range 54-191) after first transplant in patients with primary GF and secondary GF, respectively. An haploidentical donor was used in 13 patients (72%). Seventeen patients (94%) received a RIC regimen and anti-thymocyte globulin (ATG) was part of conditioning regimen in 15 patients (83%), combined with thiotepa and fludarabine in 12 (67%). Neutrophil engraftment was achieved in 15 patients (83%) at a median time of 16 days (range 12-130) after transplant. Platelet engraftment was achieved in 12 patients (67%) at a median time of 29 days (range 13-90) after transplant. Complete chimerism was achieved in 16 patients (88%) at a median time of 19 days (range 8-100) after transplant. The most common complication after salvage therapy were infections. Most patients (n=14,77%) developed at least 1 documented

infection after transplant: 13 patients had at least 1 viral infection, 11 bacterial and 5 fungal infections. 100-day overall survival (OS) and 1-year OS were 67 and 44%, respectively, with infections being the first cause of death in this cohort (n=8, 44%).

Table 1.

	Primary graft failure (n=7)	Secondary graft failure (n=11)
Donor		
Haplo-HSCT	6 (85.7%)	7 (63.6%)
MRD	0	2 (18.2%)
MUD	0	1 (9.1%)
MMUD	1 (14.3%)	1 (9.1%)
Conditioning		
RIC	6 (85.7%)	11 (100%)
MAC	1 (14.3%)	0
Engraftment and chimerism		
Complete chimerism	7 (100%)	9 (81.8%)
Neutrophil engraftment	7 (100%)	9 (81.8%)
Platelet engraftment	5 (71.4%)	8 (72.7%)
Survival		
100 day-OS	4 (57.1%)	8 (72.7%)
1 year-OS	2 (28.6%)	6 (54.5%)

Haplo-HSCT: Haploidentical Hematopoietic Steam Cell Transplantation; MMUD: Mismatched Unrelated Donor; MRD: Matched Related Donor; MUD: Matched Unrelated Donor; RIC: Reduced-Intensity Conditioning; MAC: Myeloablative Conditioning

Conclusions: In our experience, timely and individualized second allo-HSCT may improve outcome after primary or secondary GF. A vast majority of patients achieved engraftment and full donor chimerism, which resulted in a high 100-day survival.

A383

REDUCED EARLY POST-TRANSPLANT GLUTAMINE LEVELS ARE ASSOCIATED WITH SYSTEMIC INFLAMMATION AND SEVERE AGVHD

Sarah Weischendorff[1], *Nakisa Kamari-Kany*[1], *Maria Ebbesen-Sørum*[1], *Marianne Ifversen*[1], *Katrine Kielsen*[1,2], *Klaus Müller*[1,2]
[1]*Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark,* [2]*University of Copenhagen, Copenhagen, Denmark*

Background: Severe acute graft-versus-host disease (aGvHD) remains a major cause of transplant-related morbidity and mortality. Conditioning-induced gastrointestinal mucosal injury may initiate local cytokine release, which can drive systemic inflammation and ultimately promote alloreactivity.
Glutamine, the most abundant free amino acid, is important for maintaining gut integrity as the primary metabolic fuel for enterocytes, and it sustains cellular antioxidant capacity through its role in glutathione synthesis. Glutamine availability also influences systemic immune homeostasis by regulating leukocyte metabolism, activation, and proliferation including regulatory functions.
Thus, we hypothesized that an early post-transplant decrease in plasma glutamine may be associated with cytotoxicity-associated systemic inflammation and aGvHD development.

Methods: A total of 75 children (1–18 years) undergoing myeloablative, matched-donor HSCT in Denmark between 2015 and 2020 were included. Underlying diagnoses comprised malignant (n=47) and benign (n=28) diseases. Donors were either HLA-matched siblings (n=26) or unrelated donors (n=49) (Table 1). aGvHD was diagnosed and graded according to the MAGIC criteria. Plasma glutamine levels were quantified using mass-spectrometry at five time points: before conditioning and days 0, +7, +14, and +21. Statistical analyses included mixed model repeated measures analyses for time-course comparisons, logistic regression analysis and Spearman's rank-order correlation.

Table 1:

Characteristic	Value
Number of patients, no. (%) Males	75 (100) 41 (55)
Median age at transplantation, years (range)	9.7 (1.2-17.3)
Diagnosis, no. (%) Acute leukemia Other malignancies Benign diseases	 33 (44) 14 (19) 28 (37)

Donor type, no. (%) Matched sibling donor HLA-Matched unrelated donor (9/10 or 10/10)	 49 (65) 26 (35)
Stem cell source, no. (%) Bone marrow Peripheral blood	 71 (95) 4 (5)
Conditioning regimen, no. (%) TBI 12 GY + CY/VP16 BU-CY-MEL FLU + THIO/TREO Other regimens	 14 (19) 21 (28) 28 (37) 12 (16)

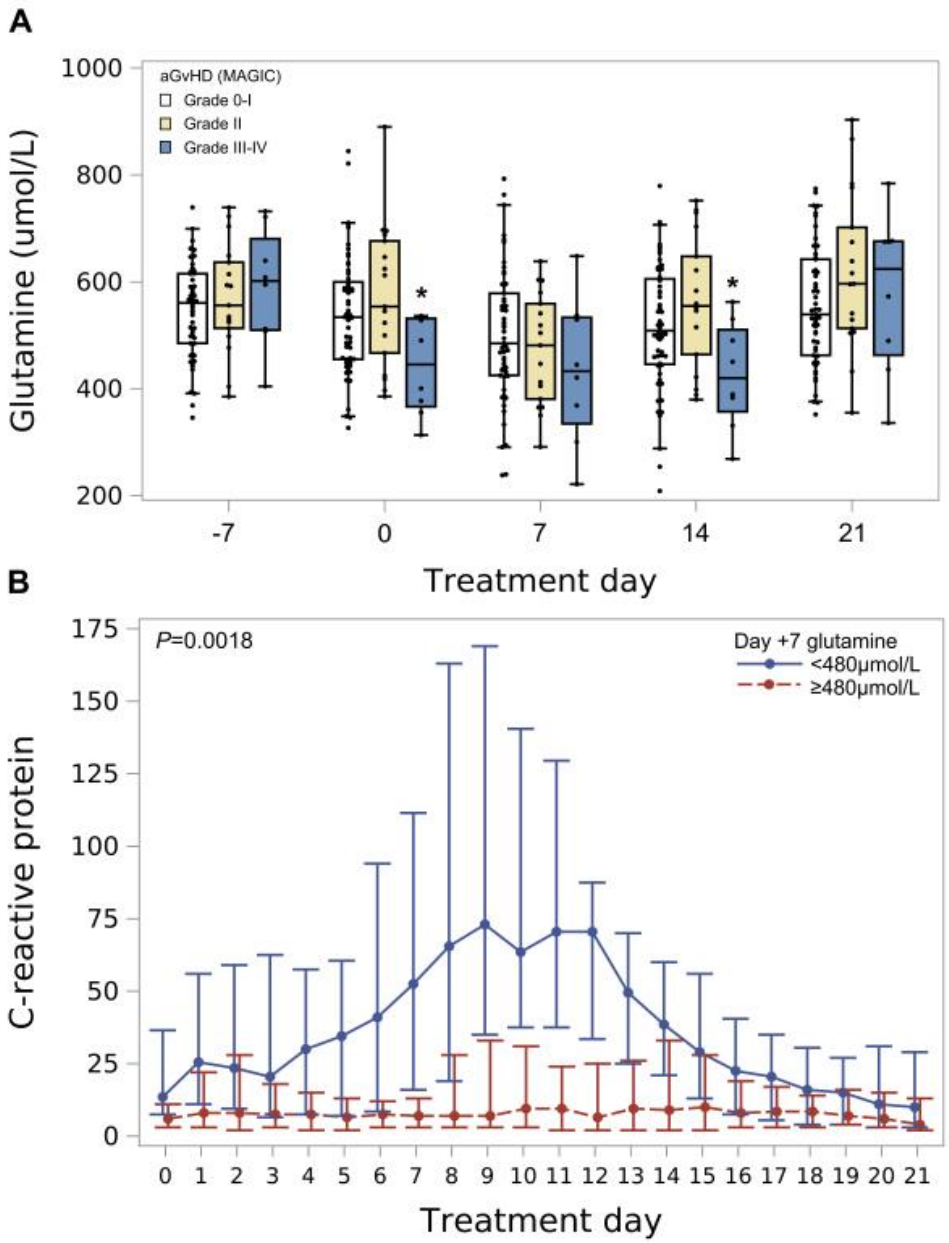
Results: A total of 25 patients (33%) developed grade II–IV aGvHD at median day +14 (range: 5–34), including eight cases with grade III–IV. Lower GI involvement occurred in five patients.

Plasma glutamine levels declined from a median pre-conditioning value of 558 µmol/L (369–1117) to a nadir of 478 µmol/L (222–793) on day +7 (P<0.0001), followed by gradual recovery.

In multivariable analyses adjusted for sex, age, diagnosis, and donor type, patients who developed grade III–IV aGvHD had significantly lower glutamine levels across days 0–14 compared with those with grade 0–I and grade II (Figure 1A). Each 50 µmol/L decrease in glutamine at day 0 was associated with an increased risk of severe aGvHD (OR=1.56; 1.01–2.42; P=0.046). No significant differences were observed between patients with lower GI aGvHD and those with extraintestinal aGvHD.

On day +7, glutamine levels were inversely correlated with C-reactive protein (CRP) (r_s=–0.69, P<0.0001). Patients with below-median glutamine at day +7 displayed a markedly higher inflammatory burden, reflected by persistently elevated CRP, most pronounced during the second week after HSCT (Figure 1B).

Figure 1:



Conclusions: This study demonstrates a significant decline in plasma glutamine levels during the early post-HSCT period, potentially due to a high metabolic demand as well as low dietary intake and impaired endogenous synthesis. Reduced glutamine levels were associated with the development of severe aGvHD and increased systemic inflammation. These findings support the role of glutamine as an important modulator of intestinal integrity and early inflammatory responses after transplantation. Further studies are warranted to determine whether maintaining adequate glutamine availability could mitigate early inflammatory complications and reduce the risk of severe aGvHD.

COMPARISON OF THE INFECTIOUS AND IMMUNOLOGICAL SAFETY OF A LOW-BACTERIAL AND MODIFIED DIET IN ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION IN ADULTS

*Maxim Kucher[1], Nikita Volkov[1], Julia Tarakanova[1], Tamara Gogoleva[1], Natalia Saltykova[1], Julia Vlasova[1], **Alexander Kulagin**[1], Ivan Moiseev[1]*
[1]Raisa M. Gorbacheva Institute of Pediatric Oncology, Hematology, and Transplantation, Pavlov First Saint Petersburg State Medical University, Saint Petersburg, Russian Federation (the)

Background: Malnutrition is an aggravating factor in hematopoietic stem cell transplantation (HSCT). The absorption of nutrients, among other factors, is closely related to the functional activity of the intestinal microbiota. Due to the need for the intestinal microbiome protection, which is a key element in homeostasis and is under complex negative effects in HSCT, a theory aimed at liberalizing dietary restrictions is being developed, which creates the basis for improving the patient's self-feeding and leads to a number of positive outcomes. The aim of the study was to evaluate the infectious and immunological safety of a modified diet (MD) in comparison with traditional low-bacterial diet (LBD).

Methods: From 2022 to 2023 at the RM Gorbacheva Research Institute 406 allogeneic HSCT recipients with acute leukemia over 18 years old, who followed a LBD (n=177) or MD (n=229) were enrolled to the randomized crossover trial. The concept of LBD included generally accepted anti-infective restrictions in HSCT, the absence of gluten, lactose, and yeast-containing products. Under MD, only the principles of anti-infective measures were preserved in the preparation, storage, transportation and dishes consumption, and the prohibition of a sharply limited list of foods that are difficult to digest and capable of mechanically injuring the oropharynx and gastrointestinal tract mucous membrane.

Results: The patient groups were homogeneous in diagnosis, graft source, HLA-compatibility between the recipient and the donor, conditioning regimen intensity and graft-versus-host disease (GvHD) prophylaxis, except for the age: MD group – 42.3 years, LBD group – 38.4 years, p=0.009. The one-year overall survival was similar in both groups: 72% for MD and 75% for LBD, p=0.6. Relapse-free one-year mortality was comparable between the groups: 8.7% for MD versus 9.1% for LBD, p=0.9. Graft engraftment at D+30 did not differ: 83% and 92%, respectively, p=0.2. The incidence of GvHD grade 3-4 was 3.4% in the MD group and 6.8% in the LBD group, respectively, p=0.14. The incidence of bloodstream infections at D+30 was lower in the MD group (14.4%) compared with the LBD group (45.2%), respectively, p<0.001.

Conclusions: Using the example of the presented cohort of patients who underwent allogeneic HSCT, the use of MD has potential advantages over LBD in the form of a tendency to decrease bloodstream infections and the severe GvHD incidence. Further studies with a large number of participants are needed to confirm these findings.

Background: Post-allogeneic hematopoietic cell transplantation (HCT) respiratory failure is associated with high mortality, especially in patients requiring mechanical ventilation. Non-infectious, non-cardiogenic interstitial lung disease (ILD) is a rare condition with many differential diagnoses and no standardized treatment strategy. Toxic and immunologic causes are suspected based on scarce pathophysiological data. The aim of this study was to describe the clinical presentation, diagnostic work-up, treatment and outcome of such non-infectious, non-cardiogenic rapidly progressive ILD requiring intensive care unit (ICU) admission in allogeneic HCT recipients.

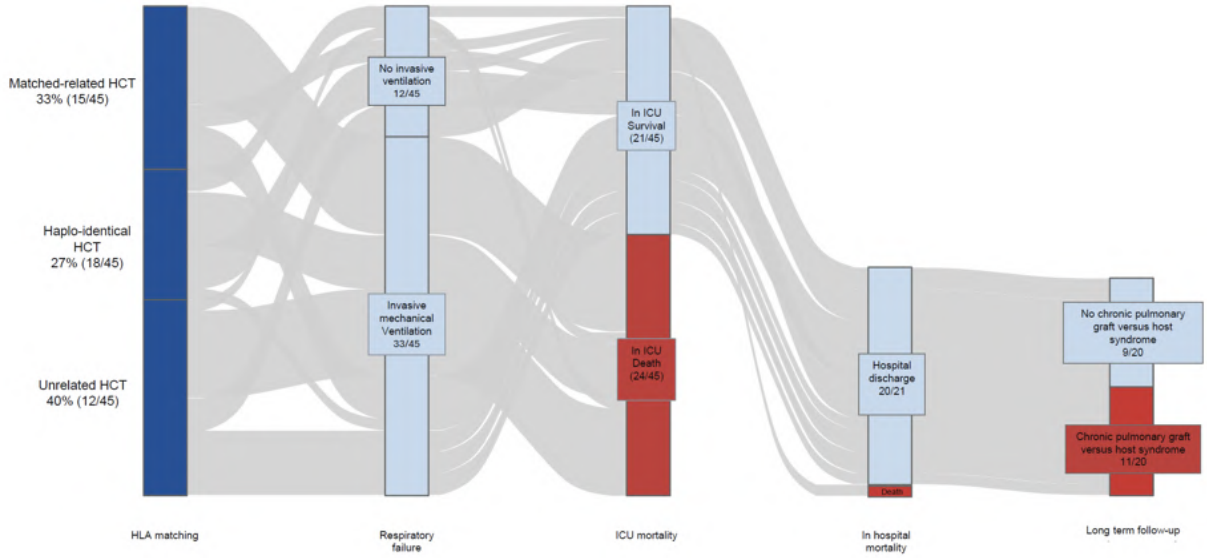
Methods: This French retrospective multicentre cohort study used Grrr-OH network and EBMT registry to identify cases from 01/01/2013 to 31/01/2024. Inclusion criteria were ≥18 years allogeneic HCT recipients hospitalized in ICU for inaugural ILD (evolving since <1 month) with interstitial pattern on chest tomodensitometry and requiring ≥6L oxygen. Exclusion criteria were ILD >1 month before ICU admission, infectious documentation or cardiogenic related respiratory failure.

Results: Forty-five patients were included. The characteristics of the patients are summarized in table 1.
Thirty of the 45 patients had a history of acute GVHD, among them 4/30 (11%) had refractory acute GVHD requiring JAK2 inhibitors, and 6/45 had a history of non-pulmonary chronic GVHD.
At the time of ICU admission, 13/45 (29%) still received systemic steroids and 25/45 (56%) an immunosuppressive treatment. Among them 6/45 (20%) patients still had an active grade ≥2 acute GVHD. The median dose of prednisone at ICU admission was 10 mg per day (IQR, 5–60 mg).
Respiratory symptoms developed at a median of 143 days (IQR 44–309) after allogeneic HCT. ICU admission occurred at a median of 8 days (IQR 5-16) after the onset of respiratory symptoms.
In-hospital mortality (figure 1) occurred mostly during the ICU stay (24/25), with most patients dying of acute respiratory failure at a median of 24 days (IQR 11-30) after ICU admission. Mortality was higher in patients who require invasive mechanical ventilation (22/33 (66%) vs 3/12 (25%), p=0.02).
Most patients received systemic steroids for ILD treatment (40/40 patients with available data). There was no difference in the time to initiation of specific treatment between ICU survivors and non-survivors (median of 2 days in both arms, p=0.42). Among the 13 patients who received a second-line immunosuppressive therapy (cyclosporin (n=4), ruxolitinib (n=3), anti-TNFα (n=3), MMF (n=1), missing data (n=2)) in the ICU, 5/13 (38%) survived the hospital stay. Among 20 survivors, 10/20 (50%) later developed to chronic pulmonary GVHD in the form of bronchiolitis obliterans syndrome requiring long term inhaled bronchodilators (n= 6/10) and/or immunosuppressive agents (n=4/10) (3 patients with systemic steroids alone, 1 with steroids, anti-TNFα and a Jak2 inhibitor).

Age (median, IQR) (45/45)*	60 [40-66]
Female Sex (45/45)*	14 (31%)
HCT-CI (34/45)* ≤2	27 (79%)
Previous respiratory disorder (44/45)* - Obstructive ventilatory disorder - Restrictive ventilatory disorder	6 (14%) - 5 (11%) - 1 (2%)
Underlying disease (45/45)* - Acute leukemia or myelodysplastic syndrom - Lymphoproliferative disease - Others	 37 (84%) 3 (7%) 3 (7%)
Stem cell source (45/45)* : Peripheral blood stem cells	43 (96%)

Donor type (45/45)* - Matched related donor - Haplo-identical - Unrelated donor	15 (33%) 12 (27%) 18 (40%)
Myelo-ablative conditioning (43/45)*	23 (53%)
Total body irradiation (45/45)*	11 (24%)
Previous acute GVHD (45/45)*	30 (67%)
Previous chronic GVHD (45/45)*	6 (13%)

- *The numbers in brackets indicate the number of patients with available data



Conclusions: ILD with inaugural respiratory failure is a rare but severe complication after allogeneic HCT with a high in-hospital mortality rate. Long term follow-up shows a high overall burden of the disease with more than half of patients dying and half of survivors developing chronic pulmonary GVHD.

INCIDENCE AND RISK FACTORS OF NON-INFECTIOUS PULMONARY COMPLICATIONS FOLLOWING LOW-DOSE-RATE TOTAL BODY IRRADIATION

Zixuan Jin[1], *Junya Kanda*[1], *Mizuki Watanabe*[1], *Noriko Kishi*[1], *Katsuyuki Sakanaka*[1], *Yasuyuki Arai*[1], *Tadakazu Kondo*[1], *Kouhei Yamashita*[1], *Satoshi Morita*[1], *Takashi Mizowaki*[1], *Akifumi Takaori-Kondo*[1]
[1]*Kyoto University, Kyoto, Japan*

Background: Non-infectious pulmonary complications (NIPCs) are potentially life-threatening complications following hematopoietic stem cell transplantation (HSCT). Historically, total body irradiation (TBI) at our institution was performed at a high dose rate (17–21 cGy/min). Since high-dose-rate TBI is a known risk factor for NIPCs, we recently reduced the dose rate to <10 cGy/min. This study aimed to evaluate the cumulative incidence and risk factors of NIPCs in patients receiving low-dose-rate TBI.

Methods: We prospectively enrolled patients undergoing allo-HSCT with a conditioning regimen containing TBI at a dose rate of 7–8 cGy/min. NIPCs were defined by the presence of at least one of the following criteria in the absence of infectious etiology (confirmed via blood culture or bronchoalveolar lavage): (1) two or more refractory respiratory symptoms, (2) pulmonary consolidation on chest radiography, or (3) respiratory dysfunction/hypoxia.

Results: A total of 56 patients were included (30 males, 26 females). The mean age was 46.5 years (range: 17–69). The 1-year cumulative incidence of NIPCs was 15.2% (95% CI: 7.0–26.2%). Although a higher incidence was observed in older patients (>50 years) compared to younger patients (21.7% vs. 10.3%), the difference was not statistically significant (P = 0.191). No significant difference was observed between total TBI doses of 4 Gy (14.9%) and 12 Gy (15.9%; P = 0.946), and smoking history was not associated with NIPC incidence (P = 0.722). Notably, none of the five patients who received anti-thymocyte globulin (ATG) for GVHD prophylaxis developed NIPCs, suggesting that T-cell immunity may play a pivotal role in the pathogenesis of NIPCs. The 1-year overall survival was 60% in patients with NIPCs compared to 87% in those without.

Conclusions: Despite the implementation of low-dose-rate TBI, NIPCs remain a significant complication with a cumulative incidence of 15.2%, showing a trend toward higher incidence in older patients. The complete absence of NIPCs in the ATG group underscores the potential involvement of T-cell alloreactivity. Further comparative studies between low- and high-dose-rate TBI cohorts are warranted to establish the optimal irradiation strategy.

A PHASE III, RANDOMIZED, DOUBLE-BLIND, PLACEBO CONTROLLED STUDY OF CURCUMIN TO REDUCE MUCOSITIS IN AUTOLOGOUS TRANSPLANT SETTING

Sachin Punatar[1,2], *Neha Singh*[1], *Anant Gokarn*[1,2], *Sumeet Mirgh*[1,2], *Akanksha Chichra*[1,2], *Nishant Jindal*[1], *Gourav Bain*[1], *Lingaraj Nayak*[1,2], *Bhausaheb Bagal*[1,2], *Libin Mathew*[1], *Nitesh Chavan*[1], *Pallavi Rane*[1], *Sadhana Kannan*[1,2], *Vikram Gota*[1,2], *Navin Khattry*[1,2]
[1]*ACTREC, Tata Memorial Centre, Navi Mumbai, India,* [2]*Homi Bhabha National Institute, Mumbai, India*

Background: Mucositis is a significant complication of autologous hematopoietic stem cell transplant, with severe mucositis reported to occur in up to 70% patients receiving melphalan based chemotherapy. In a previous pilot study, we had reported that curcumin reduced incidence of severe mucositis in a cohort of patients receiving melphalan based conditioning. We conducted this randomized, placebo-controlled, double-blind study to definitively evaluate role of curcumin in this setting.

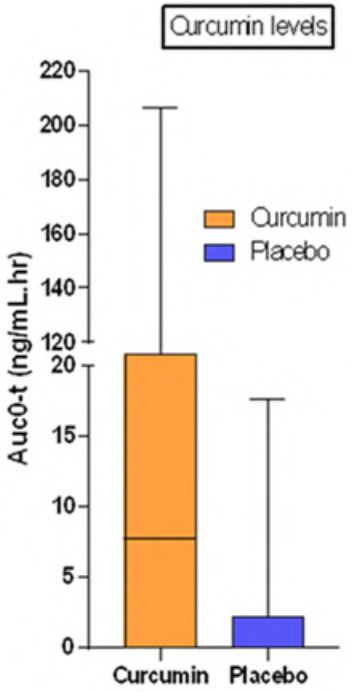
Methods: Patients aged ≥18 years undergoing autologous HSCT with either melphalan 200 mg/m^2 or BEAM or Bu-Mel were randomized centrally in 1:1 ratio (with help of computer-generated random sequence, stratified according to conditioning regimen) to receive curcumin (4 lozenges BD each containing 100 mg of curcumin, starting two days prior to conditioning chemotherapy) or matching placebo. All patients provided written informed consent, had ECOG PS 0-2, and had adequate organ function. Those receiving anti-oxidants, NSAIDs, aspirin or systemic steroids for past 3 months with last dose taken within a week prior to enrolment were excluded. Patients were assessed daily from start of lozenges till day +28 of transplant. The primary endpoint was incidence of grade III/IV mucositis. Secondary endpoints included incidence of grade III/IV nausea, vomiting, diarrhoea, the duration of these toxicities as well as requirement of opioids and total parenteral nutrition. Oral mucositis was graded according to WHO severity scale; nausea, vomiting and diarrhoea as per CTCAE v4.0. Exploratory endpoints included pharmacokinetics of curcumin and evaluation of serum and salivary cytokines. Serum and salivary cytokines were assessed prior to the 1st dose of study drug, on day 0 and then thrice a week till day +14. Pharmacokinetic analysis was done through 4 serum samples on day 7 of start of intervention. Based on information from pilot study, we hypothesized 20% reduction in grade III/IV mucositis with curcumin. A sample size of 95 in each group (total 190) was required to detect a 20% difference with 80% power. A two-sided alpha of 5% was assumed. Two interim analyses were planned, one after 75 patients completed assessment for primary endpoint and another after 125 patients. At interim analysis, it was planned to calculate conditional power and to stop enrolment for futility if conditional power was 0.2 or less.

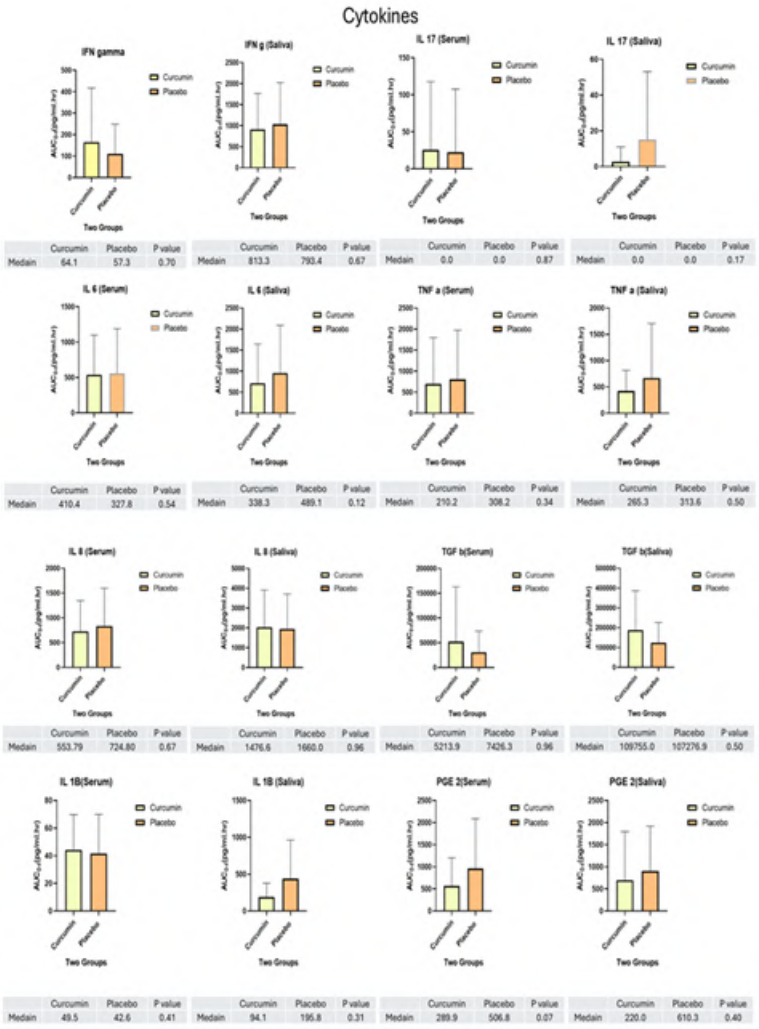
Results: Between December 2018 to April 2025, 77 patients (median age 45 years, 56 males) were enrolled. The baseline characteristics are shown in table. The incidence of grade III/IV oral mucositis was 36.8% in the curcumin group vs 25.6% in the placebo group (p=0.29). There was no difference in any of the secondary endpoints (Table). The study was terminated after the first interim analysis due to futility (Conditional power = 0.13).

Pharmacokinetic analysis confirmed a statistically significant difference in the median curcumin AUC_{0-t} between the intervention and control group (7.7 vs 0 ng•hr/ml), p=0.0003 (Figure, left part). There was no difference in any salivary or serum cytokine between two groups (Figure, right part).

	Curcumin (n=38)	Placebo (n=39)	p value
Baseline characteristics			
Age (median, range)	44 (18-63)	45 (18-63)	0.61
Gender Males Females	 29 (76.32%) 9 (23.68%)	 27 (69.24%) 12 (30.76)	0.61
Diagnosis Multiple myeloma Hodgkin lymphoma NHL Others	 28 (73.68%) 6 (15.79%) 3 (7.89%) 1 (2.64%)	 30 (76.92%) 3 (7.69%) 5 (12.82%) 1 (2.57%)	0.67
Conditioning regimen Melphalan 200 mg/m2 BEAM Bu-Mel	 28 (73.68%) 9 (23.68%) 1 (2.64%)	 30 (76.92%) 9 (23.08%) 0	0.89
Outcomes			
Mucositis grade III / IV Incidence Duration	 14 (36.8%) 4 days	 10 (25.6%) 5.5 days	 0.29 0.66
Diarrhoea grade III / IV Incidence Duration	 15 (39.4%) 3 days	 18 (46.2%) 2 days	 0.55 0.56
Nausea grade III / IV Incidence Duration	 2 (5.2%) 2 days	 5 (12.8%) 5 days	 0.25 0.12

Vomiting grade III / IV Incidence Duration	0 --	1 (2.6%) 3 days	0.32 --
Total parenteral nutrition Requirement Duration of use	19 (50%) 8 days	18 (46.1%) 7.5 days	0.73 0.88
Opioids use Requirement Duration of use	20 (50.6%) 7 days	15 (38.4%) 7 days	0.14 0.96





Conclusions: This double-blinded, placebo-controlled, phase III RCT failed to demonstrate benefit of curcumin in reducing incidence of grade III/IV mucositis associated with high-dose melphalan.

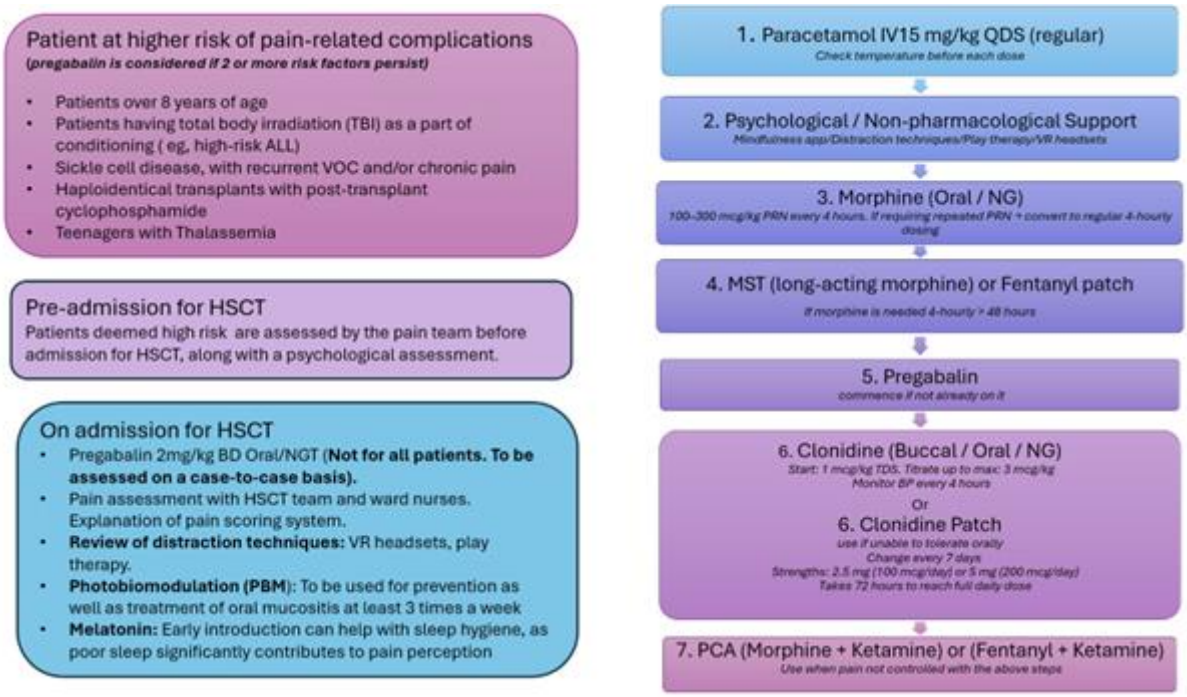
COMPREHENSIVE PAIN MANAGEMENT IN PAEDIATRIC ALLOGENIC HAEMATOPOIETIC STEM CELL TRANSPLANTATION (HSCT): RETROSPECTIVE AUDIT OF SPECIALIST PAIN TEAM REFERRALS AND DEVELOPMENT OF A PILOT PAIN-MANAGEMENT PATHWAY

Akshay Deshpande[1,2], *Rachel Desai*[1], *Vicky Taylor*[1], *Nicola Davis*[1], *Laura Gibbons*[1], *Aroosa Iqbal*[1], *Elaine Carrolan*[1], *Mel Rooney*[1], *Jason Patel*[1], *Ursula Dickson*[1], *Sarah Lawson*[1]
[1]*Birmingham Children's Hospital NHS Foundation Trust, Birmingham, United Kingdom of Great Britain and Northern Ireland (the),* [2]*University of Birmingham, Birmingham, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Children undergoing Hematopoietic Stem Cell Transplantation (HSCT) frequently experience significant and prolonged pain, from both physical complications—such as mucositis, graft versus host disease (GVHD), infections, and organ toxicity, as well as psychological distress. Current pain management practices are inadequate, leaving children vulnerable to suffering. There is an urgent need to develop evidence-based supportive care guidelines tailored to paediatric HSCT.

Methods: We conducted a retrospective audit of paediatric patients undergoing allogeneic HSCT who were referred to a specialist pain management service. Following the audit, certain high-risk groups and risk factors were identified, and a pilot pain management pathway was established (Figure 1). Multiple novel interventions are being undertaken via this pain pathway, including pre-HSCT assessment from the specialist pain nurses for patients identified as high risk, use of pregabalin in patients with chronic pain, especially with underlying sickle cell disease, nonpharmacological measures like use of play therapy, distraction techniques including virtual reality(VR) sets, photobiomodulation (PBM), focus on sleep hygiene and a stepwise escalating analgesia plan incorporating regular paracetamol at an early stage.



Results: From 1st January 2023 to 31st December 2024, 29.8% (14/47) of patients were referred and reviewed by the specialist pain team, with 27.6% (13/47) requiring patient- or nurse-controlled analgesia (PCA/NCA). Table 1 describes patient characteristics. Sex and intensity of conditioning do not impact PCA/NCA use. The odds of requiring specialist input were higher among patients older than 8 years (odds ratio 3.84, p = 0.05). Similarly, increased referrals were seen in patients undergoing HSCT for osteopetrosis, HSCT with haploidentical donors, TBI-based conditioning for ALL, and teenagers undergoing HSCT for haemoglobinopathies. The mean duration of PCA use was 16.8 days (range, 6 to 33 days), and 70% of patients required a PCA/NCA within 7 days of stem cell infusion. 53.8% (7/13) of patients required PCA for unexpected complications like perianal abscess(n=2), haemorrhagic cystitis (n=2) and severe hepatic Veno-occlusive disease (VOD) (n=1).
Since the implementation of the pathway, five patients were deemed high risk, reviewed pre HSCT by the pain team and initiated on pregabalin. Patients undergoing HSCT for non-malignant conditions did not require a PCA/NCA, and no adverse events have been reported with the regular use of paracetamol and pregabalin. Three (3/12, 25%) patients have needed PCA/NCA. All three patients were high-risk HSCT for relapsed/refractory acute leukaemia (and developed severe acute complications in the immediate post-HSCT period (grade IV GVHD, grade III VOD with GI bleeding post defibrotide and fatal grade IV VOD).

Table 1: Characteristics of patients referred to pain services

Characteristics	Referred to pain services	Not referred to pain services

Male Female	26.9% (7/26) 33.3% (7/21)	73.1% (19/26) 66.7% (14/21)
Age groups • 0-2 years • 2-5 years • 5-8 years • 8-12 years • 12-16 years	 30% (3/10) 0 14.3% (1/7) 36.4% (4/11) 50% (6/12)	 70% (7/10) 100% (7/7) 85/7% (6/7) 63.7% (7/11) 50% (6/12)
Common Transplant Indications • Acute lymphoblastic leukaemia (ALL) • Acute myeloid leukaemia (AML) • Aplastic anaemia • Osteopetrosis • Inborn errors of metabolism • Sickle cell disease • Thalassemia	 42.8% (3/7) 0 14.3% (1/7) 50% (2/4) 14.3% (1/7) 42.8% (3/7) 50% (3/6)	 57.2% (4/7) 100% (3/3) 85.7% (6/7) 50% (2/4) 85.7% (6/7) 57.2% (4/7) 50% (3/6)
Conditioning • Myeloablative • Nonmyeloablative	 29.3% (12/41) 33.3% (2/6)	 70.7% (29/41) 66.7% (4/6)
HLA matching • Fully matched • Mismatched (including mismatched cords, ≤2 HLA mismatches) ** • Haploidentical	 32.4% (11/34) 10% (1/10) 66.7% (2/3) *	 67.6% (23/34) 90% (9/10) 33.3% (1/3)
Stem cell source • Bone marrow • Cord • Peripheral blood	 34.4 % (11/32) 16.7% (2/12) 33.3% (1/3)	 65.6% (21/32) 83.3% (10/12) 66.7% (2/3)

*Both patients received post-transplant cyclophosphamide (PTCy)
**mismatched cord HSCT for high-risk paediatric AML

Conclusions: Better, more focused management of pain, using novel pharmacological and non-pharmacological measures, can improve the HSCT experience for children, and specialist pain management services and dedicated guidance are vital. Regular paracetamol can be safely used as an analgesic without masking sepsis. Use of Pregabalin is safe in the immediate post-transplant setting, with no adverse toxicities, interactions, or negative impact on engraftment. This pilot is currently underway, with real-time data analysis.

Background: Acute kidney injury (AKI) is a frequent complication after allogeneic hematopoietic cell transplantation (HCT). Its etiology is multifactorial, including pre-renal causes such as dehydration from gastrointestinal toxicity, intrinsic injury from sepsis, transplant-associated thrombotic microangiopathy and nephrotoxic drugs, and post-renal obstruction. Calcineurin inhibitors (CNIs), namely cyclosporine (CSA) and tacrolimus (TAC), contribute to nephrotoxicity but represent only part of this complex scenario. Early AKI is particularly relevant because it too occurs during the initial and most vulnerable post-transplant phase, when patients remain hospitalized and exposed to intense metabolic and inflammatory stress, and may require CNI reduction or interruption with implications for GVHD prophylaxis. We aimed to characterize the incidence and severity of early AKI and to explore its temporal association with CSA and TAC plasma levels in a large single-center cohort of allogeneic HCT recipients.

Methods: This retrospective single-center cohort included allogeneic HCT recipients transplanted from 2002 to 2023, excluding umbilical cord blood grafts. Clinical, laboratory and transplant-related variables were extracted from electronic medical records. AKI was

defined and staged according to KDIGO 2012 serum creatinine criteria (Stage 1: ≥1.5 to 1.9 × baseline or ≥0.3 mg/dL increase; Stage 2: 2.0 to 2.9 × baseline; Stage 3: ≥3.0 × baseline or ≥4.0 mg/dL). Baseline creatinine was the last stable value prior to CNI initiation, maintained for ≥5 days. Early AKI was assessed during the D1 to D21 window after CNI initiation. CSA and TAC were administered intravenously with therapeutic drug monitoring. Descriptive statistics included absolute and relative frequencies or medians with interquartile ranges. Temporal patterns of CSA and TAC concentrations were examined using LOESS smoothing according to AKI status. The study was approved by the institutional ethics committee in accordance with the Declaration of Helsinki.

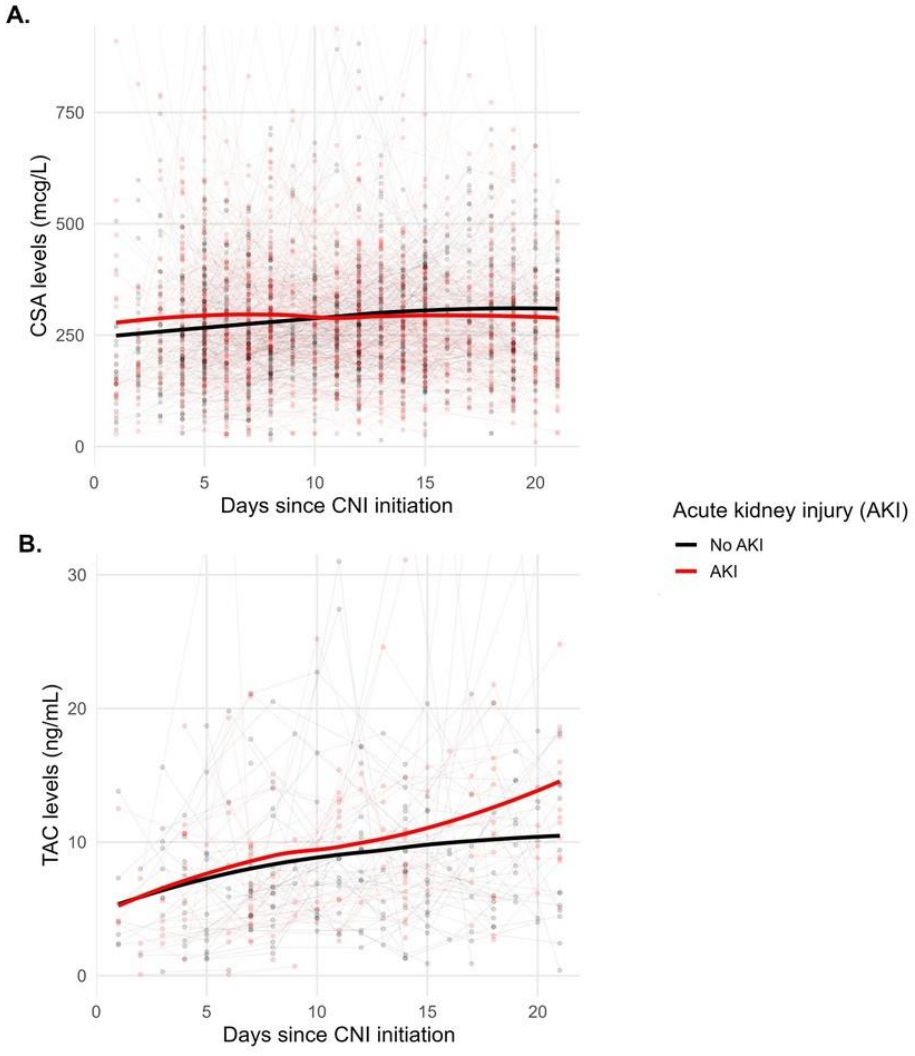
Results: A total of 634 allogeneic HCT recipients were included. The median age was 28.6 years, 67.7% were adults and 84.7% had malignant diseases. CSA was used in 563 patients (88.8%) and TAC in 71 (11.2%). Bone marrow was the predominant graft source (70.2%) and 65.3% underwent myeloablative conditioning. Early AKI occurred in 297 recipients (46.8%), while 337 (53.2%) had no AKI (Table 1). According to KDIGO staging, Stage 1 occurred in 16.4%, Stage 2 in 21.9% and Stage 3 in 8.5%. Moderate-to-severe AKI (Stages 2 and 3) was more frequent among CSA recipients (31.3%) compared with TAC (23.9%). LOESS analyses revealed distinct CNI exposure-response patterns. In the CSA group, mean levels were similar between AKI and non-AKI patients, with slightly higher early concentrations among AKI cases in the first 10 days, followed by reversal (Figure 1A). In contrast, TAC-treated patients showed a progressive widening separation between AKI and non-AKI curves, with higher TAC levels among AKI cases mainly from the second week onward (Figure 1B)**.**

Table1. Incidence and severity of acute kidney injury (AKI) in allogeneic HCT recipients

Category	Subgroup	n (%)
Overall AKI incidence	No AKI	337 (53.2)
	AKI	297 (46.8)
AKI stage (KDIGO)	No AKI	337 (53.2)
	Stage 1	104 (16.4)
	Stage 2	139 (21.9)
	Stage 3	54 (8.5)
AKI severity by CNI	CSA – No / Stage 1	387 (68.7)
	CSA – Stage 2–3	176 (31.3)

	TAC – No / Stage 1	54 (76.1)
	TAC – Stage 2–3	17 (23.9)

Abbreviations: AKI, acute kidney injury; CNI, calcineurin inhibitor; CSA, cyclosporine; TAC, tacrolimus.



Conclusions: Early AKI was frequent, with a considerable proportion of moderate-to-severe cases. CSA and TAC showed distinct temporal exposure patterns, suggesting different windows of nephrotoxic vulnerability during the early post-transplant period. These findings support individualized CNI monitoring and early risk-stratification strategies to mitigate renal toxicity in allogeneic HCT recipients.

Clinical Trial Registry: Not applicable. This study is not a clinical trial.

Disclosure: The authors declare no conflicts of interest. This study was supported by Brazilian governmental research funding agencies (FAPESP, CAPES, CNPq, and FAPERJ).

A PHASE 1 DOSE-ESCALATION STUDY OF UMBILICAL CORD BLOOD MONONUCLEAR CELL INFUSION FOR SECONDARY POOR GRAFT FUNCTION AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Yigeng Cao[1], Rongli Zhang[1], Donglin Yang[1], Yi He[1], Aiming Pang[1], ***Erlie Jiang***[1]
[1]*Institute of Hematology & Blood Diseases Hospital, Tianjin, China*

Background: Secondary poor graft function (sPGF) is a life-threatening complication following allogeneic hematopoietic stem cell transplantation (allo-HSCT), characterized by persistent cytopenias despite complete donor chimerism. Currently, no standardized treatment is available for sPGF.
Umbilical cord blood mononuclear cells (UCB-MNCs) are heterogeneous, comprising hematopoietic stem cells, immune regulatory cells, and other functional subsets. These cells have been shown to secrete hematopoietic growth factors, promote tissue repair, and modulate the immune microenvironment, suggesting potential for restoring sPGF hematopoiesis. However, the safety and optimal dosing of UCB-MNCs remain unclear, requiring prospective clinical evaluation.

Methods: We conducted an open-label, phase 1 clinical trial (ClinicalTrials.gov, NCT06792682) using a standard 3+3 dose-escalation design to assess the safety and preliminary efficacy.
Eligible patients were ≥18 years of age, met the diagnostic criteria for sPGF and had an Eastern Cooperative Oncology Group (ECOG) performance status ≤2.
In the dose-escalation phase, patients were sequentially enrolled into three cohorts receiving UCB-MNCs at doses of 2.0×10^6, 3.5×10^6, and 5.0×10^6 cells/kg per infusion. All patients received four consecutive weekly intravenous infusions with standard supportive care. Dose-expansion phase will enroll an additional six patients at the recommended dose level, using the same administration schedule.
The primary endpoint was safety, assessed by the incidence and severity of adverse events (AEs), graded according to the Common Terminology Criteria for Adverse Events (CTCAE) version 5.0. Secondary exploratory efficacy endpoints included time to neutrophil and platelet recovery.

Results: As of December 8, 2025, six patients (three each in the 2.0×10^6 cells/kg and 3.5×10^6 cells/kg cohorts) had completed the four-week UCB-MNCs infusion protocol and a minimum follow-up of seven weeks. Enrollment in the 5.0×10^6 cells/kg cohort and the dose-expansion phase is ongoing.
During treatment and follow-up, two patients experienced adverse events, including one case

of grade 2 cytomegalovirus (CMV), one case of grade 1 pulmonary infection, and one case of grade 2 chronic graft-versus-host disease (cGVHD). All adverse events were managed successfully with standard clinical interventions and resolved without long-term sequelae. None of the reported AEs were considered related to UCB-MNCs infusion.
No dose-limiting toxicities (DLTs) were observed in either cohort. Importantly, no acute infusion-related adverse events—such as fever, chills, hypotension, or allergic reactions—occurred during or within 24 hours after UCB-MNCs administration. All patients maintained stable vital signs and organ function throughout the study period, and all remained alive at the time of last follow-up.
The best post-treatment platelet counts in the low- and medium-dose cohorts were 46 (9-65) $\times 10^9$/L and 63 (15-110) $\times 10^9$/L, respectively, increasing from the baseline values of 19 (13-22) $\times 10^9$/L and 14 (5-26) $\times 10^9$/L; corresponding neutrophil counts were 1.07 (0.87-1.24) $\times 10^9$/L and 2.94 (2.46-7.33) $\times 10^9$/L, rising from the baseline of 0.73 (0.73-1.03) $\times 10^9$/L and 0.76 (0.07-1.51) $\times 10^9$/L.

Conclusions: This phase 1 dose-escalation study indicate that repeated intravenous infusion of UCB-MNCs at doses of 2.0×10^6 and 3.5×10^6 cells/kg is well tolerated in sPGF patients. Ongoing dose-escalation and expansion phases will determine the recommended dose, further characterize long-term safety, and evaluate the hematopoietic efficacy of UCB-MNCs in this high-risk population.

THE ROLE OF DEFIBROTIDE AS PROPHYLAXIS FOR VENOCCLUSIVE DISEASE IN PEDIATRIC THALASSEMIA STEM CELL TRANSPLANTATION USING IV BUSULFAN CONDITIONING. A RETROSPECTIVE SINGLE-CENTER 10-YEAR EXPERIENCE

Abdullah Alharbi[1], *Mohammed Essa*[2,3,1], *Nada Alshaikh*[1,3,2], *Rodina Abujoub*[1], *Noha Needy*[1], *Shahbaz Memon*[1,2,3]
[1]*Ministry of National Guard and Health Affairs, Riyadh, Saudi Arabia,* [2]*King Saud Bin Abdulaziz University for Health Sciences, Riyadh, Saudi Arabia,* [3]*King Abdullah International Medical Research Center, Riyadh, Saudi Arabia*

Background: Venocclusive disease (VOD) remains a significant post-transplant complication in pediatric hematopoietic stem cell transplantation (HSCT), particularly in high-risk patients, i.e., Thalassemia. Defibrotide is approved for the treatment of severe hepatic VOD/SOS after HCT in patients older than 1 month of age in the European Union. Several studies have found that defibrotide prophylaxis can reduce the incidence of VOD/SOS in high-risk patients; however, the latest literature shows no significant difference in VOD incidence with

defibrotide prophylaxis. This study evaluates our center's retrospective experience with defibrotide as prophylaxis to prevent VOD in pediatric thalassemia patients undergoing stem cell transplantation with IV busulfan-based conditioning.

Methods: We retrospectively evaluated 43 pediatric thalassemia patients (age < 14 years) who underwent HSCT with IV busulfan-based conditioning, with a targeted level dose adjusted above 60mg/h/L, at our institution from 2015 to 2024. VOD was diagnosed and graded following the latest EBMT criteria. Statistical analysis was performed using SPSS version 28.0 with descriptive statistics, Chi-square tests, Fisher's exact tests, and independent t-tests ($p < 0.05$ considered significant).

Results: 43 patients (mean age 6.7 ± 3.8 years; 60.5% male), 38 (88.4%) received defibrotide prophylaxis, predominantly from day −7 to +21 (42.1%). VOD developed in 17 patients (39.5%), with mild-to-moderate severity predominating (82.4%). Most VOD cases presented early (52.9% within 0−14 days post-transplant), with a primary clinical diagnosis (64.7%). Management included strict input/output balance, diuretics, and continued defibrotide. Notably, all 17 VOD patients achieved complete resolution, with zero PICU admissions, zero VOD-related morbidity, and zero VOD-related mortality. All patients survived (100%), with one patient had idiopathic secondary graft failure with aplastic anemia (2.2%), rescued by a second unrelated stem cell transplant. Almost five (11.6%) of 43 patients did not receive defibrotide prophylaxis; interestingly, two of those patients developed VOD (40%). No statistically significant associations were found between VOD development and gender ($p = 0.415$), age ($p = 0.539$), pre-transplant risk factors ($p = 0.446$), conditioning type ($p = 0.735$), or defibrotide prophylaxis ($p = 1.000$). The duration of hospitalization was shortened, possibly after the switch to the TBF (Thiotepa, Busulfan, and Fludarabine) regimen.

Table: Patient characteristics and outcome

		Presence of VOD No # (%)	***Presence of VOD Yes # (%)***	***Sig. Values***

(a) Chi-Square Test, (b) Fisher's Exact Test, (c) Independent T Test
Reduced toxicity-Myeloablative chemotherapy (RT-MAC), Myeloablative chemotherapy (MAC)

Conclusions: Despite a high incidence of around 39.5% patients having VOD in our pediatric thalassemia cohort, fortunately, none of the patients had severe VOD leading to any morbidity or mortality. All patients were managed at the pediatric BMT unit without any significant complications. We acknowledge the limited sample size, the retrospective nature of the study, and the limited control group. These observations suggest that the routine use of defibrotide prophylaxis in patients undergoing HCT for B-thalassemia major may not reduce the incidence of VOD post-SCT as described in the latest literature. However, we will seek a larger control group at our institute for future studies to verify our results.

A392

IMPACT OF ANTIBIOTIC USE IN EARLY FEVER AFTER HAPLOIDENTICAL HEMATOPOIETIC STEM CELL TRANSPLANTATION WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE

María José Llácer Ferrandis[1], *Diana Casares-Aguiar*[1], *Rebeca Bailén*[1,2], *Ignacio Gómez-Centurión*[1,2], *Lucía Castilla*[1], *Cristina Muñoz-Martínez*[1], *Santiago Sabell*[1], *Javier Anguita*[1,2,3], *Ramón García-Sanz*[1,2,3]
[1]*Hospital General Universitario Gregorio Marañón, Department of Hematology and Hemotherapy, Madrid, Spain,* [2]*Gregorio Marañón Health Research Institute, Madrid, Spain,* [3]*Department of Medicine, Universidad Complutense, Madrid, Spain*

Background: Early fever is a frequent complication after haploidentical hematopoietic stem cell transplantation (haplo-HSCT) with post-transplant cyclophosphamide (PTCY), most often related to cytokine release syndrome (CRS), although infectious causes must always be excluded. The impact of broad-spectrum antibiotic (BSA) use in this context remains unclear. This study evaluates the incidence of early fever after haplo-HSCT, associated infectious events, and transplant outcomes.

Methods: We conducted a single-center, retrospective study including 144 consecutive adult patients who underwent haplo-HSCT with PTCY between January 2019 and March 2024. All patients received PTCY 50 mg/kg on days +3 and +4, followed by tacrolimus and mycophenolate mofetil as graft-versus-host disease (GVHD) prophylaxis. Early fever was defined as temperature ≥37.8°C between stem cell infusion (day 0) and day +4. Twenty-three patients with fever or antibiotics before infusion were excluded.

Results: Median age was 53 years, 60.3% were male. AML wast the most frequent diagnosis (38.8%). Most had intermediate disease risk (65.3%) and high age-adjusted HCT-CI (76%). Peripheral blood was the graft source in 99% of cases, and donors were most commonly children (48.8%). The incidence of early fever was 85% (103/121), with no significant differences by conditioning regimen. Fever commonly started on day +1 (range 0–4). Median peak temperature was 38.5 °C; median C-reactive protein (CRP) was 142.8 mg/L. Fever duration was a median of 4 days (IQR 3–5). Early fever met criteria for CRS in 92.2% of cases (95/103), mostly grade 1 (86/95,90.5%). Eleven patients received tocilizumab for CRS grade ≥2. Levofloxacin prophylaxis was used in 72.8%, and empirical BSA in 82.5% (85/103), mainly piperacillin/tazobactam(67%).
A microbiological isolate was the primary cause of fever in 8 (7.8%), all catheter-related: three catheter-related bloodstream infections (S. haemolyticus, S. epidermidis, S. oralis) and five catheter colonizations (coagulase-negative Staphylococcus, methicillin-resistant, Bacilllus spp, S. epidermidis, S. maltophiilia). In three additional cases with positive isolates, fever was attributed to CRS: low-level CMV reactivation, CRS grade ≥2 with C. jejuni stool culture, and asymptomatic bacteriuria with K. pneumoniae. No differences were observed in fever onset, peak, duration, or CRP between CRS and microbiological documented cases. Antibiotic therapy was adjusted when a pahogen was identified.
Subsequently, 86.4% (89/103) developed significant infections and 15.5% (16/103) new colonizations, all due to multidrug-resistant organisms. Two patients developed infections

caused by previously identified colonizing organisms (one catheter colonization, and one catheter-related bloodstream infection). No other patient develop infections with these microorganisms.
With a median follow-up of 22 months (IQR 11.2–47.4), 12-month overall survival (OS) and event-free survival (EFS) were 73.5% (95%CI,64.7–80.5) and 61.1% (95%CI,51.9–69.2) respectively. There were no significant differences in OS (p=0.082) or EFS (p=0.487) between patients with or without early fever. Early fever was not significantly associated with neutrophil/platelet engraftment, or acute/chronic GVHD.

	Summary N=121 (100%)
Age, years, median (range)	53 (18-71)
Sex recipient (male), N (%)	73 (60,3)
Diagnosis, N (%) - AML - MDS - ALL - NHL/CLL - HL - SMPC - Other	 47 (38.8) 11 (9.1) 18 (14.9) 23 (19) 7 (5.8) 8 (6,6) 7 (5,8)
Disease Risk Index (DRI), N (%) - Low - Intermediate - High/Very high - Not applicable	 9 (7.4) 79 (65.3) 29 (24) 3 (2.5)
HCT-CI (age-adjusted), N (%) - 0 - 1-2 - ≥ 3	 4 (3.3) 25 (20.7) 92 (76)
Stem cell source – peripheral blood, N (%)	120 (99.2)
Infused CD34+ cells (×10⁶/kg), median (range)	6.8 (3.2-12.1)
Donor relationship, N (%) - sibling - father - mother - child - second-degree relative - unrelated	 31 (25.6) 8 (6.6) 4 (3.3) 59 (48.8) 18 (14.9) 1 (0.8)
Donor sex (male), N (%)	68 (56.2)
Donor age, median (range)	35 (15-66)

Conclusions: Early fever after haplo-HSCT with PTCY is common and mostly CRS-related. Only a minority of episodes are infectious. However, most patients received empirical BSA, potentially contributing to pathogen selection and subsequent infectious complications. These findings highlight the need for biomarkers and standardized criteria to guide BSA in this setting.

AUTOIMMUNE-LIKE HEPATITIS OF ALLOGENIC ORIGIN: A RARE BUT DISTINCT ENTITY IN POST-TRANSPLANT LIVER DYSFUNCTION

Claudia Mosquera Rubal[1], *Carlos De Miguel*[1], *Isabel Sanguino*[1], *Greissy Vazquez Benitez*[1], *Ana Belen Bocanegra*[1], *Guiomar Bautista*[1], *Jose Luis Calleja*[1], *Clara Salas*[1], *Rafael Duarte Palomino*[1]
[1]*Hospital Universitario Puerta de Hierro Majadahonda, Madrid, Spain*

Background: Liver disfunction (LD) is common after allogenic hematopoietic stem cell transplant (allo-HSCT). Graft-versus-host disease (GvHD) is a frequent cause of LD, and it typically occurs alongside GVHD-driven injury to other organs. Isolated hepatic GvHD is rare, with reported incidences below 3%. When multiple etiologies are suspected, liver biopsy becomes essential. Beyond conventional hepatic GVHD histopathological patterns, autoimmune-like hepatitis (AILH) constitutes a rare and poorly characterized entity. This study aims to determine the incidence and describe the clinicopathological features of AILH within our post-transplant cohort.

Methods: We conducted a retrospective study of adult patients undergoing allo-HSCT from January 2015 to December 2024. Acute LD was defined as alanine aminotransferase (ALT) or aspartate aminotransferase (AST) ≥2× the upper limit of normal (ULN) or total bilirubin (Br) ≥1.5× the ULN. Primary objective was to estimate the cumulative incidence of biopsy-proven AILH of allogeneic origin. Clinical data, transplant characteristics, biochemical parameters at LD onset, histopathological findings, treatment and outcomes were reviewed.

Results: A total of 246 allo-HSCT procedures were performed during the study period, 107 cases were clinically classified as acute GvHD, but only 2 of these presented isolated hepatic involvement (1.8% of all cases of acute GvHD, 0.8% of all allo-HSCT). In addition, 4 patients (Table 1) exhibited late isolated hepatic disease at a median of 274 days post-allo-HSCT (range, 241–292) with biopsy features consistent with AILH, accounting for 1.6% of all allo-HSCT. Histopathological evaluation (Figure 1) demonstrated a plasma-cell–rich inflammatory infiltrate involving both lobules and portal tracts, causing multifocal hepatocellular necrosis and variable cholestasis without duct loss. This histopathological pattern differs from the usual hepatic GvHD, defined by bile-duct damage (apoptotic lymphocytic cholangiolitis) with lobular hepatitis of mild degree. All four patients received glucocorticoids and calcineurin inhibitors, achieving early complete response. Nevertheless, as with AILH outside the allo-HSCT setting, they required prolonged low-dose immunosuppression due to biochemical relapses upon discontinuation of corticosteroids. All four remain on active treatment with a median of 1175 days after diagnosis (range, 372-3531).

Table 1: Clinical and transplant characteristics of the patients diagnosed with AILH.

	Patient and Transplant characteristics									Laboratory da diagnosis	
Case	Age (years)	Sex	Underlying disease	Donor type	Cell source	HLA disparity	Conditioning regimen	GvHD prophylaxis	Day of onset of LD	ALT (U/L)	AS (U/
1	39	F	HL	RD	PB	Matched	RIC	MTX + Tac	241	2042	162
2	36	M	AML	RD	PB	Matched	MAC	MTX + Tac	266	405	296
3	68	F	MM	RD	PB	Matched	RIC	MTX + Tac	282	1026	120
4	65	M	AML/MDS	RD	PB	Mismatched	RIC	PTCy + Tac + MMF	292	574	501

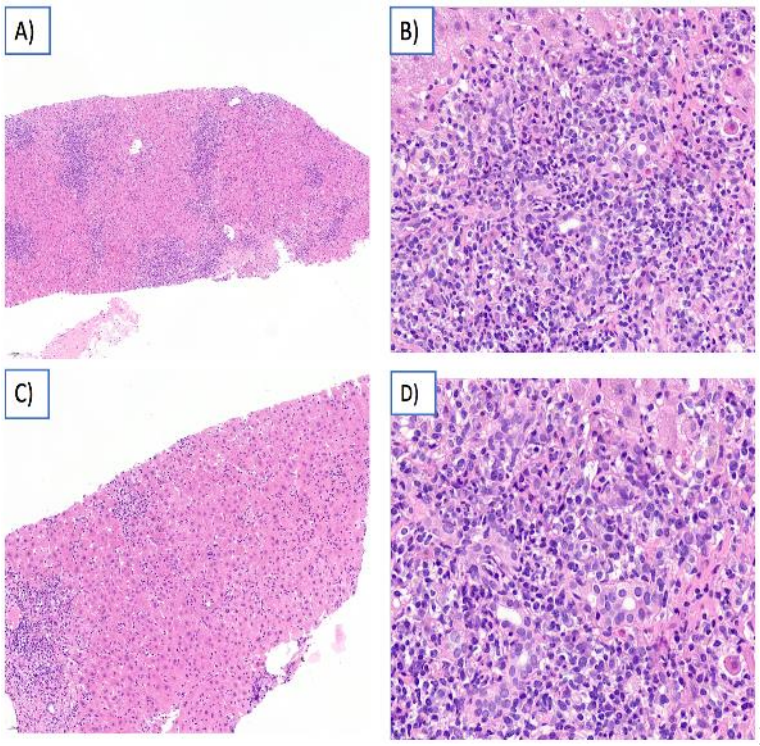

Image 1: Pathology of AILH. A): Hepatic parenchyma showing a dense inflammatory infiltrate at the portal and lobular levels (100X). B) The inflammatory infiltrate is predominantly composed of plasma cells, accompanied by lymphocytes and occasional eosinophils. Hepatocellular apoptosis is identified (400X[DP1] [DP2]). C) Lobular involvement by the inflammatory infiltrate (400X). D) Evidence of bile duct injury characterized by intraepithelial lymphocytes, cytoplasmic eosinophilia of ductal epithelium, and vacuolization (400X).

Conclusions: AILH constitutes an uncommon yet distinctive form of late alloimmune hepatic injury with autoimmune features after allo-HSCT. Its characteristic biopsy pattern allows differentiation from classical hepatic GvHD. In addition, their clinical behavior does not follow the induction of tolerance common to alloresponses in GVHD, and despite achieving rapid complete responses, they continue to require sustained long term inmunosupression.

Disclosure: No conlict of interest declared.

A394

TRANSPLANTATION-ASSOCIATED THROMBOTIC MICROANGIOPATHY: INCIDENCE AND MANAGEMENT IN SETTINGS WITH LIMITED BIOMARKERS AND NO ACCESS TO TARGETED THERAPIES

Maha Saoud[1], Insaf Ben yaiche[1], Rihab Ouerghi[1], Dorra Belloumi[1], Rimmel Kanoun[1], Anna Chabaane[1], Lamia Torjeman[1], Tarek Ben Othman[1], ***Nour Ben Abdeljelil***[1]
[1]*National Bone Marrow Transplantation Centre, Tunis, Tunisia*

Background: Thrombotic microangiopathy (TMA) is one the most serious complication after allogeneic hematopoietic stem cell transplantation (allo-HSCT) and associated with high morbidity and mortality. The objective of the study was to evaluate the cumulative incidence (CI) of transplantation-associated TMA (TA-TMA), clinical features, and management in patients transplanted with hematological disorder**.**

Methods: A retrospective descriptive study, included all consecutive patients with hematological disorder, who underwent allo-HSCT from HLA-matched sibling or haplo-identical donors, between January 2016 and December 2023. Conditioning regimens were TBI or Busulfan iv-based. Graft versus host disease (GVHD) prophylaxis consisted on cyclosporine and short course of methotrexate +/- ATG. Stem cell source was bone marrow or peripheral blood stem cells (PBSCs). The EASIX score was assessed at day 0, day +30, day +100 and at last follow-up. The diagnosis of TMA was established according to Jodele criteria with the unavailability of plasma sC5b-9 measurements. The consensus defines TA-TMA response by combining hematologic/biologic improvement with organ-specific recovery.

Results: This study included 243 patients with a median age of 27 years (range, 4 - 55y) and a sex ratio of 1.8. Underlying diseases were aplastic anemia (31.7%), ALL (30.5%), AML (22.2%), others (15.6%).
Twelve patients (5%) developed TA-TMA after a median time of 67 days (range, 15 days – 12 months). Early TA-TMA (<100 days) was observed in 83% of cases. EASIX score was significantly higher in patients with TA-TMA compared to patients without TA-TMA, at day 30, day 100 and at last follow-up ($p<10-3$,$<10-3$ and 0.022, respectively).
In multivariate analysis, acute GVHD and microbiologically documented fever were significantly associated with TA-TMA ($p= 0.048$ and 0.032, respectively).
Cyclosporine was discontinued in all cases of TA-TMA and switched to mycophenolate mofetil. Blood transfusion was required in 10 patients (83%) with a median transfusion of red blood cell 5 (range, 3-39) and platelet concentrates 7 (range, 3-78). None patient received plasma

exchange and one patient received iv N-acetylcysteine. Partial response was observed after a median time of 30 days (range, 15–110d) and complete response after a median of 90 days (range, 14–8 months).
After a median follow-up of 36 months (range, 5 day –110 months), 3-year overall survival (OS) was 42% in patients with TA-TMA vs 82% in patients without TA-TMA (p=<10-3). The CI of non-relapse mortality (NRM) was 61% and 13%, respectively (p < 0.0001). The causes of death in patients with TA-TMA were: acute respiratory distress (n=3), multiorgan failure (n=3), and septic shock (n=1). The attributable mortality of TA-TMA was 22%. The CI of relapse was 17% and 13%, respectively (p=0.74).

Conclusions: In our experience, the TA-TMA was associated with a high NRM. Early monitoring using plasma sC5b-9 levels and access to targeted therapies are essential.

Disclosure: Nothing to declare.

A395

NARSOPLIMAB IN CRITICALLY ILL PATIENTS WITH TA-TMA REQUIRING INTENSIVE CARE: A SINGLE CENTER STUDY

Ana Belén Bocanegra[1], *Carlos de Miguel*[1], *Guiomar Bautista*[1], *Mosquera Claudia*[1], *Valdenebro María*[1], *Ana Muñoz-Sanchez*[1], *Ines Lipperheide*[1], *Daniel Ballesteros*[1], *Rafael Francisco Duarte*[1]
[1]*Hospital Puerta de Hierro Majadahonda, Madrid, Spain*

Background: Transplant-associated thrombotic microangiopathy (TA-TMA) is a severe endothelial injury syndrome following allogeneic hematopoietic stem cell transplantation (allo-HSCT), frequently leading to multiorgan dysfunction and high mortality. Outcomes are particularly poor for patients requiring intensive care, and therapeutic options remain limited. Targeted inhibition of the lectin complement pathway with narsoplimab (anti–MASP-2) has emerged as a promising strategy in high-risk TA-TMA, but evidence in critically ill patients remains scarce. We describe our single-centre real-world experience with narsoplimab in allo-HSCT recipients with TA-TMA requiring ICU support.

Methods: This retrospective single-centre observational study included all adult allo-HSCT recipients diagnosed with TA-TMA who required ICU admission and received narsoplimab. Narsoplimab was provided via an Expanded Access Program (EAP) (https://www.omeros.com).

Results: Seven patients were included (Table 1). Median time from allo-HCT to TA-TMA diagnosis was 26 days (range −1 to 769); the outlier corresponds to a patient who developed TA-TMA two years after allo-HSCT in the context of lung transplantation for pulmonary GVHD (#3). Median time from TA-TMA diagnosis to ICU admission was 5 days (range −27 to 137). All patients fulfilled diagnostic and high-risk TA-TMA criteria according to the 2023 Harmonized Consensus.
ICU admission was prompted by acute kidney injury, respiratory failure, or shock. At ICU admission, median APACHE II score was 15 (range 10–26), 6/7 patients (85.7%) required

renal replacement therapy, 6/7 mechanical ventilation (one patient invasive mechanical ventilation), and 3/7 patients (42.8%) required vasopressors. Four patients had concomitant infections, and two had active GVHD. Median ICU stay was 14 days (range 4–36). Narsoplimab was initiated at a median of 3 days after TA-TMA diagnosis (range 1–144), with a median of 13 doses per patient (range 12–26), one patient remains on therapy to date. It was used as first-line therapy in all but one patient (#2), who was refractory to prior treatment with the C3 inhibitor pegcetacoplan. According to ASTCT/EBMT consensus criteria, an overall response was observed in 5/7 (71.4%) patients, complete in 1/7 and partial in 4/7 (57.1%), and 2 were nonresponders (28.6%). No infusion-related reactions were observed. Severe infections during treatment occurred in 4/7 patients (57.1%), all while in the ICU. All cases survived at day 30 from the start of treatment with narsoplimab. Five out of seven (71.4%), were discharged from ICU and remained alive at day 90 of treatment initiation, while two patients died from TA-TMA at a median of 41 days (34 and 48 days;#1 and #7, respectively). One additional patient died months after TA-TMA resolution from an unrelated post-transplant lymphoproliferative disease (#5). Five of these very high-risk critically ill TA-TMA cohort (57.1%) were alive at 1 year since the start of narsoplimab therapy.

Table 1. Baseline characteristics of patients.

Patient	Sex	Age	Hematological disease	Donor	Conditioning	Indications for ICU admission	APACHE score	Response
#1	M	22	ALL	MUD	MA	ARF	10	NR
#2	F	63	NHL	MSD	SM	ARF, AKI	10	PR
#3	M	22	ALL	Haplo	MA	PC	15	CR
#4	F	20	AML	Haplo	MA	HC	15	PR
#5	M	27	ALL	CB	MA	ARF	17	PR
#6	M	46	ALL	CB	MA	ARF, AKI	12	PR
#7	F	23	AA	MUD	SM	ARF	26	NR

M= Male; F= Female; ALL= Acute Lymphoblastic Leukemia; NHL= Non Hodgkin Lymphoma; AML= Acute Myeloblastic Leukemia; AA= Aplastic Anemia; MUD: Matched Unrelated Donor; MSD: Matched Sibling Donor; Haplo: Haploidentical donor; CB: Cord Blood; MA: Myeloablative; SM: Sub-myeloablative; ARF: Acute Respiratory Failure; AKI: Acute Kidney Injury; PC: Postoperative Care; HC: Hemorrhagic Complications; CR: Complete Response; PR: Partial Response; NR: No Response.

Conclusions: In this real-world cohort of critically ill allo-HSCT recipients, narsoplimab was feasible, well tolerated and associated with clinical responses despite the severity of illness. Although limited by small sample size, these findings support narsoplimab as a potentially effective therapeutic option for severe TA-TMA requiring intensive care. Larger multicentre studies are warranted.

Disclosure: Nothing to declare.

RESELECT1&2: INTERVENTIONAL STUDIES FOR THE TREATMENT OF POOR GRAFT FUNCTION POST ALLOGENEIC STEM CELL TRANSPLANTATION

Daniel North[1,2], *Ashvind Prabahran*[1,3,4], *Syed Asif Ali Shah*[1], *Arwen Nguyen-Ngo*[1,2], *Digsu Koye*[2], *Sabine Braat*[2], *Mayani Rawicki*[1], *Jessica Klass*[1], *Alexandra Rivalland*[1], *Duncan Purtill*[5], *Joanne Davis*[1], *Lynette Chee*[1,6], *Rachel Koldej*[1,2], *David Ritchie*[1,2,6]
[1]*Royal Melbourne Hospital, Melbourne, Australia,* [2]*University of Melbourne, Melbourne, Australia,* [3]*Monash Health, Melbourne, Australia,* [4]*Austin Health, Melbourne, Australia,* [5]*Fiona Stanley Hospital, Perth, Australia,* [6]*Peter MacCallum Cancer Centre, Melbourne, Australia*

Background: Poor Graft Function (PGF), defined by the presence of multilineage cytopenia despite complete donor chimerism, is a significant complication of allogeneic stem cell transplant (alloSCT). PGF is associated with a high burden of non-relapse mortality and lacks an established standard of care, calling for the development of novel therapeutic strategies.

Methods: RESELECT 1&2 are sequential investigator-initiated single-arm clinical trials repurposing established therapeutics to target bone marrow microenvironment (BMME) dysfunction in PGF. Both studies have the same inclusion criteria; PGF defined as complete donor chimerism and 2-3 lineage cytopenias. The primary efficacy endpoint for both studies is restoration of neutrophil and platelet count at the end of the 12-week treatment period. Prior publications identified reactive oxygen species (ROS) and endothelial cell (EC) dysfunction as features of the BMME in PGF. RESELECT1 (ACTRN12620001339943) evaluated atorvastatin as EC directed therapy and the ROS scavenger N-acetyl cysteine (NAC) in combination as treatment for patients with PGF. Correlative studies using flow cytometry and single-cell RNA sequencing were performed on peripheral blood and bone marrow mononuclear cells collected during RESELECT1. These analyses informed the design of RESELECT 2 (NCT06607367), a currently recruiting Phase II study evaluating the safety and efficacy of combination eltrombopag and ruxolitinib in the treatment of PGF.

Results: A total of ten out of twenty planned patients were recruited to RESELECT1 (Table1). Nine of the ten completed the 12-week treatment period. One patient experienced early disease relapse and discontinued study participation. Only one participant achieved a complete response, and recruitment was discontinued prematurely for futility after a prespecified interim look on ten completed patients.
Correlative analyses from RESELECT1 identified atypical monocyte and T-cell populations in patients with PGF, with transcriptomic analysis implicating IFN-γ and JAK-STAT signalling as central mediators of the dysregulated immunity in the BMME of PGF patients. This informed the decision to combine ruxolitinib, a JAK inhibitor that suppresses cytokine production in T and NK cells, and eltrombopag, a TPO mimetic with pre-clinical evidence of mitigating the suppressive effect of IFN-γ on haematopoietic function and an established role in aplastic anaemia.
A total of 20 patients will be recruited into RESELECT2 across two sites in Australia, and outcomes will be compared with a historic patient cohort. Five patients with PGF have been recruited to RESELECT2, of whom three have completed three months of therapy and have

12-week efficacy data available for evaluation (Table1). All three evaluable patients have achieved response defined by independence from growth factor and transfusion support. One patient developed clinically relevant minor bleeding in the context of persistent thrombocytopenia and ceased ruxolitinib therapy on trial day 28. Ruxolitinib associated cytopenias have not been observed in other participants to date.

Table 1: Demographic and transplant data at trial enrolment of RESELECT 1&2

Trial	RESELECT1 (Participants N=10)	RESELECT2 (Participants N=5)
Age in years at enrolment: Median (Range)	54 (46 – 74)	62 (53 – 66)
Sex, n (%)	Female 7 (70%)	Female 3 (60%)
Primary Diagnosis, n (%)	AML 5 (50%) MF 2 (20%) NHL, MDS, B-ALL 3 (30%)	MDS 2 (40%) AML, MF, MCL 1 (20%)
Donor Type, n (%)	MSD 4 (40%) MUD 3 (30%) Haplo, MMUD 3 (30%)	MSD 2 (40%) MUD 2 (40%) Haplo 1 (20%)
Conditioning Intensity, n (%)	RIC 8 (80%) MAC 2 (20%)	RIC 3 (60%) MAC 1 (20%) Unconditioned* 1 (20%)
Graft Type, n (%)	PBSC (90%)	PBSC (100%)
Days post transplant D0, Median (Range)	134 (48 – 253)	112 (49 – 434)
Screening CD3+ chimerism (%), Median (Range)	100 (85 – 100)	100 (43 – 100)
Screening $CD3^-$ chimerism (%), Median (Range)	100 (97 – 100)	100 (100 – 100)

*Unconditioned second transplant following graft failure.

AML = acute myeloid leukaemia, MF = myelofibrosis, NHL = non-Hodgkin lymphoma, MDS = myelodysplastic syndrome, B-ALL = B cell acute lymphoblastic leukaemia, MCL = mantle cell lymphoma, MSD = matched sibling donor, MUD = matched unrelated donor, MMUD = mismatched unrelated donor, haplo = Haploidentical donor, RIC = reduced intensity conditioning, MAC = myeloablative conditioning, PBSC = peripheral blood stem cell

Conclusions: Correlative analyses from the RESELECT1 trial identify immune dysregulation in the BMME as targetable mediators of PGF. Early data from the ongoing RESELECT2 trial suggests that the combination of ruxolitinib and eltrombopag holds promise as a potentially safe and efficacious intervention for PGF. Further studies are required to improve the outcomes of patients suffering from this under recognised clinical entity.

Clinical Trial Registry: RESELECT1: anzctr.org.au ACTRN12620001339943
RESELECT2: clinicaltrials.gov NCT06607367

Disclosure: This trial was funded by a project grant from Maddie Riewoldt's Vision. Trial medications for RESELECT2 were supplied by Novartis.

HEPATIC VENOUS PRESSURE GRADIENT TO DIAGNOSE VENO-OCCLUSIVE DISEASE AFTER HEMATOPOIETIC BONE MARROW TRANSPLANTATION: A SYSTEMATIC REVIEW AND META-ANALYSIS

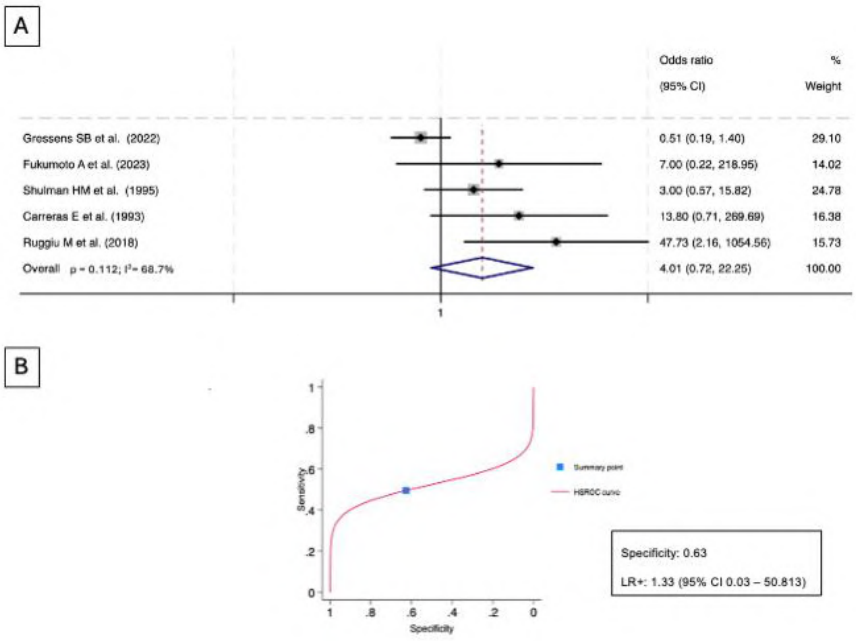
Luigi Colecchia[1], *Giovanni Marasco*[1], *Federico Ravaioli*[1], *Elton Dajti*[1], *Francesca Bonifazi*[2], *Antonio Colecchia*[3]
[1]*Department of Medical and Surgical Sciences (DIMEC), University of Bologna, Bologna, Italy,* [2]*Department of Oncological and Hematological diseases, IRCCS Policlinico di Sant'Orsola, Bologna, Italy,* [3]*CHIMOMO Department, University of Modena and Reggio Emilia, Modena, Italy*

Background: Veno-occlusive disease (VOD) is a severe and potentially fatal complication after hematopoietic stem cell transplantation (HSCT). Although portal hypertension is a key pathophysiological feature of VOD, the diagnostic value of hepatic venous pressure gradient (HVPG) measurement, historically considered the gold standard, recent evidence has questioned its accuracy. Moreover, it is an invasive technique, only available in few tertiary centers, limiting its applicability. Given these methodological limitations, non-invasive techniques such as liver stiffness measurement (LSM), commonly used in hepatology as an alternative to HVPG, have also been proposed in the HSCT setting for the diagnosis of VOD. Therefore, in this systematic review, we aimed to re-evaluate HVPG diagnostic accuracy in patients with suspected VOD after undergoing HSCT.

Methods: MEDLINE and Scopus were systematically searched up to July 17, 2025 for studies evaluating HVPG in patients with suspected VOD after HSCT. Eligible studies included patients undergoing HVPG measurement with available data on VOD diagnosis based on histology. A random-effects meta-analysis was performed to assess the association between HVPG ≥10 mmHg and VOD. Diagnostic accuracy was evaluated using a bivariate random-effects and hierarchical summary receiver operating characteristic (HSROC) model, estimating pooled sensitivity, specificity and likelihood ratios (LR).

Results: Six studies met the inclusion criteria, comprising 214 patients who underwent HVPG measurement; VOD was diagnosed in 81 patients, while 133 had alternative diagnoses. Mean HVPG values were higher in patients with VOD than in those without (13.5 vs 8.5 mmHg). HVPG ≥10 mmHg was associated with increased odds of VOD (pooled odds ratio (OR) 4.01), but this did not reach statistical significance (95% confidence interval (CI) 0.72 – 22.25; p = 0.112), with moderate between-study heterogeneity (I^2: 68.7%). (Figure 1A) Regarding the diagnostic accuracy, the pooled sensitivity was 0.50 (95% CI 0.25 – 0.75) and pooled specificity was 0.63 (95% CI 0.01 – 1.00). Positive likelihood ratios was 1.33

(95% CI 0.03 – 50.813), while the negative likelihood ratio 0.81 (95% CI 0.077 – 8.467). (Figure 1B)



Conclusions: HVPG ≥10 mmHg shows limited and imprecise diagnostic accuracy for VOD after HSCT. In fact, although higher HVPG values are more frequent in VOD, this systematic review and meta-analysis shows that HVPG values ≥10 mmHg show both a low sensitivity and specificity. Therefore, HVPG is not reliable in confirming or excluding VOD diagnosis. These findings support current guideline recommendations that HVPG should not be used as a standalone diagnostic tool and highlight the need for integrated diagnostic strategies, both with invasive (e.g. liver biopsy) and non-invasive methods (e.g. liver elastography).

PLASMINOGEN ACTIVATOR INHIBITOR-1 (PAI-1) IS AN EARLY BIOMARKER OF SEVERE SINUSOIDAL OBSTRUCTION SYNDROME AFTER PEDIATRIC HSCT

Karoline Juul Grube[1,2], *Denise Elbæk Horan*[1,2], *Hilde Hylland Uhlving*[1], *Jens-Christian Holm*[3,4], *Claus H. Nielsen*[2], *Pär I. Johansson*[1], *Katrine Kielsen*[1,2,4], *Klaus Müller*[1,2,4]
[1]*Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark,* [2]*Institute for*

Inflammation Research, Copenhagen, Denmark, [3]Copenhagen University Hospital Holbæk, Holbæk, Denmark, [4]University of Copenhagen, Copenhagen, Denmark

Background: Sinusoidal obstruction syndrome (SOS) remains a potentially life-threatening complication after allogenic HSCT. Early diagnosis and treatment can limit disease severity but are challenged due to the lack of specific diagnostic criteria. The pathogenesis of SOS is initiated by damage to sinusoidal endothelial cells, by toxic metabolites of the conditioning regimen with subsequent coagulation. Therefore, biomarkers reflecting endothelial damage and coagulation may facilitate early and more accurate diagnosis. Plasminogen activator inhibitor-1 (PAI-1) is released from activated platelets and synthesized by endothelial cells in response to inflammatory stress. We investigated PAI-1 as a biomarker for SOS and other endothelial toxicity syndromes after pediatric allogenic HSCT.

Methods: We prospectively included 114 children (median age: 8.8 years) undergoing standard HSCT at Rigshospitalet, Denmark (2010-2019) for malignant or benign diseases and 200 healthy controls (Table 1). SOS was diagnosed according to the paediatric EBMT criteria.
Plasma levels of PAI-1 were measured by Luminex before conditioning and on days 0, +7, +14, +21, +30, +90, and +180 post-HSCT. Due to PAI-1´s association with platelets, PAI-1 levels were normalized with concurrent platelet count (PLT).

Results: PAI-1/PLT ratio increased from pre-conditioning, peaked on day +14 (111 vs. 267 ng/10^9 platelets, p<0.0001) and then gradually declined. High PAI-I/PLT ratio at pre-conditioning and throughout day +180 was associated with higher patient age (all p< 0.05). Further, higher PAI-1/PLT was associated with malignant diagnosis (day +0: 175 vs. 123 ng/10^9 platelets (p=0.001); day +30: 200 vs. 97 ng/10^9 platelets (p=0.0073)), and with busulfan-based conditioning (day +21: 668 vs. 179 ng/10^9 platelets (p=0.03); day +30:266 vs. 100 ng/10^9 platelets (p= 0.0007)). PAI-I/PLT was not associated with recipient sex, donor type, graft type, ATG or aGvHD prophylaxis (p≥0.05).
Fifty-one patients were diagnosed with SOS at median day +7 (range: +2 to +58). PAI-1/PLT was significantly higher in patients diagnosed with SOS grade II-IV (n=47) than in patients with grade 0-I (n=67) from day 0 to +90 (figure A). Four patients, who were started on defibrotide for severe SOS had significantly increased PAI-1/PLT ratio (figure B).
In a multivariable analysis, a doubling in PAI-1/PLT on day 0 was independently associated with increased risk of SOS after adjusting for busulfan, malignant diagnosis and age (PAI-1/PLT: OR=1.47, 95%CI=1.03-2.17, p=0.042; busulfan: OR= 7.12, 95%CI=2.89-20.89, p=<0.0001; malignant diagnosis: OR=1.41, 95%CI=0.54-3.70, p=0.48; age above median: OR=1.42, 95%CI=0.56-3.65, p=0.46).
PAI-1/PLT was significantly higher on day 0 in patients with capillary leak syndrome (CLS) (n=15) compared to those without CLS (260 vs 140 ng/10^9 platelets, p=0.0018). No associations were observed between PAI-1/PLT and aGvHD (grade 0-I vs. II-IV) (n=52) or with engraftment syndrome (n=13).

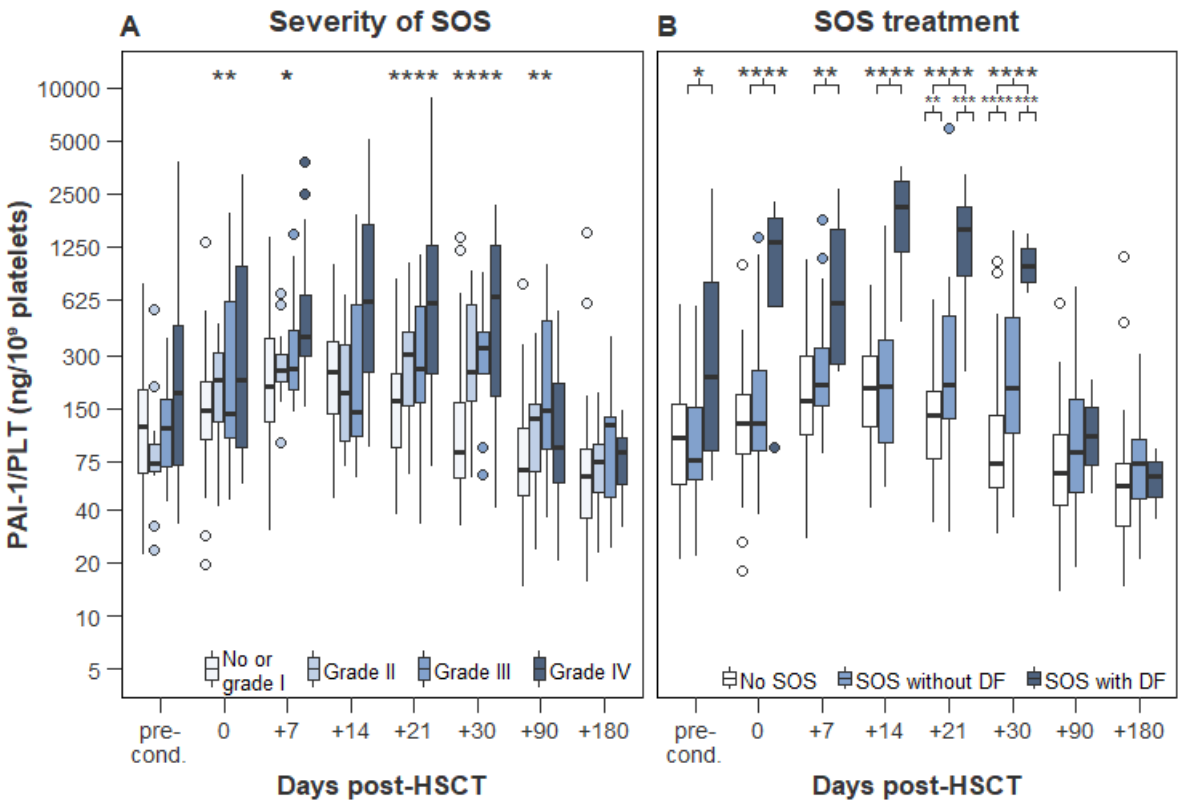

Table 1: Characteristics of study population	Patients (n=114)	Controls (n=200)
Sex, male, *n* (%)	67 (58.8%)	97 (48.5%)
Age *(years)*, median *(range)*	8.8 (1.1-17.6)	11.7 (6.0-18.8)
Diagnosis, *n (%)*		
ALL	29 (25.4%)	
AML	17 (14.9%)	
Other malignancies	23 (20.2%)	
PID	17 (14.9%)	
SAA	10 (8.8%)	
Other non-malignant diseases	18 (15.8%)	
Donor type, *n (%)*		
Matched unrelated donor (9/10 and 10/10)	81 (71.1%)	
Matched sibling donor	33 (28.9%)	

Stem cell source, *n (%)*		
Bone marrow	109 (95.6%)	
Peripheral blood	5 (4.4%)	
Conditioning regime, *n (%)*		
TBI 12 Gy + CY/VP16	23 (20.2%)	
BU-based	50 (29.9%)	
TREO-based	26 (0.9%)	
Other	15 (13.2%)	
ATG as part of GvHD-prophylaxis, *n (%)*	86 (75.4%)	
Prophylactic Defibrotide, *n (%)*	7 (6.1%)	

Conclusions: PAI-1/PLT appeared to be an early, independent biomarker for the prediction of severe SOS. In patients requiring treatment with defibrotide, this difference was significant already before the start of conditioning. These results suggest that PAI-1/PLT may serve as a prognostic biomarker for severe SOS after pediatric HSCT.

DEFIBROTIDE RESCUE FOR PEDIATRIC VENO-OCCLUSIVE DISEASE/SINUSOIDAL OBSTRUCTION SYNDROME; A SINGLE-CENTER 10-YEAR EXPERIENCE

Dua'a Zandaki[1], *Mayada Abu Shanab*[1], *Eman Khattab*[1], *Hasan Hashem*[1], *Iyad Sultan*[1], *Rawad Rihani*[1]
[1]*King Hussein Cancer Center, Amman, Jordan*

Background: Veno-occlusive Disease (VOD, aka sinusoidal obstruction syndrome) is a highly morbid and potentially fatal endothelial hepatotoxicity in the post-HSCT setting. The development of VOD has been linked to multiple risk factors relating to patient, disease, or transplant characteristics. Outcome of VOD has tremendously improved since the approval of defibrotide (DF) as a rescue agent. The EBMT criteria for diagnosing and grading VOD in pediatrics have been adopted worldwide since their publication in 2018, thus unifying clinical practice and adding to the conformity across literature. We report our 10-year single-center experience with post-HSCT VOD for pediatric patients treated with DF rescue.

Methods: We conducted a retrospective chart review. Patients included were those who received DF rescue for post-HSCT VOD in the pediatric department at King Hussein Cancer Center between 1/1/2014 and 31/12/2024. Diagnosis of VOD was made via Baltimore and EBMT criteria before and after 2018, but both criteria were retrospectively applied to the whole cohort.
The primary outcomes were DF treatment response, VOD resolution by day 100, 100-day and 1-year mortality. Secondary outcomes included overall survival (OS) estimates at 12

months, as well as analysis of risk factors for survival and VOD resolution.
Descriptive statistics were used to summarize cohort characteristics. Survival probabilities were estimated using Kaplan-Meier methodology. Cox proportional hazards regression models were used to evaluate risk factors for overall survival. Variables considered included age, VOD severity, conditioning intensity, and DF response. Analyses were performed using R (version 4.5.1).

Results: Thirty-four patients met criteria for inclusion, representing 4% of the total transplanted patients in the study period. Median age was 5.8 years (range; 0.5, 23) with 18% below 1 year and 6% above 18 years. Male:female ratio was 1.3.
Eighty-eight percent of patients underwent allogeneic HSCT, mostly for non-malignant disease (76%). Twenty-five patients (73.5%) had more than one risk factor for VOD before HSCT, the commonest risk factors being myeloablative conditioning (79%), haplo-identical donor (53%), and high pre-transplant ferritin (41%).
While all patients fulfilled diagnosis per EBMT criteria, only 53% fulfilled it per Baltimore criteria. Seven cases were late-onset VOD. DF rescue was started at median of 12 days post-HSCT (range, 4-172), for a median duration of 18 days, mostly for severe VOD (16 patients). Rate of VOD resolution by day 100 was 88.2%. Four patients died of very severe VOD and multi-organ failure at a median duration of 58 days from VOD diagnosis (range; 5,133). All-cause mortality at 100 days and 1 year was 8.8% and 18%, respectively. Overall mortality rate was 20.6%. Estimated Overall survival at 12 months was 80.4%. DF response was the only statistically significant factor found to be related to survival on Cox regression (HR 0.04, 95% CI 0.01–0.33, p=0.002). Earlier diagnosis of VOD (median 11 vs. 31 days post-HCT, p=0.023) was associated with higher likelihood of resolution.

Conclusions: DF rescue offers an effective treatment for VOD. Early recognition of VOD and response to DF are major determinants of survival. The EBMT criteria offer a reliable tool for early recognition and treatment of VOD.

ASSESSMENT OF CARDIOVASCULAR RISK BURDEN AND ITS IMPACT ON OUTCOMES AFTER ALLOGENEIC STEM CELL TRANSPLANTATION

Panagiota Gianni[1], *Adela Neagoie*[1], *Verena Wais*[1], *Katrin Strauss*[1], *Jacqueline Schnell*[1], *Frank Stegelmann*[1], *Hartmut Döhner*[1], *Donald Bunjes*[1], *Elisa Sala*[1]
[1]*University Hospital Ulm, Ulm, Germany*

Background: Cardiovascular events (CVE) represent an emerging long-term complication after allogeneic hematopoietic stem cell transplantation (allo-HSCT). Traditional cardiovascular risk factors (CVRF) are prevalent in the general population, but their specific burden and clinical consequences in allo-HSCT recipients, considering post-transplant cardiovascular outcome, overall survival (OS) and transplant-related mortality (TRM) remains insufficiently described.

Methods: We performed a retrospective, single-centre analysis including adult patients who underwent allo-HSCT for malignant or non-malignant high-risk hematologic diseases between 2013 and 2023. Patients were stratified into two groups based on the presence or absence of CVRF at the time of transplantation, including arterial hypertension, dyslipidaemia, diabetes, obesity, active or past smoking and family history of cardiovascular disease. We evaluated the association of baseline CVRF and the occurrence of CVE during post allo-HSCT long-term follow-up, as well as their impact on transplant outcomes, including OS and TRM. CVE included new onset moderate-to-severe heart failure, arrhythmias, valvular heart disease, myocardial infarction, deep vein thrombosis, pulmonary embolism, and cerebrovascular events.

Results: A total of 710 patients were included in the study, among them, 292 (41%) had no CVRF, while 418 (59%) had at least one CVRF at the time of allo-HSCT. The median follow-up of the population was 548 days (95% CI, 461-690 days). Patients and transplantations´ characteristics are listed in **Table 1**. Of note, in both cohorts more than 80% of patients had an EBMT risk-score of 3 or higher. Two-hundred and three patients out of 418 (49%) had 1 CVRF, 123 (29%) presented 2 CVRF and 92 (22%) had 3 or more CVRF. The most frequently observed CVRF was obesity (n=219, 52%), followed by arterial hypertension (n=192, 46%) and smoking (n=174, 42%). Patients presenting CVRF at the time of allo-HSCT had an increased incidence of CVE during the follow-up (27% in the CVRF-cohort versus 16.7% in the non CVRF-cohort, p=0.0011). We did not observed statistically significant differences in 1-year OS between the two groups (60% in the non CVRF-cohort versus 56% in the CVRF-cohort, p=0.47). Considering the TRM, no differences were detected considering day +100 early mortality (12% vs 11%, p=0,1097), however TRM at 1-year post-transplant was significantly higher among patients with CVRF compared with those without (57.7% vs. 46.2%, p = 0.0372) and increased proportionally with the number of cardiovascular risk factors (p = 0.0292).

	≧5, n (%)	276 (38.8%)	104 (35.6%)	172 (41%)	

Table 1: Patients and transplantations´ characteristics. AML:Acute myeloid leukemia, MDS:Myelodysplastic syndrome, MPN:Myeloproliferative neoplasms, ALL:Acute lymphoblastic leukemia, NHL:Non-Hodgkin lymphoma, MM:Multiple myeloma, SAA:Severe aplastic anemia, CR:Complete remission,PR:Partial remission,REL/REF:Relapsed / Refractory disease, SIB:HLA-identical sibling donor, MUD:Matched unrelated donor, MMUD:Mismatched unrelated donor, Haplo:Haploidentical donor, MAC: Myeloablative conditioning, RIC:Reduced-intensity conditioning,GvHD:Graft-versus-host disease, ATG:Anti-thymocyte globulin, CNI: Calcineurin inhibitor, MMF: Mycophenolate mofetil, PT-Cy:Post-Transplant cyclophosphamide, PBSC:Peripheral blood stem cells, BM:Bone marrow, EBMT risk score: European Society for Blood and Marrow Transplantation Risk Score

Conclusions: Our data suggest that patients with CVRF have a higher risk to develop CVE during the post-transplant long-term follow-up. Furthermore, despite baseline differences, OS and early TRM were comparable between groups, with 1-year TRM being higher in patients with CVRF and increasing with the number of CVRF. These results underscore the importance of integrating cardiovascular risk assessment and management into transplant care to reduce transplant-related toxicity and improve patient outcomes.

TRANSPLANT ASSOCIATED THROMBOTIC MICROANGIOPATHY CLINICAL CHARACTERISTIC, RISK FACTORS, THERAPEUTIC MANAGEMENT AND OUTCOME: A SINGLE CENTER RETROSPECTIVE COHORT STUDY

*Nada Alshaikh[1], **Ayman Almozaini**[2], Mohammed Essa[1], Bader Alahmari[2], Memon Shahbaz[1], Husam Alsadi[2], Hala Saad[1], Khalid Alharbi[2], Rahaf Salem[2], Arwa Althubaity[2], Rodaina Abujoub[1], Suha Alkhtaisat[2], Noha Needy[1], Mohsen Alzahrani[2]*
[1]King Abdula Children Specialist Hospital Ministry of National Guard, Riyadh, Saudi Arabia, [2]Ministry of National Quard Hospital, Riyadh, Saudi Arabia

Background: Transplant-associated thrombotic microangiopathy (TA-TMA) is a serious and potentially life-threatening complication of hematopoietic stem cell transplantation (HSCT), caused by endothelial injury leading to microangiopathic hemolytic anemia, thrombocytopenia, and multi-organ dysfunction. Its true incidence remains underestimated due to heterogeneous diagnostic criteria and overlap with other post-transplant complications such as graft-versus-host disease and viral infections. This study evaluated the clinical characteristics, management, and outcomes of TA-TMA HSCT population.

Methods: A retrospective cohort study was conducted including patients who underwent HSCT between 01 September 2013 and 01 April 2025. TA-TMA was diagnosed using criteria aligned with established international consensus definitions, mainly the Jodele et al Criteria. diagnostic framework. Data were extracted from medical records and transplant databases that included demographics, underlying diagnoses, transplant and donor characteristics, conditioning regimens, engraftment kinetics, post-transplant complications, CNI exposure, therapeutic interventions, and survival outcomes. Descriptive statistics were used to summarize clinical features, and survival analyses were performed to evaluate outcomes at day +100, day +180, and median overall survival.

Results: During the study period, 36 patients developed TA-TMA following HSCT. The median age at transplantation was 24.5 years (range: 1.0–59.0), with a male predominance (53%). Underlying diagnoses were malignant in 58% and non-malignant in 42%, most commonly leukemias (44%) and sickle cell disease (31%). All TA-TMA cases occurred after allogeneic HSCT, with matched related donors accounting for 50%, haploidentical donors 31%, and matched unrelated donors 19%. Reduced-intensity conditioning was used in 69% of cases. TA-TMA developed following a first HSCT in 67% and after a second transplant in 33%. The median time to TA-TMA diagnosis was 61.5 days post-HSCT (range: 2–381). All patients demonstrated laboratory evidence of microangiopathic hemolytic anemia, including schistocytes, elevated LDH (median 891.5 U/L), and thrombocytopenia, fulfilling Jodele diagnostic criteria. Hypertension was present in 89%, and renal involvement in 72%. Acute GVHD was observed prior to or concurrent with diagnosis in 55%, while viral reactivation occurred in 72%, mainly CMV and EBV. At diagnosis, majority of patients were receiving tacrolimus or cyclosporine, and CNI withdrawal was implemented in all cases. A-TMA–directed therapy included supportive care alone in 25% (Defibrotide, plasma Exchange), CNI withdrawal alone in 6%, and complement-targeted therapy in 69%. Eculizumab and

Ravulizumab were used in 31% and 39% of patients, respectively. Hematologic response was achieved in 56%. Overall survival was 83% at day +100 and 72% at day +180, with a median overall survival of 312 days. TA-TMA–attributable mortality occurred in 17% of patients. Lower survival rates were observed in patients with Concurrent GVHD at 34.7% (P=0.907).

Conclusions: Transplant-associated thrombotic microangiopathy (TA-TMA) remains a serious early complication following allogeneic HSCT, frequently associated with infection, GVHD, and viral reactivation. A higher incidence was observed in matched-related donor transplants compared with haplo-identical and matched-unrelated donors, likely reflecting the center's higher utilization of matched-related donors. Early diagnosis using Jodele criteria, prompt calcineurin inhibitor withdrawal, and complement-targeted therapy were associated with improved short-term survival. Nonetheless, TA-TMA-related mortality remained substantial, underscoring the need for standardized diagnosis, early risk-adapted intervention, and prospective studies to improve long-term outcome.

Clinical Trial Registry: None.

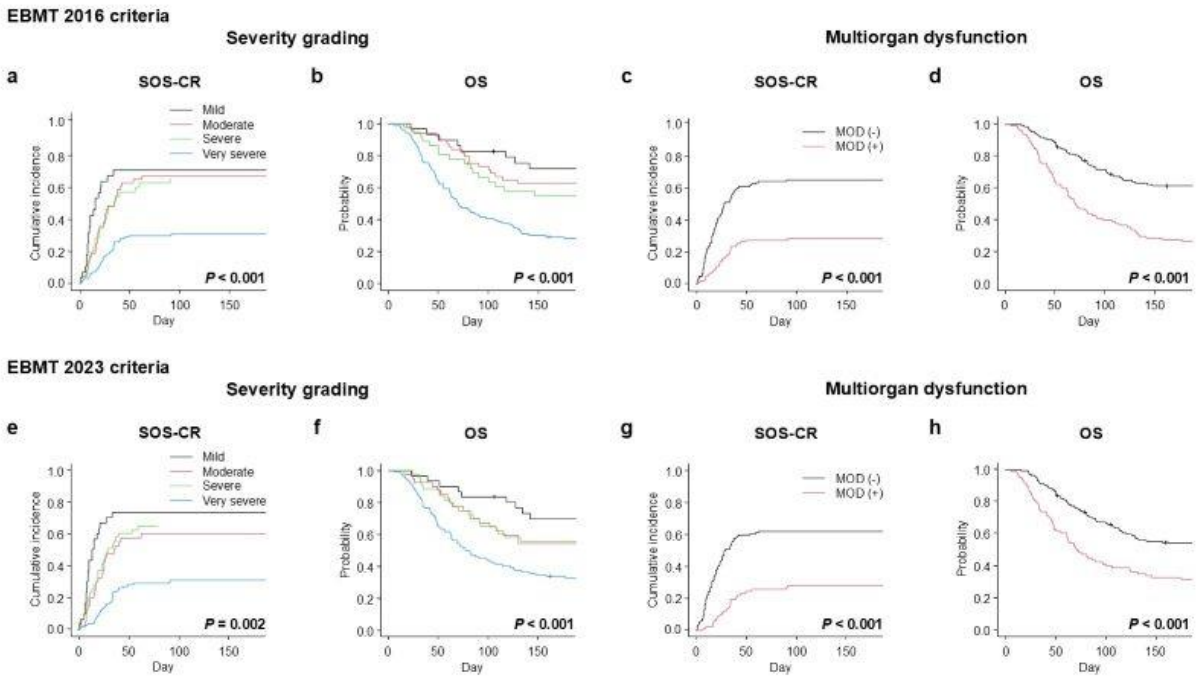
Background: Hepatic sinusoidal obstruction syndrome (SOS) is a severe and life-threatening complication after allogeneic hematopoietic stem cell transplantation (HSCT). Defibrotide (DF) has been demonstrated the efficacy for the treatment of SOS.

Methods: We conducted a nationwide survey to evaluate the efficacy and safety of DF for SOS. We collected data of patients who developed SOS after HSCT and were treated with DF between 2019 and 2021 from the Transplant Registry Unified Management Program. The

detailed background of SOS and treatment outcomes were obtained by additional questionnaires.

Results: A total of 221 patients with the median age of 51 years were analyzed. The median interval from HSCT to SOS diagnosis was 18 days (range, 0 - 365 days). The Modified Seattle criteria were met in 125 patients, the EBMT 2016 classical criteria were met in 66 patients, the EBMT 2016 late-onset criteria were met in 87 patients, and only the EBMT 2023 probable criteria were met in 6 patients, respectively. The EBMT 2016/2023 severity grading were mild in 29/30 patients, moderate in 49/40 patients, severe in 36/43 patients, and very severe in 106/107 patients, and multiorgan dysfunction were observed in 96/83 patients. The median interval from diagnosis to start of DF was 0 day (range, -1 - 46 days), with a median duration of DF treatment of 18 days (range 1 - 93 days). With a median follow-up of 1190 days from the diagnosis of SOS in survivors, the cumulative incidence of complete remission of SOS (SOS-CR) was 48.9% and the probability of overall survival (OS) at 100 days and 1-year after HSCT were 57.3 and 34.6%, respectively. Achievement of SOS-CR significantly predicted better OS (CR: 64.7% vs. non-CR: 6.2%, $P < 0.001$). Both the EBMT 2016 and 2023 severity grading and multiorgan dysfunction significantly associated with SOS-CR and OS (Figure 1). Multivariate analysis showed that higher age (HR, 1.574; 95% CI, 1.037 – 2.389; $P = 0.033$), male of sex (HR, 1.648; 95% CI, 1.112 – 2.442; $P = 0.013$), and prior HSCT (HR, 1.859; 95% CI, 1.205 – 2.869; $P = 0.005$) were significantly associated with SOS-CR, and higher age (HR, 1.833; 95% CI, 1.313 – 2.559; $P < 0.001$), prior HSCT (HR, 1.920; 95% CI, 1.327 – 2.779; $P < 0.001$), and higher performance status (HR, 1.559; 95% CI, 1.028 – 2.364; $P = 0.037$) were significantly associated with OS. Grade 3 or higher adverse events were observed in 85 (38.5%) patients, including 27 patients (12.2%) of bleeding-related events.

Figure. 1



Conclusions: Our study showed the efficacy and safety of DF for the treatment of SOS comparable to previous studies. Both the EBMT 2016 and 2023 severity grading showed significant predictive ability for the prognosis of SOS treated with DF.

EASIX SCORE AS A PREDICTOR FOR TRANSPLANTATION-ASSOCIATED THROMBOTIC MICROANGIOPATHY IN PAEDIATRIC PATIENTS UNDERGOING ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Maria Isabel Benitez Carabante[1,2], *Sofía Alperi García*[1,2], *Melissa Panesso Romero*[1,2], *Clara Serra Marrugat*[1,2], *Laura Alonso García*[1,2], *María Luz Uría Oficialdegui*[1,2], *Cristina Díaz de Heredia*[1,2]

Background: The Endothelial Activation and Stress Index (EASIX) score [(creatinine × LDH) ÷ platelets]) has emerged as a marker of endothelial damage and predictor of endothelial complications and non-relapse mortality (NRM) after allogeneic hematopoietic stem cell transplantation (allo-HSCT). Transplantation-associated thrombotic microangiopathy (TA-TMA) is a major complication of HSCT associated with high morbidity and mortality, and initiating targeted therapy at an early stage of the disease may significantly improve outcomes. We explore the EASIX score as a predictive tool for TA-TMA.

Methods: We conducted a retrospective study at a single centre. All consecutive patients undergoing allo-HSCT between 2019 and 2023 were included. The EASIX score was calculated before conditioning (pre-EASIX), on the day of transplantation (EASIX-0) and subsequently on days 7, 14, 21 and 30. The score was log2-transformed according to the literature. TA-TMA was diagnosed according to the Jodele criteria. We analysed the correlation between the EASIX score and the occurrence of TA-TMA. Variables associated with the occurrence of TA-TMA were evaluated using univariate and multivariate analyses with a Cox proportional hazards model.

Results: A total of 143 patients were included, with malignant (n=63;44.1%) and non-malignant (n=80;55.9%) diseases. Median age at transplantation was 7.69 years (IQR 3.04-12.77) and 87 patients were male (60.8%). Most patients received an unrelated donor transplant (n=73,51%), followed by matched related donor (n=39,27.3%) and a mismatched donor transplant (n=31,21.7%). The most common stem cell source was bone marrow, and most patients received a myeloablative or reduced toxicity conditioning regimen (n=114,79.7%).
Globally, 14 patients (9.5%) were diagnosed with TA-TMA, with a cumulative incidence of

8.96% (95%CI 5.19-15.24) 1 year after HSCT.

Table 1 shows the characteristics of patients with or without TA-TMA.

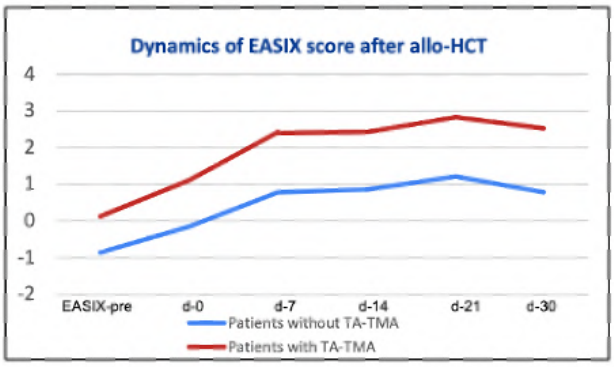
Variable	Patients without TA-TMA (n=129)	Patients with TA-TMA (n=14)	All patients (n=143)	p-value
Age at HSCT, median (range)	7.00 (2.61; 11.30)	14.99 (9.74; 17.28)	7.69 (3.04; 12.77)	**0.0001**
Sex, n (%) Male Female	 79 (61.2%) 50 (38.8%)	 8 (57.1%) 6 (42.9%)	 87 (60.8%) 56 (39.2%)	0.7655
Underlying disease, n (%) Non-malignant Malignant	 73 (56.6%) 56 (43.4%)	 7 (50%) 7 (50%)	 80 (55.9%) 63 (44.1%)	0.6372
Donor, n (%) Matched family donor Unrelated donor Haploidentical donor	 39 (30.2%) 62 (48.1%) 28 (21.7%)	 0 (0%) 11 (78.6%) 3 (21.4%)	 39 (27.3%) 73 (51%) 31 (21.7%)	**0.0171**
Stem cell source, n (%) Bone marrow Peripheral blood Cord blood	 90 (69.8%) 29 (22.5%) 10 (7.8%)	 9 (64.3%) 5 (35.7%) 0 (0%)	 99 (69.2%) 34 (23.8%) 10 (7%)	0.5007
Conditioning regimen, n (%) MAC / RTC RIC	 105 (81.4%) 24 (18.6%)	 9 (64.3%) 5 (35.7%)	 114 (79.7%) 29 (20.3%)	0.1599
Serotherapy, n (%) No Yes	 25 (19.4%) 104 (80.6%)	 1 (7.1%) 13 (92.9%)	 26 (18.2%) 117 (81.8%)	0.4659
***Ex vivo* T cell depletion** No Yes	 121 (93.8%) 8 (6.2%)	 12 (85.7%) 2 (14.3%)	 133 (93%) 10 (7%)	0.2540

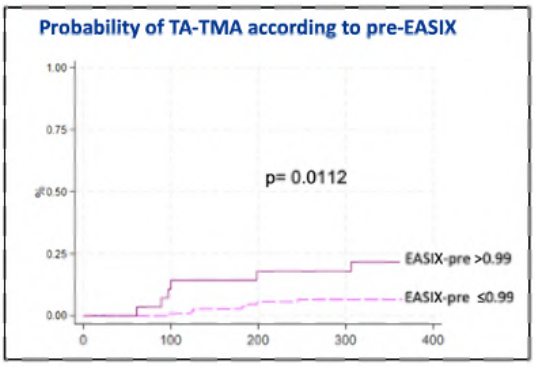
Pre-EASIX, median (IQR)	-0.87 (-1.90; 0.22)	0.99 (-0.45; 2.44)	-0.68 (-1.87; 0.44)	**0.0009**
EASIX-0, median (IQR)	-0.16 (-1.53; 0.87)	1.28 (0.11; 2.65)	0.03 (-1.42; 1.13)	**0.0024**
EASIX-7, median (IQR)	0.78 (-0.08; 1.86)	1.63 (1.14; 2.26)	0.89 (-0.04; 1.94)	0.0988
EASIX-14, median (IQR)	0.86 (0.03; 1.85)	1.56 (1.40; 2.37)	1.02 (0.04; 1.88)	**0.0071**
EASIX-21, median (IQR)	1.22 (0.55; 1.91)	1.61 (0.90; 2.18)	1.26 (0.60; 1.99)	0.0947
EASIX-30, median (IQR)	0.78 (0.05; 1.78)	1.75 (1.19; 3.09)	1.11 (0.18; 1.94)	**0.0117**

EASIX score was superior from admission to day +30 in patients diagnosed with TA-TMA [(pre-EASIX 0.99 vs. -0.87 (p=0.0009), EASIX-0 1.28 vs. -0.16 (p=0.0024), EASIX-14 1.56 vs. 0.86 (p=0.0071), EASIX-30 1.75 vs. 0.78 (p=0.0117)]. In the univariate analysis, the pre-EASIX, EASIX-d0, and EASIX-d14 were statistically associated with the occurrence of TA-TMA: HR 1.52, 95%CI 1.14-2.02, (p=0.0048); HR 1.30, 95%CI 1.05-1.60, (p=0.0153); and HR 1.53, 95%CI 1.06-2.20 (p=0.0236). The other variable significantly predictive of TA-TMA in the univariate analysis was the age at HSCT (HR 1.23, 95%CI 1.09-1.38; p=0.0006).
In the multivariable analysis, both the age (HR 1.17, CI 95% 1.04-1.32 (p=0.0080) and the pre-EASIX strongly predicted the risk of TA-TMA (HR 1.44, 95%CI 1.01-2.04 (p=0.0412). A significant association was also found between the temporal evolution of EASIX and the development of TMA (p=0.0070)
One-year NRM was 9.58% (95% CI 5.67-15.93), with significantly higher EASIX-d21, 2.21 vs. 1.22 (p=0.0488). However, in the multivariate analysis we did not find an association

with the EASIX score and the NRM.

Figure 1. EASIX in patients with or without TA-TMA





Conclusions: Endothelial complications after allo-HSCT are associated with high morbidity and mortality. Our study suggests that the EASIX score could be a useful tool for predicting the development of TA-TMA in paediatric patients undergoing allo-HSCT, and it could guide diagnostic and clinical interventions in patients at risk. However, these results need to be validated in larger cohort of patients.

POSITIVE OUTCOMES AMONG PEDIATRIC HCT PATIENTS TREATED WITH DARATUMUMAB FOR AUTO-IMMUNE HEMOLYTIC ANEMIA

Lauren Stafford[1], *Vinod Prasad*[1], *Brittany Paige De Priest*[1], *Carmem Bonfim*[1], *Jennifer Jaroscak*[1], *Paul L. Martin*[1], *Timothy A. Driscoll*[1], *Joanne Kurtzberg*[1], *Kris Michael Mahadeo*[1]
[1]*Duke University, Durham, United States of America (the)*

Background: Autoimmune hemolytic anemia (AIHA) is a rare complication following hematopoietic cell transplant (HCT), with an incidence between 4-6%. There are no defined therapies and prospective clinical trials addressing the best approach to treatment. Approach to treatment in the United States have included corticosteroids, rituximab and intravenous immunoglobulin (IVIG) as usually approved by payors for initial management. Yet this post-HCT complication is severe and usually refractory to these treatments. AIHA is considered to be mediated by donor/host derived antibodies and B cell dysregulation. Daratumumab is an anti-CD38 MoAb that potentially targets CD38 expressing nonmalignant autoantibody-producing plasma cells and may be effective for patients with post-HCT AIHA. This study aims to characterize the safety and efficacy of daratumumab for the treatment of post-transplant refractory autoimmune hemolytic anemia.

Methods: Retrospective study among all patients transplanted at our institution between January 2018-December 2025. Demographic and clinical variables were extracted from the electronic medical record, including clinical course and treatment history for patients with a diagnosis of AIHA. Descriptive statistics were used to summarize findings.

Results: The incidence of AIHA during the study period was 0.05%. Patients with AIHA were transplanted at a median age of 20.5 (6-162) months of age and the majority (70%) were transplanted for non-malignant indications (inborn errors of metabolism (50%), primary immune deficiencies (30%). All patients received a myeloablative preparative regimen and 90% received an unrelated cord blood HCT (1 patient received an alpha-beta T cell depleted related haploidentical HCT). The median time from HCT to diagnosis of AIHA was 185 (111-361) days.
Among patients that developed AIHA, 70% were refractory to initial therapy with corticosteroids and rituximab. All patients with refractory AIHA were treated with daratumumab (16 mg/kg/dose, starting weekly) with a median of 13 infusions until resolution. Premedication for daratumumab infusion included diphenhydramine, solumedrol, acetaminophen and famotidine. Daratumumab infusions were well tolerated without reported toxicity. Treatment course for patients with refractory AIHA who received daratumumab are summarized in Table 1.

Subject	HCT Indication	Age at HCT (months)	Preparative Regimen	Donor	Time Post-HCT to AIHA (days)	Prior Treatment for AIHA	Number of Infusions of Daratumumab to resolution of AIHA	A B
1	Hurler Syndrome	4	Bu/Cy/ATG	UCB	344	Corticosteroids, Rituximab, IVIG	7	N
2	Wiskott-Aldrich Syndrome	28	Bu/Cy/ATG	UCB	361	Corticosteroids, Rituximab, IVIG	13	N
3	HLH	6	Bu/Flu/Cy		257	Corticosteroids, Rituximab, IVIG	4	N
4	Hurler	4	Bu/Cy/ATG	UCB	111	Corticosteroids, Rituximab, IVIG	21	N
5	VODI	13	rATG Flu/Treo /TBI 400cGy	Alpha-beta depleted r-Haplo	190	Corticosteroids, Rituximab, IVIG	31	N
6	AML	90	Bu/Flu/Mel	UCB	132	Corticosteroids, Rituximab, IVIG	4	N

7	Hurler	4	Bu/Cy/ATG	UCB	180	Corticosteroids, Rituximab, IVIG	38

Table 1: Treatment course for patients with refractory AIHA who received daratumumab

Conclusions: The majority of patients with AIHA post-HCT were refractory to initial treatment with corticosteroids and rituximab. Daratumumab was well tolerated in this patient cohort. All patients with refractory AIHA treated with daratumumab achieved resolution. Prospective trials are needed to optimize the approach to initial management of patients with AIHA and those with refractory disease.

DAY 0 EASIX SCORE PREDICTS NON-RELAPSE MORTALITY, BUT NOT GRAFT-VERSUS HOST DISEASE OR RELAPSE FOLLOWING ALLOGENEIC STEM CELL TRANSPLANTATION: A SINGLE-CENTER REAL-WORLD ANALYSIS

Ion Antohe[1], *Diana-Marina Fortoes*[2], *Elena Dolachi-Pelin*[2], *Angela Dascalescu*[1]
[1]*Universitatea de Medicina si Farmacie "Gr. T. Popa" Iasi", Iasi, Romania,* [2]*Regional Oncology Institute, Iasi, Romania*

Background: The Endothelial Activation and Stress Index (EASIX) is emerging as a surrogate marker of endothelial dysfunction after allogeneic stem cell transplant (allo-SCT) and, while it has been linked to transplant outcomes, its relationship with non-relapse mortality (NRM), graft-versus-host disease (GVHD), and relapse remains incompletely defined in real-world settings.

Methods: We conducted a retrospective unicenter analysis in patients recieving allo-SCT at the Regional Oncology Institute from Iași, Romania. The EASIX score was calculated as follows: LDH (U/L) xCreatinine (mg/dl) /platelet count (10^9/L). Day 0 EASIX (log2-transformed) was evaluated in relation to NRM, acute GVHD (aGVHD), chronic GVHD (cGVHD), relapse, and overall survival (OS). Competing-risk endpoints were analyzed using cumulative incidence functions with Gray's test, and Fine–Gray regression was applied for univariate and multivariable analyses. OS was estimated using the Kaplan–Meier method. All statistical analyses were performed using SPSS v.26 and R v4.5.2.

Results: A number of 98 patients were included in this study, in whom 101 allo-SCT procedures were peformed. Day 0 EASIX was available in 84 patients. A higher log-2 EASIX was strongly associated with increased NRM. The cumulative incidence of NRM differed significantly between patients with high versus low EASIX, as defined by median split and across EASIX quartiles (Gray's test $p < 0.001$). Furthermore, NRM risk augmented progressively across increasing EASIX quartiles. In Fine–Gray regression, increasing EASIX

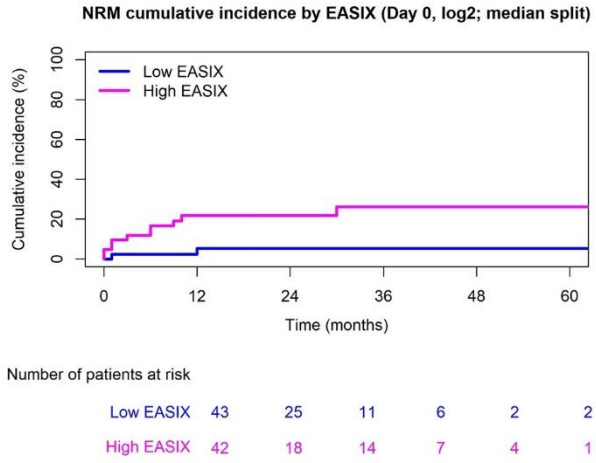
was associated with a significantly higher sub-distribution hazard for NRM, with a significant trend across quartiles (p = 0.0049).In contrast, day 0 EASIX was not associated with the incidence of relapse. Similarly, associations between EASIX and aGVHD or cGVHD were weak and inconsistent, with no clear separation of cumulative incidence curves. Patients with high EASIX experienced inferior OS compared with those with low EASIX, an effect driven primarily by excess NRM rather than relapse.

Table 1. Baseline Patient Characteristics.

Baseline Characteristics	n (%) (n=98)*
Age (years), median	41
Female sex	46 (46.9%)
Underlying disease AML ALL Other	 55 (54.5%) 22 (21.8%) 24 (23.7%)
Allo-SCT-related Characteristics	n (%) (n=101)*
HCT-CI > 2	11 (10.9%)
1st Transplant	98 (97%)
2nd Transplant	3 (3%)
Conditioning regimen Myeloablative Reduced intensity	 55 (54.5%) 46 (45.5%)
Donor type Sibling donor Matched unrelated donor Haploidentical donor	 40 (39.6%) 46 (45.5%) 15 (14.9)
GVHD Prophylaxis Tacrolimus+MMF CsA+MTX PTCy ATG	 93 (92.1%) 8 (7.9%) 73 (72.3%) 4 (4%)
Acute GVHD	24 (23.8%)
Chronic GVHD	14 (13.9%)

Table 1. Baseline Patient Characteristics.

ALL= Acute Lymphoblastic Leukemia, AML= Acute Myeloid Leukemia, ATG= Anti-Thymocyte Globulin, CsA= Cyclosporin A, GVHD= Graft-Versus Host Disease, MMF= Mycophenolate Mofetil, MTX= Methotrexate, PTCy= Post-Transplant Cyclophosphamide, SCT= Stem Cell Transplant
*Percentages are calculated per patient (n=98) or per transplant event (n=101), as indicated.



Conclusions: In our real-world allo-SCT cohort, day 0 EASIX was a strong predictor of non-relapse mortality but did not predict relapse or GVHD. These findings suggest that EASIX primarily reflects baseline endothelial vulnerability predisposing patients to transplant-related toxicity. EASIX may therefore represent a practical and easily applicable tool for early risk stratification and for guiding individualized supportive and preventive strategies aimed at reducing non-GVHD transplant-related mortality after allo-SCT.

Disclosure: Nothing to declare.

A409

ANAKINRA AS TREATMENT FOR SECONDARY HAEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS FOLLOWING ALLOGENIC STEM CELL TRANSPLANT: A RETROSPECTIVE ANALYSIS IN A UNIVERSITY HOSPITAL TRANSPLANT CENTRE

Richard Williams[1], Adrian Maraj[1], Mariam Amer[1], Christopher Dalley[1], Kim Orchard[1], Deborah Richardson[1], ***Hwai Jing Hiew***[1]

[1]*University Southampton Hospital, Southampton, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Secondary Haemophagocytic Lymphohistiocytosis (sHLH) is a rare but recognised life-threatening complication following allogeneic haematopoetic stem cell transplantation (allo-HSCT). Anakinra is an approved treatment for sHLH, but few studies have evaluated its use in the post-allograft setting.
The aim of this review was to evaluate the efficacy of anakinra in post-allograft sHLH. The primary end point was the 30-day mortality incidence following anakinra initiation. Secondary endpoints included: the 100-day mortality incidence, the Intensive Care Unit (ICU) admission incidence and median length of stay, the median length of treatment, and response to treatment measured by serum ferritin levels.

Methods: Between March 1st 2022 to March 1st 2025, a retrospective case-series analysis of anakinra-treated post-allograft sHLH cases in a University Hospital transplant centre was performed. Patients that met the sHLH criteria based on: HLH-2004 protocol, Hscore >169, modified Hscore >132, ferritin >10 000 mcg/L, or confirmed tissue diagnosis, that received at least one dose of anakinra were included in the analysis. Data was extracted from electronic patient records.

Results: During this period, 12 patients met the inclusion criteria. The median age at diagnosis was 56 years old (range 34 to 69), 7/12 were male (58%), 11 had matched unrelated donor transplants and 1 had a haplo-identical transplant. The median pre-treatment ferritin level was 6419 mcg/L (range 1014 to 91141). Transplant indications are summarised in Table 1. One patient had two separate occasions of sHLH, making a total 13 cases of sHLH. 12 (92.3%) occurred within one year of allo-HSCT and one case 2.5 years post-HSCT, following a donor lymphocyte infusion. 158 patients received an allo-HSCT at this centre during this period, making the sHLH incidence 7.59%.
The 30-day mortality post anakinra initiation was 23% (n=3/13) and the 100-day mortality was 38.5% (n=5/13). 30.7% (n=4/13) required an ICU admission with a 9-day median length of stay (range 4-13). All those admitted to ICU were alive at day 30, with one subsequently deceased by day 100. The median length of anakinra treatment was 54 days (range 10 to 127). Comparing the baseline ferritin to end of treatment levels, the median change was -53.2% (range -93.9 to +63.5%) in those who survived (n=8), vs -5.5% (range -35.7% to +200%) in those who died (n=5).
Median ferritin levels at baseline were higher in the 30-day mortality cohort compared to the 30-day survival cohort (8812 vs 3007 mcg/L). A similar pattern was seen in the Day 100 mortality vs survival cohort (4720 vs 2057 mcg/L). The mortality rate at Day 30 was higher in those on concurrent immunosuppression. The median age was similar across all groups. Subject numbers were too small to comment on concurrent viral infections and other HLH treatments.

Table 1: **Post allograft sHLH: demographics and**	**Total cases (n= 13)**	**Day 30 survival cohort (n= 10)**	**Day 30 mortality cohort (n= 3)**	**Day 100 survival cohort (n= 8)**	**Day 100 mortality cohort (n= 5)**

outcomes with anakinra use

Concurrent infection CMV (%)	1 (7.7%)	1 (10%)	0 (0%)	1 (12.5%)	0 (0%)
On concurrent immunosuppression (ciclosporin/MMF/sirolimus) (%)	7 (53.8%)	4 (40%)	3 (100%)	4 (50%)	3 (60%)
Other HLH treatment (%): IVIG alone methylprednisolone alone IVIG + methylprednisolone	5 (38.5%) 6 (46.2%) 2 (15.4%)	4 (40%) 4 (40%) 2 (20%)	1 (33.3%) 2 (66.7%) 0 (0%)	4 (50%) 3 (37.5%) 1 (12.5%)	1 (20%) 3 (60%) 1 (20%)

Conclusions: From our data, sHLH remains an uncommon complication following allogeneic HSCT. Anakinra appears to be effective in post-allograft sHLH with over 60% of patients alive at day 100 in a condition typically associated with a high mortality rate. Elevated baseline ferritin levels may be predictive of severity, including mortality, despite anakinra use. This could be evaluated with further studies.

EARLY POST-TRANSPLANT ELECTROLYTE DISTURBANCES IN ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANT RECIPIENTS: INCIDENCE AND SEVERITY

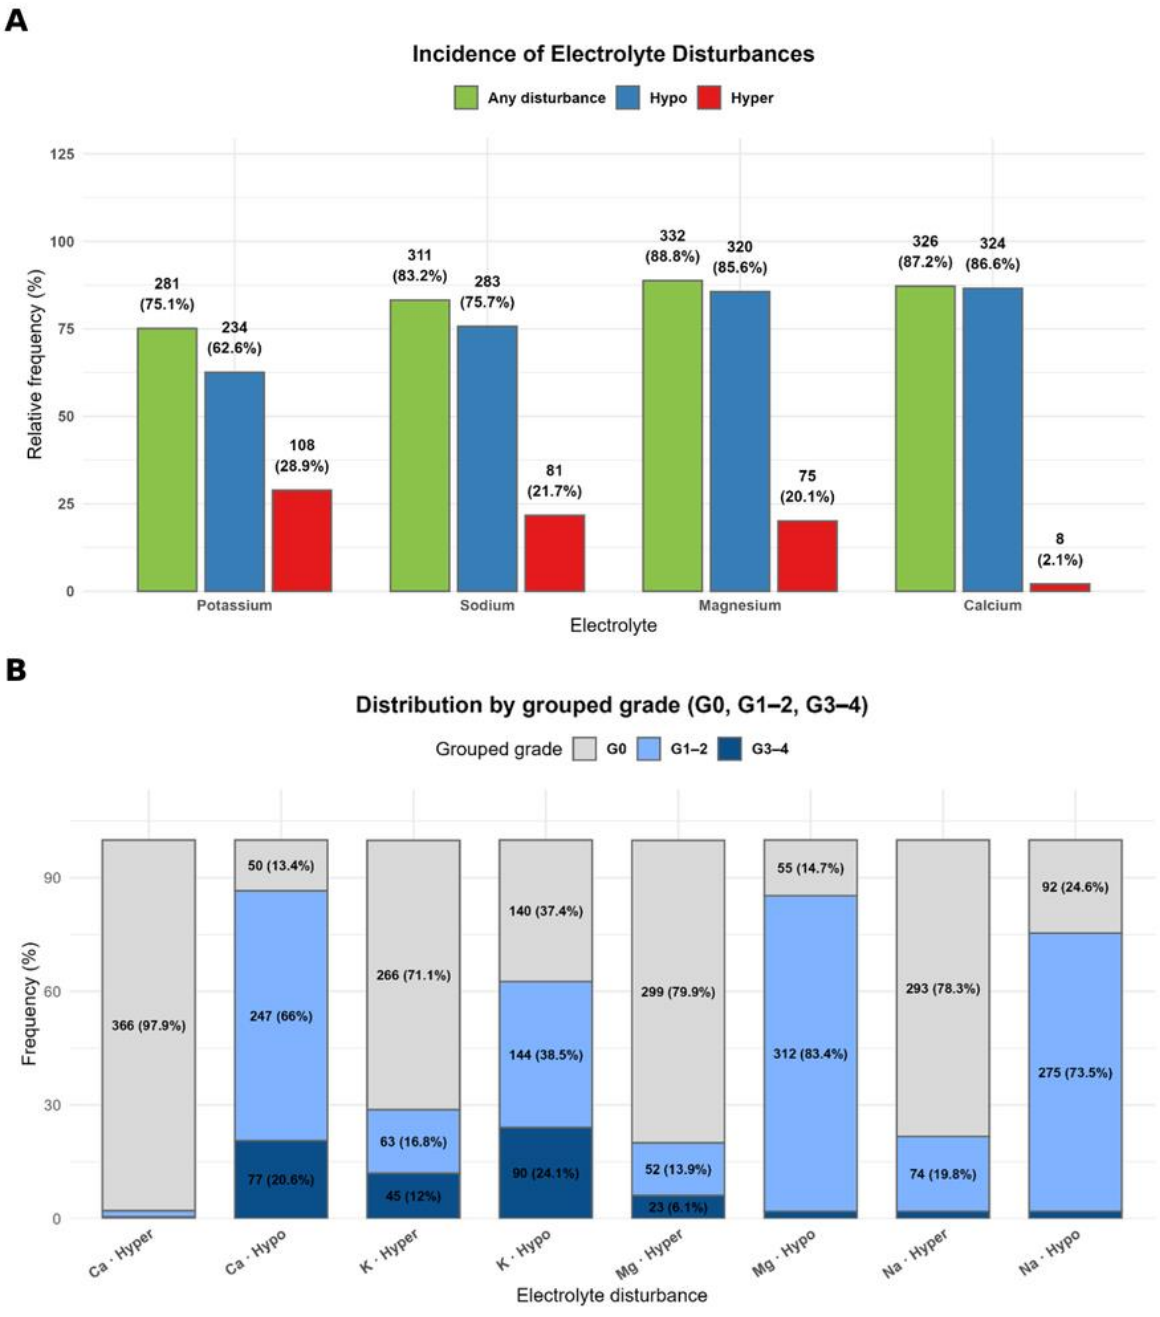
Luiz Carlos da Costa-Junior[1,2], *Maria Clara Ferreira Camargo*[3], *Marina Izu*[2], *Rita de Cássia Barbosa da Silva Tavares*[2], *Simone Cunha Maradei*[2], *Elias Hallack Atta*[2], *Maria Claudia Rodrigues Moreira*[2,4], *Marta Colares Nogueira*[2], *Décio Lerner*[2], *Teresa de Souza Fernandez*[5], *Paulo Caleb Júnior de Lima Santos*[1,3]

[1]Postgraduate Program in Medical Sciences, Faculdade de Medicina da Universidade de São Paulo (FMUSP), São Paulo, Brazil, [2]Bone Marrow Transplant Center, Instituto Nacional de Câncer (INCA), Rio de Janeiro, Brazil, [3]Department of Pharmacology, Escola Paulista de Medicina, Universidade Federal de São Paulo (EPM-Unifesp), São Paulo, Brazil, [4]Bone Marrow Transplant Program, Hospital Universitário Clementino Fraga Filho (HUCFF), Universidade Federal do Rio de Janeiro (UFRJ), Rio de Janeiro, Brazil, [5]Cytogenetic Laboratory, Cell and Gene Therapy Program, Instituto Nacional de Câncer (INCA), Rio de Janeiro, Brazil

Background: Electrolyte disturbances are common and clinically significant in the early post–allogeneic HCT period. Abnormalities involving sodium, potassium, magnesium, and calcium may precipitate hemodynamic instability and arrhythmia, and potassium disturbances represent a well-recognized cause of cardiac arrest. During the first 21 days after infusion, patients face metabolic, inflammatory, gastrointestinal, and renal stressors that increase susceptibility to electrolyte imbalance. However, the true incidence and severity of these early disturbances remain poorly described. This study evaluated the frequency and clinical severity of electrolyte disturbances within the first 21 days after allo-HCT.

Methods: This was a retrospective, single-center study including all patients who underwent allogeneic HCT between January 2010 and December 2023 and had laboratory data available for sodium, potassium, magnesium, and calcium during the first 21 days post-transplant. Patients receiving umbilical cord blood grafts were excluded. Data was extracted from electronic medical records. Electrolyte disturbances were classified according to CTCAE v5.0 as deficiency (hypo-) or excess (hyper-) and graded from 1 to 4; grades 1–2 were considered mild or moderate, and grades 3–4 were severe. Clinical and transplant variables were summarized as absolute and relative frequencies or as medians and standard deviations. The study was approved by the institutional ethics committee and conducted in accordance with the Declaration of Helsinki.

Results: A total of 374 allogeneic HCT recipients were included, with a mean age of 28.2 ± 18.4 years; 67.1% were adults and 58.8% were male. Most patients had malignant diseases, mainly acute lymphoblastic leukemia (32.1%) and acute myeloid leukemia (25.1%). Bone marrow was the predominant graft source (70.1%). Donors were related (44.9%), unrelated (33.7%), or haploidentical (21.4%). Myeloablative conditioning was used in 55.6% of cases and cyclosporine-based prophylaxis in 63.9%. Electrolyte disturbances were highly prevalent in the first 21 days after transplant, with deficiencies markedly more frequent than excesses. Potassium abnormalities occurred in a large proportion of patients. Hypokalemia was observed in 62.6%, including 38.5% with grade 1–2 and 24.1% with grade 3–4. Hyperkalemia occurred in 28.9%, with 12% classified as severe. Sodium disturbances were also common. Hyponatremia affected 75.7% of patients, predominantly grade 1–2; severe hyponatremia occurred in approximately 2.2%. Hypernatremia was documented in 21.7%. Magnesium disturbances showed one of the highest incidences. Hypomagnesemia affected 85.6% of the cohort, mostly grade 1–2, with 2.2% reaching grades 3–4. Hypermagnesemia occurred in 20.1%, including 6.1% severe. Calcium abnormalities were the most frequent overall. Hypocalcemia was present in 86.6% of patients, including 66% with grade 1–2 and 20.6% with grade 3–4. Hypercalcemia was rare at 2.1%. The overall pattern demonstrated a predominance of hypomagnesemia, hypocalcemia, and hyponatremia, with clinically meaningful proportions of severe hypokalemia, hypocalcemia, and hyperkalemia.



Conclusions: While most abnormalities were mild or moderate, a relevant proportion of patients developed severe disturbances, particularly hypokalemia, hyperkalemia, and hypocalcemia, which may contribute to hemodynamic instability and arrhythmias during this high-risk period. Incidence and severity were comparable between cyclosporine and tacrolimus. These findings emphasize the need for systematic electrolyte monitoring and timely correction strategies to reduce preventable early post-transplant morbidity.

Clinical Trial Registry: Not applicable. This study is not a clinical trial.

HEMOSTATIC ALTERATIONS AND HISTOPATHOLOGICAL FINDINGS OF SINUSOIDAL OBSTRUCTION SYNDROME AFTER ALLOGENEIC HSCT FROM A REFERENCE CENTER IN LATIN AMERICA

Severiano Baltazar Arellano[1], *Enrique Baez de la Fuente*[1], *Guillermo Sotomayor Duque*[1], *Araceli Leal Alanis*[1], *Hernan Ramirez Duran*[1], *Dolores Catalina Cortez Flores*[1], *Carolina Rodriguez Ibarra*[2]
[1]*Hospital de Especialidades No. 25, Instituto Mexicano del Seguro Social, Monterrey, Mexico,* [2]*ADIUM, Mexico City, Mexico*

Background: Sinusoidal obstruction syndrome (SOS/VOD) remains a life-threatening complication after allogeneic hematopoietic stem cell transplantation (allo-HSCT), despite advances in conditioning strategies, prophylaxis, and treatment, identification of early hemostatic markers may help timely diagnosis and succesful treatment. We aimed to analyze hemostatic alterations and describe histopathological findings in patients who developed SOS/VOD after allo-HSCT.

Methods: We conducted a retrospective observational study including patients diagnosed with SOS/VOD based on clinical and/or histological criteria according to McDonald et al. Clinical diagnosis required jaundice, hepatomegaly with right upper quadrant pain, and ascites and/or unexplained weight gain. Histological confirmation was based on liver biopsy or autopsy findings, after exclusion of other causes of liver injury. Clinical characteristics, transplant-related variables, and hemostatic parameters—fibrinogen, factor VII activity (FVII), plasminogen activator inhibitor-1 (PAI-1), and protein C activity were analyzed from the start of conditioning until day +28 post-transplant. Statistical analysis included univariate analysis, Student's t-test, chi-square testing, and linear correlation analysis.

Results:

Twenty-six patients treated at a reference center in Mexico (UMAE No. 25, IMSS, Monterrey) who developed SOS/VOD after allo-HSCT between 2001 and 2016 were included. Median age was 28 years (14–42). Diagnoses included acute lymphoblastic leukemia (n = 15), acute myeloid leukemia (n = 5), and other hematologic disorders (n = 6). Most transplants were HLA-matched (6/6, n = 23); two were 5/6 matched and one haploidentical. Conditioning was busulfan/cyclophosphamide-based in 25 patients and busulfan/fludarabine-based in one. GVHD prophylaxis consisted of cyclosporine plus methotrexate (n = 25) or post-transplant cyclophosphamide with tacrolimus and mycophenolate (n = 1). Grafts were not T-cell depleted. All patients received SOS/VOD prophylaxis with heparin and ursodeoxycholic acid.

SOS/VOD severity (Seattle criteria) was mild (n = 5), moderate (n = 12), or severe (n = 9), with onset between days +6 and +15 post-transplant (92.3%). Hemostatic changes preceded SOS/VOD, including increased fibrinogen and PAI-1, and decreased FVII and protein C activity. Significant correlations were observed among these parameters (Table 1). Histology was available in 17 patients, confirming SOS/VOD in 10, with findings ranging from subintimal edema and sinusoidal fibrosis to extensive necrosis and hemorrhage; hepatic hemosiderosis was observed in six cases (Figure 1).

Table 1. Hemostatic alterations preceding the onset of sinusoidal o

PATIENTS	FIBRINOGEN	FVIIc
*Mean time (days) to onset and mean levels of hemostatic parameter abnormalities.	Days/Level	Days/Level
SOS/EVO-H	3.9/539	3.03/43.7
Period I (0-5 days) Period II (6-10 days) Period III (11-15 days)	2.8/565 3.1/627.7 2.0/603.7	2.6/45 2.5/40 1.8/27.1

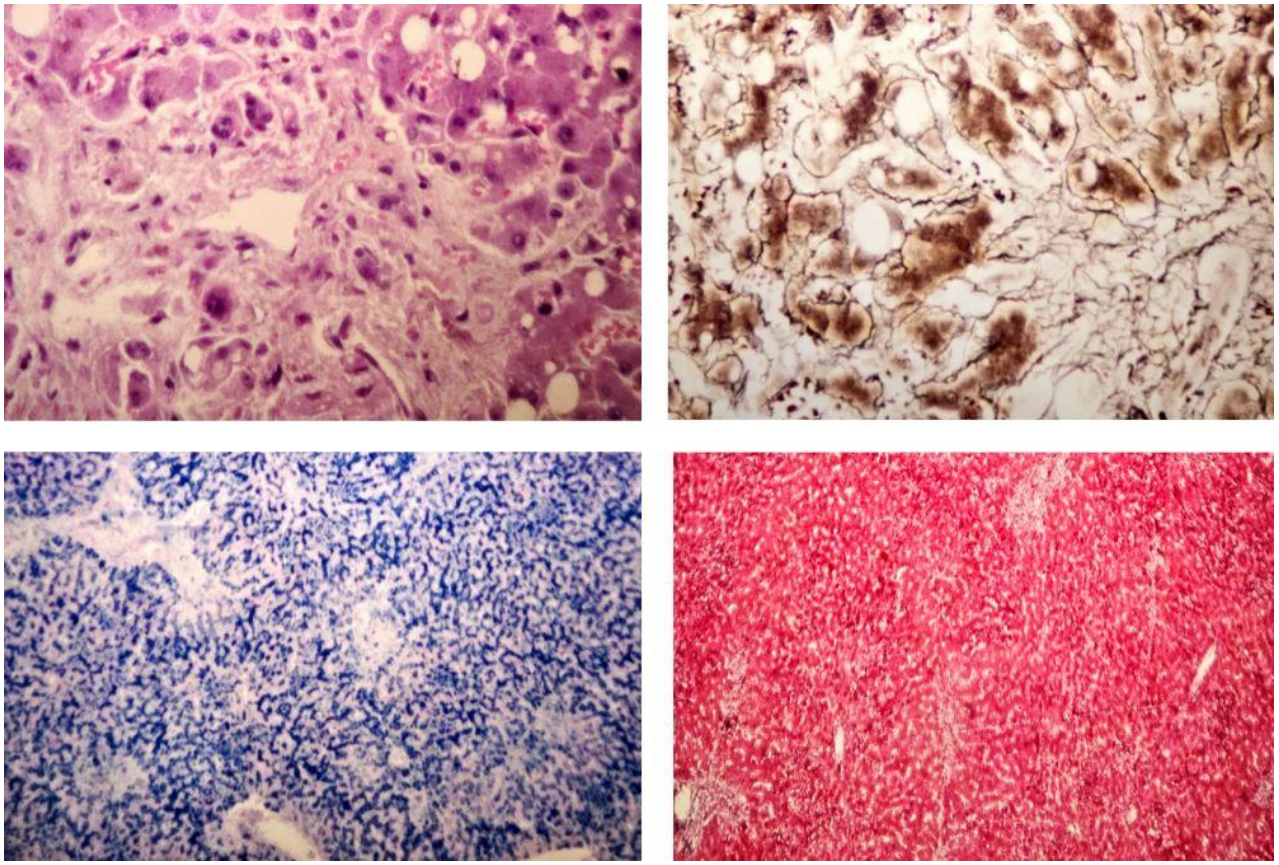

Figure 1. Representative liver histopathology. Hematoxylin–eosin staining shows hepatocyte necrosis (upper right). Silver staining shows focal sinusoidal fibrosis and partial occlusion of a central venule with subendothelial edema (upper left). Perl's Prussian blue (lower right) and Masson's trichrome stains (lower left) reveal marked hepatic hemosiderosis, centrilobular loss, and mild portal fibrosis.

Conclusions: Early hemostatic alterations related to SOS/VOD included hypofibrinolysis, elevated fibrinogen and PAI-1, and reduced FVII and protein C activity. These findings support a key role of endothelial injury and thrombin generation in SOS/VOD pathogenesis and suggest that hemostatic markers may aid in early diagnosis and risk stratification.

THE CLINICAL SIGNIFICANCE AND SAFETY OF BRONCHOSCOPY AFTER ALLO-HSCT

Seiya Bamba[1], *Junya Kanda*[1], *Noriyoshi Yoshinaga*[1], *Tomoyasu Jo*[1], *Yasuyuki Arai*[1], *Toshio Kitawaki*[1], *Kouhei Yamashita*[1], *Akifumi Takaori-Kondo*[1]
[1]*Kyoto University Hospital, Kyoto, Japan*

Background: Pulmonary complications are occasionally observed after allogeneic hematopoietic stem cell transplantation (allo-HSCT). However, bronchoscopy is often avoided due to concerns regarding coagulopathy, leaving the etiology unclear.

Methods: We conducted a retrospective cohort study of all patients who underwent their first bronchoscopy for pulmonary complications after allo-HSCT at Kyoto University between 2005 and 2025 to evaluate its clinical significance and safety. We also assessed whether corticosteroids were administered for pulmonary complications and evaluated treatment responses using CT scans (CR/PR/SD/PD). Furthermore, we analyzed multiple parameters potentially associated with corticosteroid treatment decisions and responsiveness.

Results: A total of 72 patients were included, with a median age of 49 years (range, 18-70). At bronchoscopy, 40 patients (56%) required no supplemental oxygen, 25 (35%) were on low-flow oxygen devices with a median flow rate of 2 L/min (range, 1-6), and 7 (10%) were intubated. Median platelet count at examination was 110,000/μL (range, 10,000-481,000); 18 (25%) received platelet transfusion on the examination day. Transbronchial lung biopsy (TBLB) was performed in 24 (33%), and bronchoalveolar lavage fluid (BALF) cytology in all. Diagnoses included cryptogenic organizing pneumonia (24; 33%), fungal pneumonia (10; 14%), diffuse alveolar hemorrhage (7; 10%), Pneumocystis jirovecii pneumonia (5; 7%), idiopathic pneumonia syndrome (5; 7%), diffuse alveolar damage (3; 4%), pulmonary alveolar proteinosis (2; 3%), and bronchiolitis obliterans (1; 1%). Eight cases (11%) were histologically diagnosed by TBLB. Ten cases (14%) were diagnosed based on cytology, culture, PCR, or galactomannan antigen testing. Seven cases (10%) were diagnosed grossly, and 47 (65%) were diagnosed clinically. Corticosteroids were administered in 43 patients (60%), and 39 of them (91%) responded to treatment (CR: 16; PR: 23). Because almost all corticosteroid-treated cases were responsive, we focused on identifying factors associated with the decision to initiate corticosteroids rather than treatment response. Logistic regression analyses identified BALF lymphocytes > 20% and LDH > 263.5 U/L (ROC curve analysis showed the appropriate cutoff of LDH levels to be 263.5; AUC=0.75) as factors associated with corticosteroid treatment even after adjustment for potential confounders (odds ratio (OR), 7.29; 95% confidence interval (CI), 1.79-38.7; p=0.0094 for BALF lymphocyte >20%, OR, 5.31; 95% CI, 1.28-28.9; p=0.031 for LDH > 263.5). Other factors including CRP > 1.35 mg/dL (AUC=0.62) and cumulative TBI ≥ 8 Gy were not significantly associated with corticosteroid treatments (OR, 2.09; 95% CI, 0.51-8.91; p=0.30 for CRP > 1.35, OR, 2.52; 95% CI, 0.65-10.6; p=0.19 for cumulative TBI ≥ 8 Gy), though they were significant in univariate analyses. Procedural complications occurred in only 5 patients (7%),

including 3 following TBLB, all of which were manageable with supportive care alone. There were no procedure-related severe adverse events or mortality.

Conclusions: Bronchoscopy after allo-HSCT is a safe and clinically informative procedure that frequently provides actionable diagnostic information. BALF lymphocyte proportion and LDH levels may help guide corticosteroid treatment decisions. Even in the post-allo-HSCT setting, bronchoscopy is valuable for addressing pulmonary complications with minimal risk.

COLD AGGLUTININ SYNDROME FOLLOWING ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Trym Døviken[1], *Nils Morten Leknes*[2], *Anders Vik*[2], *Malu Lian Hestdalen*[1], *Tor Henrik Tvedt*[1]
[1]*Oslo University Hospital, Oslo, Norway,* [2]*Tromsø University Hospital, Tromsø, Norway*

Background: The diagnosis and treatment of autoimmune and alloimmune hemolysis in the post-transplant setting is challenging due to the lack of standardized diagnostic criteria and interference in blood samples caused by factors such as ABO incompatibility, as well as chronic mild hemolysis secondary to medications and microangiopathy. The following case presentation illustrates the challenges in accurate diagnosis and classification of AIHA.

Methods: A 36-year-old female underwent myeloablative allogeneic transplantation with a peripheral blood stem cell graft from a male, ABO-matched, 10/10 HLA-matched unrelated donor. GVHD prophylaxis included Thymoglobulin©, Fresenius, 4 mg/kg, cyclosporin, and methotrexate. The early post-transplant course was largely uneventful, except for mild acute graft-versus-host disease of the skin.
At three months post-transplant, donor chimerism remained at 99% for myelod cells and 85% for T cells. There were no cytopenias, and no CMV- og EBV-reactivation. The immune reconstitution showed CD3 counts of 839 x 10^6/L, CD4 counts 223 x 10^6/L, CD8 counts 600 x 10^6/L and CD19 223 x 10^6/L and there were normal levels of IgG and IgM.

Results: From day +120, the patient was treated on an outpatient basis with a five-day course of nirmatrelvir/ritonavir for SARS-CoV-2 infection, and admitted at day +142 with anemia, suppressed haptoglobin, elevated LDH and bilirubin, with normal free hemoglobin and no hemoglobinuria (Table 1). The blood smear revealed spherocytes, no red cell agglutination, and no schistocytes. The direct antiglobulin test (DAT) was strongly positive for C3d, while the cold agglutination titer was 1:16. Antibody screening (IAT), a test which reveals the presence of antibodies in the patient serum targeting potential donor red blood cells, showed agglutination in all tested cells at room temperature, which resolved with strict handling of the sample at 37°C.
The patient was transfused using a blood warmer, and treatment with prednisolone (1 mg/kg) was initiated. Due to no increase in hemoglobin levels (Figure 1), daily therapeutic plasma exchange (TPE) was started. After three days of TPE, with no improvement in hemolysis, treatment with the C5 inhibitor eculizumab was initiated at day+146. Within a

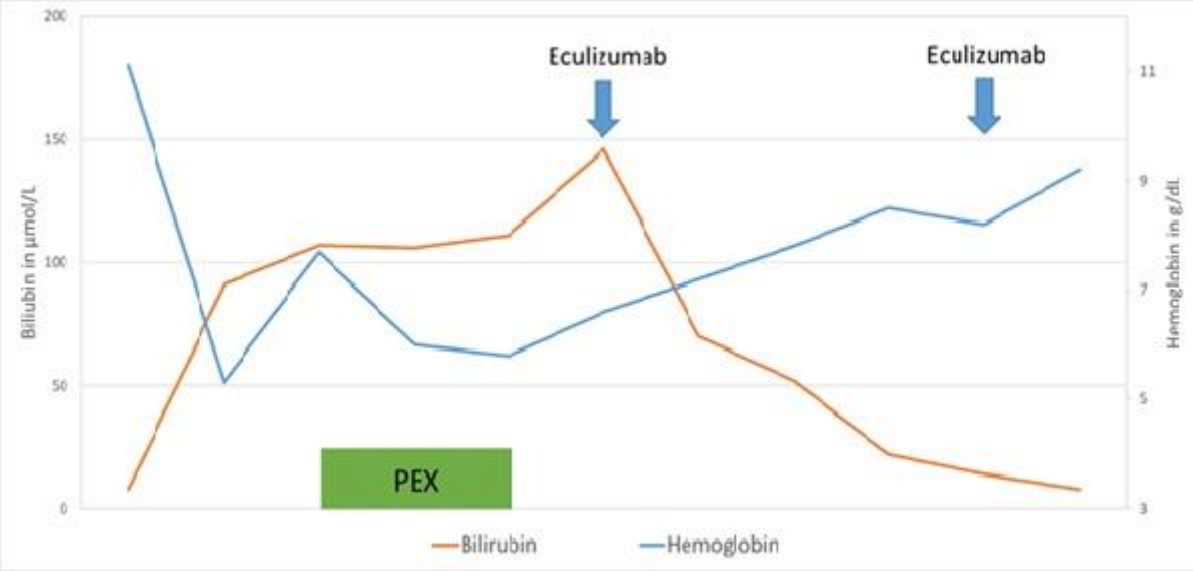
few days, hemoglobin increased and the bilirubin dropped to normal range (Figure 1). By six days, the LDH, reticulocytes and haptoglobin were within normal range. A second dose of eculizumab was administered on day +152. Hemoglobin levels gradually normalized, and no further hemolytic episodes have occurred.
Deep frozen serum harvested prior to commencing TPE was analyzed at a reference laboratory to specify the type of AIHA. The IAT was again positive against all tested cells at room temperature, and anti-I panel was negative. Cold antibody-screening was negative.

Table 1

Day post HSCT	Day AIHA	Hemoglobin (g/dL)	Reticulocytes (x10^9/L)	Leukocytes (x10^9/L)	LDH (U/L)	Bilirubin (micromol/L)	Haptoglobin (g/L)	CRP (mg/L)	C3 (g/L)	C4 (g/L)
+120	-23	11,1		4,5	154	8		< 5		
+128	-15	11,1		3,5	152	8		< 5		
+142	1	5,3	33	9,5	281	91		6	0,85	0,17
+143	2	7,7		11,5	350	107		8		
+144	3	6,0		17,9	225	106		< 5		
+145	4	5,8	169	13,5	211	111		< 5	0,34	0,06
+146	5	6,6	212	7,0	189	146		< 5		
+147	6	7,2	191	5,1	226	70	< 0,1	6	0,66	0,12
+148	7	7,8	201	4,9	242	52	< 0,1	< 5		
+149	8	8,5	162		249	22	< 0,1	< 5	1,01	0,21
+152	11	8,2	89	3,0	204	14	0,6	< 5	1,01	0,27

+159	18	9,2	86	3,2	154	8	0,7	< 5	0,82	0,21
+166	25	10,2	56	4,2	130	7	0,8	< 5	0,89	0,20

Figure 1



Conclusions: This case highlights the challenges of accurately classifying AIHA, particularly after transplantation, where interfering antibodies may obscure serological findings and complicate therapeutic decision-making. Laboratory findings of pan-agglutination at room temperature resolving with heating, together with C3d deposition on red blood cells, supported cold agglutinin syndrome. The rapid response to C5 inhibition suggests that complement-targeted therapy may be a viable option in selected treatment-refractory patients.

Disclosure: Nothing to declare.

P180

IMPACT OF NUTRITIONAL STATUS IN THE POPULATION OF PATIENTS UNDERGOING ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION ON TREATMENT OUTCOMES – VALIDATION OF NUTRITIONAL ASSESSMENT TOOLS

Patrycja Mensah-Glanowska[1,2], *Katarzyna Skóra*[1], *Marta Szostek*[1], *Edyta Stanek*[2], *Mateusz Kubarek*[2], *Beata Piątkowska-Jakubas*[1,2]

[1]Jagiellonian University Medical College, Krakow, Poland, [2]University Hospital in Krakow, Krakow, Poland

Background: Allogeneic hematopoietic stem cell transplantation (allo-HSCT) is a key therapeutic modality for patients with hematologic malignancies. Although numerous studies suggest that malnutrition adversely affects post-transplant outcomes, no validated nutritional assessment tool reliably predicts prognosis in allo-HSCT recipients. This study aimed to evaluate the impact of nutritional status on clinical outcomes in hemato-oncology patients undergoing allo-HSCT using traditional body mass index (BMI) assessment as well as the Nutritional Risk Index (NRI) and the Prognostic Nutritional Index (PNI).

Methods: A retrospective analysis was conducted in 166 adult patients who underwent allo-HSCT at the Bone Marrow Transplant Unit, Department of Hematology, Jagiellonian University Medical College, between 2015 and 2018. Nutritional status was assessed using BMI, NRI, PNI, and serum albumin levels at three time points: admission, day +30, and day +60–90 post-transplantation. Clinical outcomes were evaluated during a 2-year follow-up period. Patients were stratified into subgroups with better or worse nutritional status according to each indicator. Changes in nutritional parameters were analyzed using Student's t-test and the Wilcoxon signed-rank test. The impact of nutritional status on outcomes was assessed using Cox proportional hazards regression and the Cox-Mantel test, and overall survival (OS) and disease-free survival (DFS) were evaluated using Kaplan-Meier analysis.

Results: Nutritional status deteriorated significantly following allo-HSCT across all assessed parameters. Median BMI declined from 25.3 kg/m² at admission to 23.8 kg/m² at day +30 and 23.0 kg/m² at day +60-90. Median NRI decreased from 114.8 at admission to 105.8 at day +30 and 103.9 at day +60-90, with a growing proportion of patients crossing the clinically relevant cutoff of 97.5. Median PNI dropped markedly from 49.7 to 43.6 by day +30 and remained low thereafter, while serum albumin declined from 4.4 g/dL at admission to 4.0 g/dL post-transplant, accompanied by a significant increase in hypoalbuminemia. Hypoalbuminemia at admission independently predicted inferior overall survival (OS; HR = 4.24, p = 0.01) and disease-free survival (DFS; HR = 3.44, p = 0.02). Albumin remained prognostically significant at day +30 and day +60-90 (HR ≈ 2.0, p = 0.04). Two-year OS was 70.5% in patients with albumin ≥3.5 g/dL versus 44.4% in hypoalbuminemic patients (p = 0.04). NRI <97.5 and PNI below ROC-derived cutoffs were associated with significantly worse OS and DFS at later time points (p = 0.05), with early divergence of survival curves. In contrast, BMI showed no association with OS or DFS at any time point. 2-year OS was approximately 65-70%, and DFS 55-60%.

Conclusions: Allo-HSCT is associated with a significant decline in nutritional status, regardless of the assessment method used. Serum albumin concentration is a strong and consistent predictor of both OS and DFS. The demonstrated prognostic value of NRI and PNI supports their clinical use as complementary nutritional assessment tools in allo-HSCT. The most striking finding of this analysis is that albumin may serve as a simple, widely accessible prognostic marker for transplant outcomes. In contrast, BMI assessed at any time point did not correlate with survival and appears unsuitable for risk stratification in allo-HSCT recipients.

Disclosure: Nothing to declare.

P181

MELPHALAN-INDUCED INTESTINAL MUCOSITIS IN HEMATOPOIETIC STEM CELL TRANSPLANT: RAPID RESPONSE TO SHORT-COURSE ORAL BUDESONIDE

Elias Tayar[1], *Samip Master*[2,3,1], *Gloria Obi*[2,4], *Audrey Scholoff*[5,6], *George Carrum*[5,6], *Rammurti Kamble*[2,4,1]
[1]*HCA Houston Healthcare Clear Lake, Webster, United States of America (the),* [2]*Texas Oncology, Webster, United States of America (the),* [3]*Deke Slayton Cancer Center, Webster, United States of America (the),* [4]*Sarah Cannon Research Network, Webster, United States of America (the),* [5]*Baylor College of Medicine, Houston, United States of America (the),* [6]*Houston Methodist Hospital, Houston, United States of America (the)*

Background: High-dose melphalan (HDM) is widely used as conditioning for autologous hematopoietic stem cell transplant (ASCT), particularly in multiple myeloma, but it frequently causes severe gastrointestinal mucositis. Approximately 30–40% of patients develop grade III–IV diarrhea, which usually resolves after neutrophil engraftment. However, persistent diarrhea beyond 24 hours post-engraftment leads to significant morbidity, electrolyte imbalances, and prolonged hospitalization. Currently, there is no established therapy once supportive measures fail.

Methods: We retrospectively analyzed patients undergoing ASCT with melphalan-based conditioning who developed grade III–IV diarrhea persisting > 24 hours after engraftment. Infectious etiologies were excluded by stool cultures and PCR testing. Patients received oral budesonide (3–9 mg/day) in addition to standard supportive measures. Clinical outcomes included time to diarrhea improvement, budesonide duration, hospital discharge timing, and adverse events.

Results: Twenty patients met inclusion criteria (median age 66 years, range 44–74). Diagnoses included multiple myeloma (n = 14), lymphoma (n = 5), and T-cell Acute Lymphoblastic Leukemia (n = 1). Melphalan doses were 200 mg/m² (n = 11) or 140 mg/m² (n = 9). Budesonide was started a median of 2 days after engraftment (range 0 to +11); six patients began 1–4 days earlier. Diarrhea improved in 19 of 20 patients (95%)—typically within 1 day (range 1–7)—with a median treatment duration of 2 days. Median time to hospital discharge after starting budesonide was 2 days (range 1–7). No adverse effects, delayed engraftment, or infections were observed.

Table 1. Clinical characteristics and outcomes of patients treated with oral budesonide for persistent melphalan-induced diarrhea

Variable	Findings
Patients (n)	20

Median age, years (range)	66 (44–74)
Sex (M/F)	10 / 10
Underlying diagnosis	MM (n=14); Lymphoma (n=5); T-ALL (n=1)
Melphalan dose	200 mg/m² (n=11); 140 mg/m² (n=9)
Median day of neutrophil engraftment (range)	+12 (9–18)
Timing of budesonide initiation	Median +2 days post-engraftment (–4 to +11)
Budesonide dose	6–9 mg/day (3 mg BID–TID)
Median duration of therapy (range)	2 days (1–13)
Clinical response	19/20 (95%) improved; median 1 day (1–7) to resolution
Median time to discharge post-budesonide (range)	2 days (1–7)

Conclusions: Short-course oral budesonide resulted in rapid and sustained resolution of severe melphalan-induced diarrhea, with excellent tolerability and no infectious or hematologic complications. By exerting a potent local anti-inflammatory effect with minimal systemic exposure, budesonide represents a safe, practical intervention that may reduce morbidity, hospitalization duration, and healthcare cost in transplant recipients. Prospective trials are warranted to validate its role in managing chemotherapy-related gastrointestinal toxicity.

Disclosure: All Authors have **nothing to declare**. The study received **no external funding or industry support**. All data were collected as part of routine clinical care.

P182

IMPACT OF THERAPEUTIC PLASMA EXCHANGE ON IMPROVEMENT OF ERYTHROID ENGRAFMENT IN MAJOR INCOMPATIBLE AB0-GROUP AFTER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION: A SINGLE-CENTER ANALYSIS

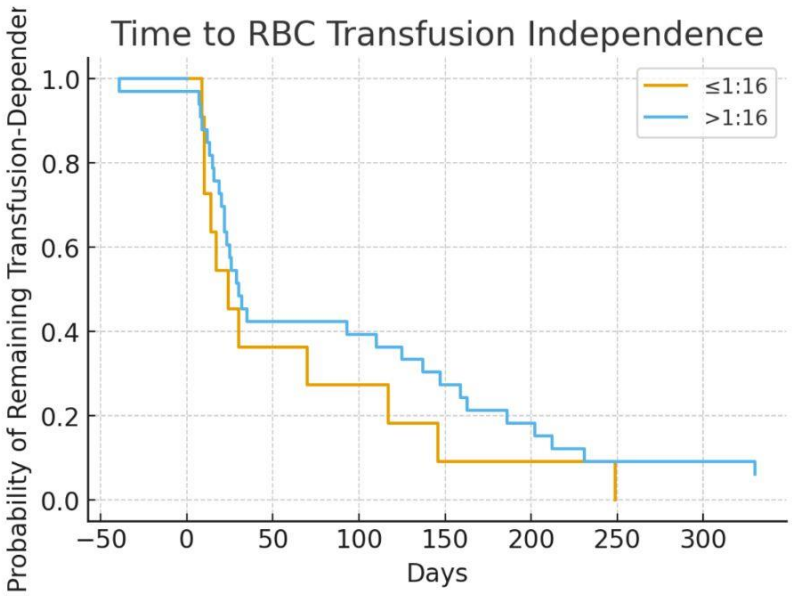
Maria Caterina Mico'[1], *Giorgia Policastro*[1], *Tiziana Moscato*[1], *Filippo Antonio Canale*[1], *Virginia Naso*[1], *Gaetana Porto*[1], *Barbara Loteta*[1], *Andrea Rizzuto*[1], *Marta Pugliese*[1], *Alfonso Trimarchi*[1], *Erica Bilardi*[1], *Massimo Martino*[1]
[1]*Grande Ospedale Metropolitano Bianchi Melacrino Morelli, Reggio Calabria, Italy*

Background: ABO-incompatible allogeneic hematopoietic stem cell transplantation (allo-HSCT) is increasingly performed, but hemolytic complications, delayed erythroid engraftment

and prolonged red blood cell (RBC) transfusion dependence remain major concerns. Therapeutic plasma exchange (TPE) is widely used to reduce anti-A and anti-B isoagglutinins before graft infusion, but the relationship between post-transplant isoagglutinin titers, anemia duration, transfusion burden and overall survival (OS) is poorly defined.

Methods: We retrospectively analyzed 44 consecutive patients undergoing major ABO-incompatible allo-HSCT at our center (CTMO – RC, Italy) between January 2020 and June 2025, allo of whom received pre-transplant TPE (1–3 procedures). Anti-A1 and anti-B isoagglutinin titers were measured before and after TPE. OS was calculated from transplant to death or last follow-up. Anemia duration was defined as the time from transplant to first documented hemoglobin (Hb) >8 g/dL. RBC transfusion dependence was defined as the interval between the first and last RBC transfusion occurring on or after the day of transplant. Kaplan–Meier curves were generated for OS, time to Hb >8 g/dL and time to transfusion independence, and patients were compared according to post-TPE anti-A/B isoagglutinin titers, focusing on (I) IgM/IgG ≤1:16 vs >1:16 and (II) IgM ≥1:128 vs <1:128. All TPE procedures were well tolerated, and no side effects were reported.

Results: Median age at transplant was 56,5 years, and the majority of patients had acute mieloid leukemia (43,2%), acute lymphoblastic leukemia (18,2%) and myelodysplastic syndrome (11,4%). With a median follow-up of approximately 1.8 years for survivors, estimated OS was 75% at 1 year and 68% at 2 years. Post-transplant anemia (Hb <8 g/dL) was common; median anemia duration was 20 days (IQR 13–39), with a minority experiencing prolonged anemia ≥90 days. Overall, 93% of patients required at least one post-transplant RBC transfusion, with a median transfusion period of 24 days (IQR 10–135) (figure 1). Patients achieving low post-TPE anti-A/B IgM/IgG titers (≤1:16) showed a shorter median duration of anemia (14 days) compared with those with residual titers >1:16 (approximately 3–4 weeks). A similar trend was observed for time to RBC transfusion independence, with shorter transfusion periods in patients with lower post-TPE titers. When stratified by a higher cut-off (post-TPE IgM ≥1:128 vs <1:128), both anemia duration and transfusion exposure tended to be longer in the high-titer group, although differences did not reach statistical significance in this limited cohort. In our population, more effective antibody reduction (lower post-TPE titers) was associated with faster hematologic recovery and a reduced RBC transfusion burden. OS did not differ significantly across titer strata. No infectious complications due to TPE have been documented.



Conclusions: In this small single-center cohort, pre-transplant TPE for major ABO incompatibility was associated with a shorter duration of post-transplant anemia and earlier RBC transfusion independence. The advantage of using TPE in the setting of ABO incompatibility lies in the absence of infectious complications, which may occur with other procedures used for the same purpose (e.g Rituximab). TPE therefore represents a safe and effective strategy for managing ABO incompatibility, minimizing infectious risk while preserving transplant feasibility.

EARLY POST-TRANSPLANT EOSINOPHILIC GASTROENTERITIS IN TWO ALLOGENIC HSCT RECIPIENTS

Claudia Mosquera Rubal[1], *Carlos De Miguel*[1], *Isabel Sanguino*[1], *Greissy Vazquez Benitez*[1], *Ana Belen Bocanegra*[1], *Guiomar Bautista*[1], *Jose Luis Calleja*[1], *Clara Salas*[1], *Rafael Duarte Palomino*[1]
[1]*Hospital Universitario Puerta de Hierro Majadahonda, Madrid, Spain*

Background: Eosinophilic gastroenteritis (EGE) is an uncommon inflammatory disorder characterized by gastrointestinal symptoms and marked eosinophilic infiltration of the gut (≥20 eosinophils per high-power field, HPF). Gastrointestinal (GI) complications are frequent after allogeneic hematopoietic stem cell transplantation (allo-HSCT), but EGE seems exceptionally rare, with only a few histologically confirmed cases reported to date.

Methods: We retrospectively reviewed two cases of EGE in allo-HSCT recipients, identified as part of a prospective protocol in our center that systematically performs upper and lower gastrointestinal tract biopsies in all allo-HSCT recipients with GI symptoms and potential GVHD. Clinical, laboratory, endoscopic, histopathological data and therapeutic management and outcomes are summarized descriptively.

Results: Case 1: A 58-year-old woman on day +54 after an HLA-matched related donor (MRD) allo-HSCT for AML was admitted with a 10-day history of nausea, vomiting, and diarrhea associated with pronounced eosinophilia (31.3×10^3/μL). Gastroscopy and rectosigmoidoscopy revealed dense eosinophilic infiltrate in the esophageal, gastric, and duodenal lamina propia and submucosa biopsies (up to 26 eos/HPF), findings consistent with EGE (Image 1A-1B), but without features typical of GVHD. Rectal biopsies showed eosinophilic infiltration damaging colonic crypts (Image 1C). A lactose-free diet was initiated and continues to this day, leading to clinical improvement and complete resolution of eosinophilia and GI symptoms within 2 weeks. Serum IgE levels were within the normal range (157 KU/L), and an allergy work-up showed negative results.
Case 2: A 62-year-old man on day +50 after a MRD allo-HSCT for TP53-mutated AML presented with nausea, vomiting, and diarrhea associated with marked eosinophilia in peripheral blood (9.6×10^3/μL). Gastroscopy and rectosigmoidoscopy showed only macroscopic signs of diffuse gastritis but systematic biopsies of the gastrointestinal tract revealed not only eosinophilic gastritis and duodenitis but also a diffuse eosinophilic infiltrate involving the colorectal mucosa and submucosa, with no evidence of GvHD. Microbiological studies were negative. The patient's symptoms resolved along with the peripheral eosinophilia in less than 2 weeks with the avoidance of dairy products and the administration of omeprazole (20 mg/day) without corticosteroid therapy. Eight months lather the patient remains asymptomatic maintaining a lactose-free diet.

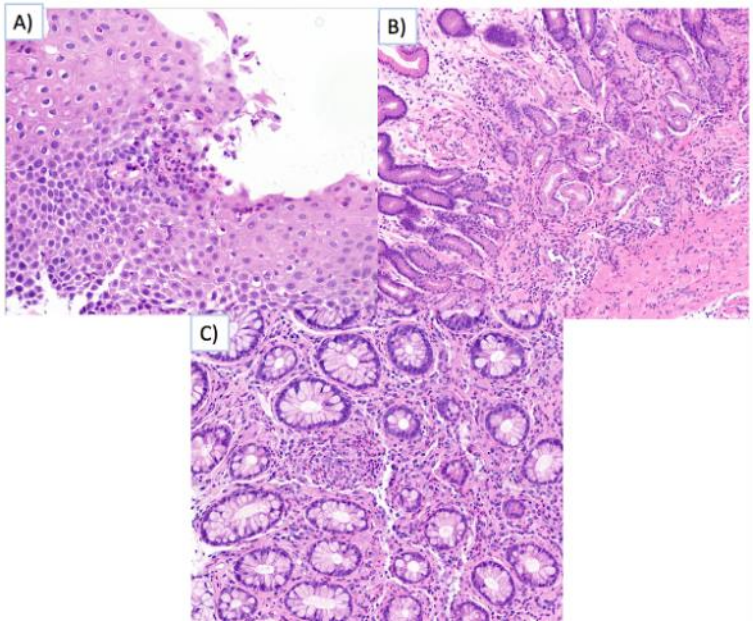

Image 1: A) Esophageal mucosa showing squamous epithelium with the presence of

eosinophils forming microabscesses, along with epithelial spongiosis and desquamation (400X). B) Gastric mucosa demonstrating a diffuse eosinophilic infiltrate within the lamina propia, occasionally permeating the glandular epithelium (400X). C) Colorectal mucosa with abundant eosinophils in the lamina propia permeating and disrupting the colonic crypts (400X).

Conclusions: EGE is a rare GI complication after allo-HSCT that may mimic other transplant complications such as infectious colitis and GvHD. Systematic endoscopic and histologic evaluation was critical to establishing the diagnosis and avoiding unnecessary immunosuppression. Both patients showed excellent response with a lactose-free diet, behaving as if they had developed lactose intolerance. Immune-mediated complications can be transferred from the donor to the allo-HSCT recipient. Histopathological findings in this clinical setting may also support a predominantly allergic etiology, although the physiopathology behind this entity remains poorly understood, highlighting the need for further studies to clarify its mechanisms and guide optimal management.

Disclosure: No conflict of interest declared.

OPTIMIZED TREATMENT OF HEMORRHAGIC CYSTITIS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION WITH ALLOGENEIC PLATELET-RICH PLASMA

Tatsiana Talako[1], *Mikhail Uss*[1], *Oksana Nechay*[1], *Alena Dziuba*[1], *Oksana Morozova*[1], *Yuri Strongin*[1], *Tamara Vasilyeva*[1], *Hanna Melnikovich*[1], *Aliaksandr Avadok*[1], *Volha Levandovskaya*[1], *Mikhail Potapnev*[2], *Nataly Milanovich*[1], *Anatoly Uss*[1]
[1]*Minsk Scientific and Practical Center for Surgery, Transplantology and Hematology, Minsk, Belarus,* [2]*Republican Scientific and Practical Center for Transfusiology and Medical Biotechnology, Minsk, Belarus*

Background: Hemorrhagic cystitis (HC) is a common complication after allogeneic hematopoietic stem cell transplantation (alloHSCT). Severe cases of HC can persist and not improve due to worsening acute graft-versus-host disease (GvHD) or various viral infections. Platelet-rich plasma contains many growth factors and cytokines that influence inflammation and tissue regeneration.

Methods: We present 4 cases of late-onset HC treated with addition of allogeneic platelet-rich plasma (alloPRP) to the treatment of HC. The patients received alloHSCT from matched unrelated donors (n=3) and from sibling (n=1) with myeloablative conditioning regimen (BuCy). Two patients developed acute GvHD. All patients received conservative treatment of HC: hyperhydration, alkalization, analgesics, platelet transfusions, bladder irrigation by urinary catheter (with normal saline, repeated syringe aspiration, aminocaproic acid) and still had frequent and painful urination, haematuria with blood clots, proteinuria. Visual analog scale was used for pain assessment, urine analysis and ultrasound examinations of the bladder were done.

Results: Patient 1: 42 y.o. female with chronic myeloid leukemia developed HC at day +40 after alloHSCT. She received conservative treatment of HC with partial effect and had recurrent episode of HC at day +80. AlloPRP was added to the treatment: 8 intravesical instillations (every 48 hours) with an exposure time of 30 min. After alloPRP treatment she showed a decrease in the bladder wall thickness (from 7 mm to 4 mm) and proteinuria (from 2.18 to 1.85 g/L).
Patient 2: 42 y.o. male with acute myeloblastic leukemia (AML) presented with HC at day +32 after HSCT. He received 5 intravesical instillations of alloPRP (every 72 hours) along with conservative treatment of HC. After alloPRP treatment the thickness of the bladder wall has reduced from 8.4 mm to 5.8 mm, proteinuria decreased from 2.8 to 0.36 g/L.
Patient 3: 47 y.o. female with AML developed HC at day +46 after HSCT. She received 7 intravesical instillations of alloPRP (3 instillations every 24 hours, then 4 – every 72 hours). A reduction in the thickness of the bladder wall (from 10 mm to 6 mm) and proteinuria (from 3.69 to 1.04 g/L) was achieved after alloPRP treatment.
Patient 4: 30 y.o. female with post-essential thrombocythemia myelofibrosis experienced HC at day +59 after HSCT. She received 3 intravesical instillations of alloPRP (every 24 hours). After alloPRP treatment we detected a decrease in the thickness of the bladder wall from 6.5 mm to 5.3 mm and in proteinuria (from 5.89 to 0.3 g/L).
All patients experienced a decrease in pain intensity (the mean is by 27.5 mm), in urination frequency and disappearance of the blood clots in urine. The degree of haematuria didn't change after alloPRP instillations and remained at the level of 200 Rbc/ul. Subsequently, we obtained positive PCR test results for BK polyomavirus in the blood and urine of all patients.

Conclusions: Intravesical alloPRP instillations reduce the bladder wall thickness, pain intensity and have positive effects on the other clinical manifestations of HC. The effectiveness of post-HSCT HC therapy can be improved by adding alloPRP to the treatment strategy.

Disclosure: Nothing to declare

P185

POST-TRANSPLANT PURE RED CELL APLASIA: A SINGLE CENTER EXPERIENCE WITH PLASMA EXCHANGE AND HIGH DOSE ERYTHROPOIETIN

Ambra Taglietti[1], *Denise Maravalle*[1], *Maria Chiara Merlo*[1], *Catia Bigazzi*[1], *Piero Galieni*[1]
[1]*Hematology and Cell Therapy, P.O. C. & G. Mazzoni, Ascoli Piceno, Italy*

Background: Post-Transplant Pure Red Cell Aplasia (PT-PRCA) is a rare complication of ABO incompatible allogeneic hematopoietic stem cell transplants (HSCT). It is believed to be mediated by residual recipient isohemagglutinins (IHA), which hinder donor erythroid precursor development, inducing hyporegenerative anemia. Prolonged PT-PRCA is associated to heavy transfusion requirements and iron overload. Differential diagnoses include infections, hematologic disease relapse, graft failure, autoimmune hemolytic anemia, and thrombotic microangiopathy. Given the possibility of spontaneous recovery, PT-PRCA criteria

for treatment and standard of care have yet to be established. Therapeutic approaches include immunosuppression/immunomodulation (steroids, cyclosporine A, anti-B cell strategies as Rituximab, and anti-plasma cell treatments as Bortezomib and Daratumumab); erythropoiesis enhancement (recombinant human erythropoietin [rhEPO], thrombopoietin mimetics); and eradication of residual IHA (immunoglobulins, plasma exchange [PEX]). We report our experience with 6 PT-PRCA patients who underwent treatment with PEX and high dose rhEPO.

Methods: Single center retrospective observational study at the Hematology and Cell Therapy Unit of the Mazzoni Hospital in Ascoli Piceno. All patients signed an informed consent form. PT-PRCA was defined as persistence of anemia and reticulocytopenia, and isolated erythroid hypoplasia/aplasia in an otherwise normal bone marrow. Threshold for IHA titer was set at 1:64. PT-PRCA treatment regimen comprised 8 biweekly PEX sessions and high dose rhEPO (80.000 IU) administration 3 days after each PEX procedure.

Results: We report the data from 6 patients who received HSCT from July 2020 to March 2023. The patients, transplant and PT-PRCA characteristics are reported in Table 1. 5/6 patients were diagnosed with acute myeloid leukemia, 1/6 had myelodysplastic syndrome. All patients received myeloablative conditioning and underwent ABO mismatched HSCT. All patients developed transfusion-dependent PT-PRCA and underwent specific treatment with PEX and high dose rhEPO. 2/6 patients also received Rituximab prior to PEX initiation. All patients obtained a complete response, with transfusion independency and normalization of hemoglobin values. Median response time from treatment initiation was 90 days.

P186

LEVETIRACETAM FOR THE PREVENTION OF BUSULFAN-INDUCED SEIZURES IN HEMATOPOIETIC CELL TRANSPLANTATION

Yongjune Lee[1], *Sungnam Lim*[1], *Seonyang Park*[2]
[1]*Inje University College of Medicine, Haeundae Paik Hospital, Busan, Korea (the Republic of),*
[2]*Haeundae Paik Hospital, Busan, Korea (the Republic of)*

Background: High dose busulfan (Bu) is widely used in conditioning regimens for patients undergoing hematopoietic stem cell transplantation (HSCT). Since seizure is a major complication of high-dose Bu, antiepileptic prophylaxis, such as phenytoin was given. As various anticonvulsant drugs have been reported, we conducted a retrospective analyze the preventive effects and adverse events with levetiracetam alongside intravenous Bu.

Methods: We retrospectively evaluated the levetiracetam prophylaxis during high dose Bu conditioning between July 2019 and October 2025. Levetiracetam was administered at ad dose of 500 mg twice daily beginning 12 hours to Bu through 24 hours after the last Bu dose. Busulfan-based conditioning regimens included: BuCy, BuFlu, BuFluATG.

Results: A total of 93 patients were enrolled in this study, 56 (60.2%) were male. The median age at HSCT was 52 years (range, 18 to 75). Seventy-two (77.4%) had acute myeloid leukemia/myelodysplastic syndrome, ten (10.8%) had acute lymphoblastic leukemia, four (4/3%) had lymphoma, and seven (7.5%) had myeloproliferative neoplasm. The seizure prevention rate was 100% for levetiracetam and there was no significant drug-related adverse effect.

Conclusions: Levetiracetam is considered useful as a preventative drug against seizure during intravenous Bu infusion because it is easy to administer and there was no drug-related adverse effect.

Disclosure: Nothing to declare.

P187

PATTERNS AND PREDICTORS OF ORAL MUCOSITIS FOLLOWING HAEMATOPOIETIC STEM CELL TRANSPLANT (HSCT): A PROSPECTIVE SINGLE-CENTRE EXPERIENCE

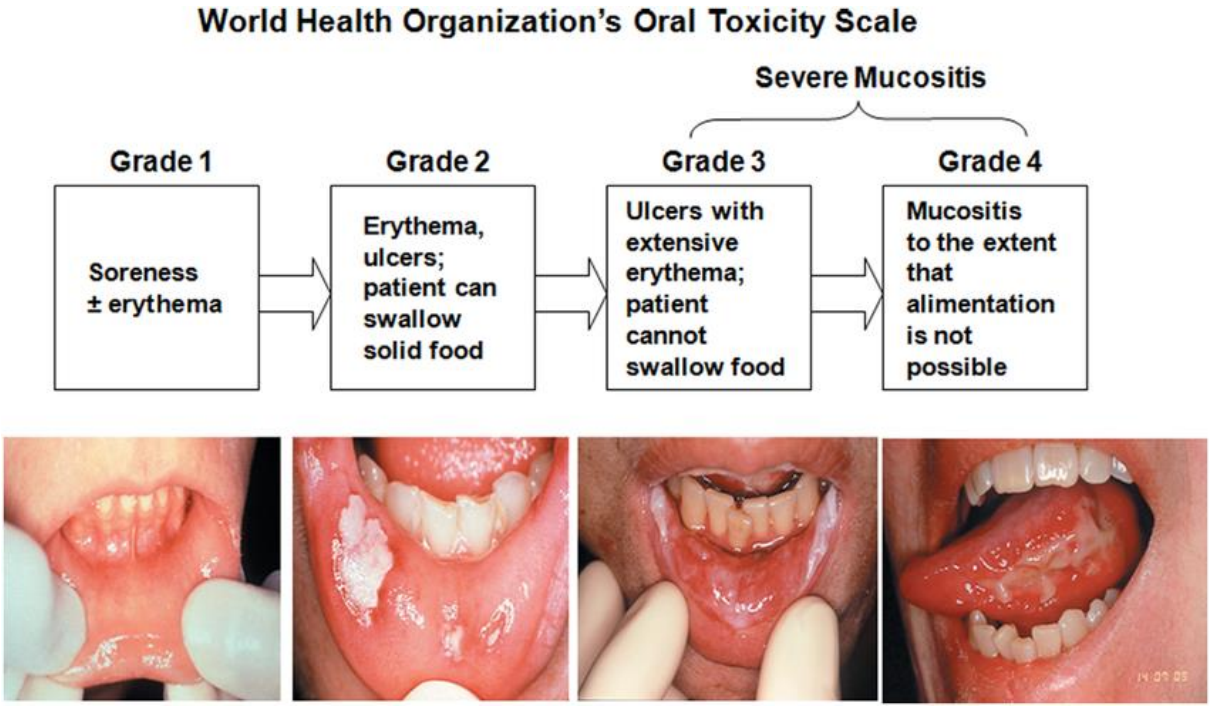
N. Kaushik[1], *Sanjukta Rao*[1], *Veronica Lobo*[1], *Sushma Baishya*[1], *Michael Pais*[1], *T. V. Ruthvik*[1], *R. Ganapathi*[1], *Cecil Ross*[1], *Chaitanya H Balakrishnan*[1], *Seetharam Anandram*[1]
[1]*St John's Medical College Hospital, Bengaluru, India*

Background: Oral mucositis (OM) is an almost universal and disabling complication of transplant arising from cytotoxic injury of conditioning regimen to the oral mucosa that is particularly susceptible to injury. It contributes to significant pain, nutritional compromise, infectious risk and prolonged hospital stay. As most other acute complications following transplant are life-threatening, oral mucositis is often overlooked as there is no mortality from this seemingly innocuous complication. OM adds abundantly to the morbidity from transplant. Prospective data on this important post HSCT adverse event remain scarce. We aimed to assess the incidence and severity of oral mucositis following HSCT, to compare outcomes across transplant type and conditioning intensity, and to explore the association of supportive and preventive strategies, including oral cooling, with mucositis severity.

Methods: This prospective observational study included adult patients undergoing HSCT between the study period. Oral mucositis was graded using WHO criteria (Figure). Severe mucositis was defined as grade ≥3. Demographic and transplant-related details, conditioning intensity, body mass index (BMI), analgesic requirement, and preventive measures were recorded. Oral cooling was used as a preventive strategy in selected patients. Categorical variables were compared using Fisher's exact test and continuous variables using the Mann–Whitney U test. A p value <0.05 was considered statistically significant.

Parameter	**Comparison / Group**	**Key findings (severe OM) n, (%)**	**P value**
Incidence of severe OM (Grade ≥3)	Overall	12/29 (41.4%)	-
Transplant Type	Auto n = 15 Allo n =14	7/15 (46.7%) 5/14 (35.7%)	0.71
Conditioning intensity (Allo only)	MAC n = 5 RIC n = 9	3/5 (60%) 2/9 (22.2%)	0.27
Onset of OM (median days)	MAC vs RIC Auto vs Allo	5 vs 5 3.5 vs 5	0.75 0.53
Resolution of OM (median days)	MAC vs RIC Auto vs Allo	14 vs 13 12.5 vs 14.5	0.75 0.60

BMI (median kg/m^2)	Grade ≥3 vs < 3 OM	23.37 vs 25.55	0.43
Preventive strategy - Oral cooling	n = 4	3/4 severe OM (75%)	not significant



Results: A total of 29 patients were included in the final analysis. The median age was 49.5 years (range 21–77 years), and 65.5% were male. Fifteen patients underwent autologous HSCT and 14 underwent allogeneic HSCT. Severe oral mucositis (grade ≥3) occurred in 12 patients (41.4%). The incidence of severe mucositis did not differ significantly between autologous and allogeneic transplantation (46.7% vs 35.7%, p = 0.71). Patients receiving myeloablative conditioning showed a higher incidence of severe mucositis compared to those receiving reduced intensity conditioning (60% vs 22.2%), although this difference was not statistically significant (p = 0.27).
The median onset and resolution of mucositis were comparable between myeloablative and reduced intensity conditioning, as well as between autologous and allogeneic transplantation. Opioid analgesic requirement was observed exclusively in patients with severe mucositis, reflecting greater symptom burden, though this association did not reach statistical significance (p = 0.16). Median BMI was lower in patients with severe mucositis compared to those with non-severe mucositis, without statistical significance (p = 0.43). Four patients received oral cooling as a preventive measure, 3 of whom developed severe mucositis, suggesting that oral cooling system did not appear to reduce the incidence of severe oral

mucositis; however, interpretation is limited by very small numbers and potential confounding.

Conclusions: Oral mucositis remains a common complication following HSCT. A substantial proportion of patients develop severe disease requiring opioid analgesia. No statistically significant predictors of severe mucositis were identified in our study. However conditioning intensity and BMI appear to play a role. The hypothesis that oral cooling systems may mitigate OM severity was not supported in our limited data. Larger studies with systematic documentation of preventive strategies are needed to better define risk factors and alleviation strategies for oral mucositis in HSCT.

Disclosure: None to disclose.

P188

ENGRAFTMENT SYNDROME IN AUTOLOGOUS HAEMATOPOIETIC STEM CELL TRANSPLANTATION: INCIDENCE, ASSOCIATED FACTORS AND CLINICAL IMPACT

Alejandro Lada Colunga[1], Alberto Porro Camarero[1], Macarena Castillo Godoy[1], Ana Pilar González Rodríguez[1], Ana Julia González Huerta[1], Pilar Palomo Moraleda[1], ***Joud Zanabili al Sibai****[1], Soledad González Muñiz[1], Lucia Morais Brais[1], Ángel Ramírez Payer[1], Carmen Loredo Álvarez[1], Laura González Suárez[1], Marco Hernández Martín[1]*
[1]Hospital Universitario Central de Asturias, Oviedo, Spain

Background: Engraftment syndrome (ES) is an inflammatory complication of autologous haematopoietic stem cell transplantation (ASCT) occurring around neutrophil recovery and characterised by non-infectious fever and capillary leak manifestations.

Methods: We performed a single-centre, retrospective study including 130 consecutive ASCT episodes performed between 2023 and 2025. Collected variables included demographics, underlying disease, disease status, number of prior treatment lines, HCT-CI score, conditioning regimen and graft characteristics (CD34+ $\times 10^6$/kg, infused volume and viability). Pre-ASCT laboratory parameters were C-reactive protein (CRP), lactate dehydrogenase, creatinine and platelet count. Variables related to ES were collected according to the Maiolino criteria and included non-infectious fever (≥38ºC without microbiological documentation or response to antimicrobials within ±24 h of engraftment), weight gain >3%, maculopapular rash, non-infectious diarrhoea and non-infectious pulmonary infiltrates. Additional data included CRP and procalcitonin at fever, time to neutrophil recovery, use or withdrawal of filgrastim, steroid treatment, length of stay, ICU admission and day +100 mortality. Statistical analyses were performed using SPSS. Comparisons between ES and non-ES episodes were performed using chi-square or Fisher's exact test for categorical variables and Mann–Whitney U test for continuous variables.

Results: Median age at ASCT was 61 years (IQR 51–66), and 68% of episodes occurred in male patients. Underlying diseases were multiple myeloma (50%), B-cell non-Hodgkin

lymphoma (21%) and other diagnoses (T-cell non-Hodgkin lymphoma, Hodgkin lymphoma, primary CNS lymphoma, amyloidosis [5 cases], plasma cell leukaemia, solid tumours and non-malignant diseases); amyloidosis showed a significantly higher incidence of ES compared with other diagnoses (p≈0.03). Median HCT-CI was 2 (IQR 0–3). Median CD34+ dose was 3.98 ×10⁶/kg (IQR 3.00–5.27), infused volume 408 mL (IQR 288–532) and graft viability 84% (IQR 76–89). Median length of stay was 16 days (IQR 14–19). Clinical ES was diagnosed in 22/130 episodes (16.9%), while 56/130 (43.1%) fulfilled Maiolino criteria. Compared with non-ES episodes, ES was associated with higher pre-ASCT creatinine (p≈0.01) and a trend towards higher HCT-CI (p≈0.08); CD34+ dose (median 4.40 vs 3.93 ×10⁶/kg; p≈0.64) and infused volume (median 442 vs 404 mL; p≈0.29) were similar between groups. ES typically developed around day +10 and was characterised by non-infectious fever (100%), weight gain >3% (~77%), non-infectious diarrhoea (~60%), rash (~33%) and non-infectious pulmonary infiltrates (~25%). CRP at fever was higher in ES (p≈0.01), whereas procalcitonin was comparable. Length of stay was longer in ES (median ~18 vs 16 days; p≈0.02), with no significant differences in ICU admission or day +100 mortality. Among episodes fulfilling criteria but not clinically labelled as ES (35/130; 26.9% of the cohort), an alternative diagnosis was documented in 68.6% and 11.4% improved after filgrastim withdrawal.

Conclusions: In our single-centre ASCT cohort (2023–2025), engraftment syndrome defined by the Maiolino criteria was a frequent complication associated with increased inflammatory response and longer hospitalisation, without a clear impact on early mortality. Amyloidosis appeared to be associated with a particularly high risk of ES.

Disclosure: Nothing to declare.

PROPHYLAXIS WITH DEFIBROTIDE VERSUS EARLY TREATMENT OF SEVERE VOD IN PEDIATRIC ONCO-HEMATOLOGICAL PATIENTS: A MONOCENTRIC EXPERIENCE

Ilaria Capolsini[1], Maria Speranza Massei[1], Maria Alessandra Innocente[1], Carla Cerri[1], Maria Elena Latini[2], Giovanni Martino[3], Marco Prestipino[4], Salvatore Messina[5], Simonetta Saldi[6], Laura Marchesini[7], Tiziana Zei[8], Barbara Luciani Pasqua[9], Antonio Pierini[10], ***Katia Perruccio***[11]

[1]*Pediatric Oncology Hematology, Perugia, Italy,* [2]*Radiology, Perugia, Italy,* [3]*Istopathology Section, Perugia, Italy,* [4]*Pediatric Surgery, Perugia, Italy,* [5]*Nuclear Medicine, Perugia, Italy,* [6]*Radiotherapy, Perugia, Italy,* [7]*Anestesiology, Perugia, Italy,* [8]*Graft Processing, Perugia, Italy,* [9]*Transfusion Medicine, Perugia, Italy,* [10]*Perugia Transplant Program, Perugia, Italy,* [11]*Pediatric Oncology Hemathology, Perugia, Italy*

Background: Severe hepatic veno-occlusive disease/sinusoidal obstruction syndrome (VOD/SOS) is a potentially life-threatening complication of hematopoietic stem cell transplantation (HSCT). New EBMT criteria allow to early identify patients at high risk of developing VOD and to early diagnose and treat this toxic seriuous adverse event. This

monocentric report had focused on the role of prophylaxis versus early treatment with Defibrotide in selected very high risk pediatric and young adult patients who received SCT.

Methods: From 01/2018 to 09/2025, in our Center we performed 49 allogeneic transplants in HR acute leukemia patients: 26 from haploidentical donors, 13 from matched unrelated donors (MUD), 10 from identical siblings; and 14 autologous SCT in patients affected by solid tumors, in particular neuroblastoma and Ewing's sarcoma. Patient median age was 9 years (range 1-24). Four patients received a second allo-SCT for acute leukemia relapse (n=1) or graft-failure (n=3), and 3 a second auto-SCT as consolidation therapy for solid tumors, in most cases high risk neuroblastoma.

Results: We observed a total of 10 cases of severe VOD (16%): 3 after allo-SCT (6%), and 7 after auto-SCT (50%). They were 6 males and 4 females, with a median age of 6.5 years (range: 1-22). VOD diagnosis and staging was done according to new EBMT criteria. Prophylaxis with Defibrotide was administered in 5 procedures, 3 allogenic (1 relapsed acute lymphoblastic leukemia, ALL, who had received Inotuzumab Ozogamicin as salvage therapy, and 2 acute myeloid leukemia, AML), and 2 autologous transplantations (for HR neuroblastoma). Defibrotide was started with conditioning regimen at the dosage of 25 mg/Kg/day and suspended after engraftment, in absence of any sign or symptom of VOD; treatment was continued until VOD sign and/or symptoms diseapperance in case of severe VOD diagnosis. In patients who did not received prophylaxis, in case of post-HSCT VOD diagnosis, defibrotide was given at a median day of +14 from graft infusion (range: 11-42 days), always at the dosage of 25 mg/Kg/die for a median of 21 days (range: 10-54 days). Five out of 10 patients who did received prophylaxis, three developed VOD and 2 did not (60% vs 40%). The remaining 5 patients did not received prophylaxis, even if they were considered at very high risk of VOD, and they all developed severe VOD (100%), but they received treatment very early, at the first VOD sign and/or symptom (in particular, platelet refractoriness). All patients recovered from VOD, only one developed multi-organ failure, MOF, but none died for VOD.

Conclusions: We did not observed a significant difference in patients who received Defibrotide prophylaxis compared to patients who received a very early treatment according to new criteria, but we can confirm a trend in improvement incidence and outcome in patients who received defibrotide as prophylaxis instead treatment. Moreover, we observed a very high incidence of severe VOD in patients affected by HR neuroblastoma and Ewing's sarcoma who received Busulfan in the conditioning regimen. In these selected patients, VOD prophylaxis with defibrotide would represent a good strategy to improve outcome.

Disclosure: Nothing to declare.

P190

POSSIBLE ROLE OF FLUDARABINE IN EARLY POST TRANSPLANT CEREBRAL TOXICITY. A SINGLE CENTRE EXPERIENCE

*Stefano Bonfanti[1], Francesca Duca[1], **Elsa Masedu**[1], Silvia Viola[1], Giulia Bassi[1], Paola Perfetti[2], Marilena Fedele[2], Andrea Aroldi[2], Elisabetta Terruzzi[2], Carlo Gambacorti-Passerini[2,1], Matteo Parma[2]*
[1]University of Milano Bicocca, Monza, Italy, [2]Fondazione IRCCS San Gerardo dei Tintori, Monza, Italy

Background: Neurological complications in patients undergoing allogeneic hematopoietic stem cell transplantation (HSCT) represent a clinically significant event, frequently associated with substantial decline in overall health status and quality of life, and often culminating in poor outcomes. These manifestations arise from a broad range of etiologies, including but not limited to iatrogenic injury, infectious processes, vascular events, neurodegenerative conditions, and metabolic disturbances. Based on their temporal onset, neurological complications are conventionally categorized as pre-engraftment, early post-engraftment, and late post-engraftment.

Methods: In this single-center retrospective observational study, we evaluated 7 patients who underwent allogeneic hematopoietic stem cell transplantation between July 2023 and September 2025 at our institution and subsequently developed post-transplant neurological complications.
Among the 7 patients (median age, 63 years), 4 had acute myeloid leukemia—including 1 undergoing a second allogeneic transplant—whereas 1 had B-cell acute lymphoblastic leukemia, 1 T-cell non-Hodgkin lymphoma, and 1 plasmacytic leukemia.
All patients received conditioning regimens containing fludarabine: specifically, 3 received treosulfan–fludarabine, 3 reduced-intensity thiotepa–fludarabine–busulfan (RIC TBF), and 1 full-intensity TBF.
In our cohort, donors included 3 HLA-identical related donors, 2 unrelated registry donors, and 2 haploidentical related donors.
For GVHD prophylaxis, 4 patients received cyclosporine (CSA), methotrexate (MTX), and rabbit anti-thymocyte globulin (ATG); 1 received CSA, tacrolimus, and ATG; and 2 received post-transplant cyclophosphamide, mycophenolate mofetil (MMF), and tacrolimus.

Results: The median onset of neurological symptoms was 45 days after transplantation (range, 14–55). All patients underwent brain MRI and cerebrospinal fluid (CSF) evaluation by lumbar puncture after neurologic symptoms. CSF analysis was positive for HHV-6 (15,000 cp/mL) in only 1 case, while the remaining 6 samples were microbiologically negative.
On imaging, 4 cases were reported as therapy-related leukoencephalopathy, 2 showed multifocal T2/FLAIR hyperintensities, and 1 revealed severe chronic multi-infarctional encephalopathy, all of them markedly worsened compared with the pre-transplant MRI.
All patients received high-dose intravenous methylprednisolone as first-line treatment; in 5 of the 7 cases, therapy was combined with intravenous immunoglobulins (IVIG).
Cyclosporine was discontinued in all patients receiving it as part of GVHD prophylaxis.

Conclusions: At present, 4 patients remain in outpatient follow-up, including one with significant persistent neurological motor deficits, who has shown partial improvement after rehabilitation. The remaining 3 patients died because of these complications. Autopsy was performed in all 3 deceased patients and revealed spongiform leukoencephalopathy in each case.
Radiological and histopathological findings suggest a predominant iatrogenic aetiology, most likely related to fludarabine exposure which is also the common background in all the patients.
Given the small sample size, further studies are required to substantiate this hypothesis.

PAIN MANAGEMENT WITH NARCOTIC INFUSION IN PEDIATRIC HEMATOPOIETIC STEM CELL TRANSPLANTATION: A SINGLE-CENTER RETROSPECTIVE STUDY

Eman Khattab[1], *Rawad Rihani*[1], *Hasan Hashem*[1], *Mayada Abu Shanap*[1], *Dua'A Zandaki*[1], *Shireen Al-Awady*[1], *Anwar Alnassan*[1]
[1]*King Hussein Cancer Center, Amman, Jordan*

Background: Hematopoietic stem cell transplantation (HSCT) offers a potential cure for children with malignant and non-malignant diseases that are otherwise incurable. However, HSCT is associated with multiple comorbidities, and many post-transplant complications are accompanied by significant pain requiring careful assessment and management.

Methods: This retrospective study included pediatric patients who underwent HSCT at the Pediatric HSCT Program at King Hussein Cancer Center (KHCC) between January 2025 and mid-December 2025.

Results:

Side effects	Number of patients
Urinary retention	1
Constipation	1
Pruritus	5
Elevated bilirubin	1
Hallucinations	1

A total of forty-eight patients underwent HSCT during the study period. The majority received allogeneic transplants, with thirty-five patients undergoing allogeneic HSCT.

Thirty-seven patients (77%) required narcotic infusion during their transplant course. The median age was 7 years (range: 1.2–24.1 years). Among these patients, twenty-seven underwent allogeneic HSCT and ten received autologous HSCT.

Malignant diseases were the indication for transplantation in twenty-three patients, including acute lymphoblastic leukemia (n=9), acute myeloid leukemia/myelodysplastic syndrome (n=3), lymphoma (n=4), high-risk neuroblastoma (n=2), and retinoblastoma (n=1). Fourteen patients underwent transplantation for non-malignant conditions, including hemoglobinopathies (n=6), severe aplastic anemia (n=4), and other disorders such as Fanconi anemia, DADA-2 mutation, Wiskott–Aldrich syndrome, and familial hemophagocytic lymphohistiocytosis (n=4).

Pain assessment was conducted using either the Wong–Baker Faces Pain Scale or the Numeric Rating Scale. Oral and anal mucositis was the most common indication for narcotic infusion, occurring in thirty-three patients. Bone pain and cystitis were indications in three patients each.

Narcotic infusions were generally well tolerated. No patients discontinued treatment due to uncontrolled side effects or experienced life-threatening adverse events. Infusion was discontinued in one patient due to tampering with the infusion pump.

Switching from morphine to fentanyl infusion was required in fifteen patients, primarily due to uncontrolled pain (n=9) or pruritus (n=4). Only two patients required the addition of ketamine infusion for refractory pain.

The median time to initiation of narcotic infusion was 5 days post-transplant (range: 2–580 days), and the median duration of infusion was 8 days (range: 3–35 days).

Conclusions: Mucositis was the most prevalent cause of pain during the post-transplant period in pediatric HSCT recipients. Narcotic infusion proved to be a safe and well-tolerated strategy for pain management, with a low incidence of significant adverse effects and no life-threatening complications observed.

Disclosure: I have nothing to declare.

TAKOTSUBO CARDIOMYOPATHY MIMICKING ACUTE CORONARY SYNDROME DURING AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

Audronė Vaitiekienė[1,2], Miglė Kulbokė[1,2], Titas Tiškevičius[1], Asta Senavaitytė[1,2], Egidija Kukarskytė[1], Rima Jūratė Gerbutavičienė[2], Ignas Gaidamavičius[1,2], Martyna Beitnerienė[1,2], Rūta Dambrauskienė[1,2], Milda Rudžianskienė[1,2], Emilija Lidžiūtė[3], Darija Jankauskaitė[3], Rolandas Gerbutavičius[1,2], ***Domas Vaitiekus***[1,2]
[1]*Hospital of Lithuanian University of Health Sciences Kaunas Clinics, Kaunas, Lithuania,* [2]*Lithuanian University of Health Sciences, Kaunas, Lithuania,* [3]*Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania*

Background: Cardiovascular complications during hematopoietic stem cell transplantation (HSCT) are clinically relevant and may be life-threatening, particularly when they mimic acute coronary syndromes. Takotsubo cardiomyopathy (TTC), also known as stress-induced cardiomyopathy, is characterized by transient specific pattern left ventricular systolic dysfunction, electrocardiographic changes, and elevation of cardiac biomarkers in the absence of significant coronary artery disease. Emotional and physical stressors, including oncological treatments and transplantation procedures, are recognized triggers. Early differentiation between acute coronary syndrome and TTC is crucial to guide management and avoid unnecessary invasive procedures.

Methods: A 62-year-old woman was diagnosed with a solitary plasmacytoma of the pubic bone after presenting with right groin pain. Initial treatment followed the VTD regimen (bortezomib, thalidomide, dexamethasone). Due to elevated liver enzymes, thalidomide was discontinued and therapy was adjusted to CYBORDEX (cyclophosphamide, bortezomib, dexamethasone). After five months, the patient was evaluated for autologous HSCT. She had arterial hypertension, no family history of coronary artery disease, and was a non-smoker. Her general condition was good (ECOG-0).
Pre-transplant echocardiography showed preserved left ventricular ejection fraction (LVEF 55%), impaired diastolic relaxation, slightly dilated left atrium, mild valvular insufficiencies, and no pulmonary hypertension. In the absence of contraindications, stem cell mobilization with cyclophosphamide and G-CSF was performed, followed by autologous HSCT with infusion of 3.3×10^6 CD34+ cells/kg.
During transplantation procedure, the patient developed nausea, vomiting, hypotension, and a transient episode of unconsciousness with convulsions. Shortly after the procedure, chest pain occurred. Electrocardiography revealed new diffuse T-wave inversions, and troponin I increased from 0.07 µg/L to 1.89 µg/L (normal <0.04 µg/L). Echocardiography demonstrated reduced LVEF with regional wall motion abnormalities involving the apical and mid-ventricular segments, with preserved basal contraction.

Results: A working diagnosis of non-ST elevation myocardial infarction was made. Due to post-transplant immunosuppression and infection risk, urgent coronary angiography was deferred and conservative medical therapy was initiated (beta-blocker, ACE inhibitor, statin, nitrates, aspirin). Follow-up echocardiography 16 days later showed complete recovery of left

ventricular systolic function (LVEF 59.6%) with resolution of regional wall motion abnormalities.
Coronary angiography performed 20 days after HSCT revealed only a mild (35%) stenosis of the left anterior descending artery. Cardiac magnetic resonance imaging at six weeks demonstrated normal global systolic function (LVEF 64%), absence of myocardial edema or ischemic scar, and mildly increased native T1 values suggestive of diffuse myocardial changes. Based on clinical presentation, imaging findings, reversibility of dysfunction, and lack of significant coronary disease, the final diagnosis of TTC was established.

Conclusions: This case highlights Takotsubo cardiomyopathy as an important and under-recognized differential diagnosis of acute coronary syndrome during autologous HSCT. Transplant-related physical stress and acute procedural complications may act as triggers. Awareness of this condition among transplant teams is essential to ensure appropriate diagnosis, optimize management, and prevent unnecessary invasive interventions. Multidisciplinary collaboration between haematology, cardiology, and nursing staff plays a key role in achieving favourable outcomes.

Disclosure: Nothing to disclose.

P193

A CASE OF CAPILLARY LEAK SYNDROME FOLLOWING HAPLOIDENTICAL ALLOGENEIC STEM CELL TRANSPLANTATION IN A PATIENT WITH ACUTE MYELOID LEUKEMIA

Sharmane Salve King[1], Maria Clariza Santos[1,2], ***Jean Rachel Catapia***[1]
[1]Makati Medical Center, Makati City, Philippines (the), [2]Philippine General Hospital, Manila, Philippines (the)

Background: Capillary leak syndrome (CLS) is a rare and life-threatening complication of hematopoietic stem cell transplantation (HSCT), typically occurring early in the post-HSCT course. It is characterized by generalized endothelial damage leading to vascular hyperpermeability and fluid shifting to the interstitial space.

Methods: This report describes a 61-year-old woman with acute myeloid leukemia who developed CLS following haploidentical allogeneic HSCT.

Results: The patient was diagnosed with AML with poor-risk cytogenetics due to the presence of DEK-NUP214 and FLT3-ITD mutations. She achieved remission with incomplete hematologic recovery after induction therapy with cytarabine and idarubicin, followed by a combination of azacitidine, venetoclax, and gilteritinib. Evaluation and workup prior to allogeneic HSCT identified a haploidentical, related stem cell donor with a minor ABO blood group mismatch and absent donor-specific antibodies. The stem cell recipient underwent reduced-intensity conditioning with thiotepa (5 mg/kg), fludarabine (120 mg/m²), and busulfan (5.5 mg/kg). A total CD34 count of 6.8 million cells/kg was infused.
Immediately post-infusion, she developed mild cytokine release syndrome (CRS), as

evidenced by fever, desaturation, hypertension, and tachycardia. After supportive medications were given, there was temporary resolution of signs and symptoms. Post-transplant cyclophosphamide (40 mg/kg) was given on day +3 for graft-versus-host disease (GVHD) prophylaxis, after which she developed new-onset arrhythmia and hemorrhagic cystitis. With persistently positive fluid balance and generalized edema despite maximizing the use of diuretics, the patient developed severe pulmonary congestion leading to acute respiratory failure and hypotension requiring vasopressor support as early as day +4. A high index of suspicion for CLS was considered, prompting the medical team to start methylprednisolone and implement aggressive supportive treatment. Due to the refractoriness of the patient's CLS and her rapid clinical deterioration, 1 dose of bevacizumab 5 mg/kg was given. However, she did not respond to the treatment, ultimately leading to her demise.

Conclusions: This case highlights the diagnostic and therapeutic challenges in patients who develop fatal CLS post-HSCT. Because its clinical features frequently overlap with other post-HSCT complications, maintaining a high index of suspicion is crucial in the timely recognition and management of this rare syndrome. The lack of standard diagnostic criteria and effective treatment options for CLS despite the recent advances in transplantation medicine necessitates further research.

Disclosure: Nothing to declare.

P194

ALLOGENEIC STEM CELL TRANSPLANT FOR NEAR ETP ACUTE LYMPHOBLASTIC LEUKAEMIA IN A DECEASED-DONOR RENAL TRANSPLANT RECIPIENT: A CASE STUDY AND LITERATURE REVIEW

Linda Lingxu Li[1], *Sarah Tan*[1]
[1]*Te Whatu Ora Auckland City Hospital, Auckland, New Zealand*

Background: Patients with previous end-stage organ failure, who develop haematological disorders, may require allogeneic stem cell transplantation (AlloSCT) for potential cure and/or long-term disease control. Although successful AlloSCT are reported, the risk of solid organ graft failure and rejection in literature are inconsistent. Limited evidence and guidance on optimal immunosuppressive therapies (IST) peri-engraftment makes clinical management and outcome prediction challenging.

Methods: A 36-year-old female presented with near ETP Acute Lymphoblastic Leukaemia (ALL) following a 10-week history of neck swelling. The patient is a deceased-donor renal transplant recipient 15 years ago for IgA nephropathy with mycophenolate mofetil, cyclosporine and prednisone as post renal transplant IST. She achieved complete remission, both morphological and flow minimal residual disease (MRD) negativity, with the ALL06 treatment protocol. Treatment course was complicated by recurrent cytomegalovirus (CMV) reactivation including CMV colitis. Consolidative AlloSCT using an HLA identical sibling donor was subsequently performed with a reduced-intensity conditioning regimen (fludarabine and

8 Gy total body irradiation). Post-transplant cyclophosphamide (PtCy) and cyclosporine were used for graft versus host disease (GvHD) prophylaxis as per our institutional protocol with peripheral blood stem cells as graft source. A second oral immunosuppressive agent was not added given the increased infection risk with prior viral reactivation.
On Day 16 post-transplant there was evidence of neutrophil engraftment but this was accompanied by acute renal injury with rapid clinical deterioration, oliguria, fever and localised pain at the renal graft site. A renal biopsy was undertaken which demonstrated histological evidence of acute vascular rejection and necrosis confirming graft kidney rejection. The patient proceeded to emergency transplant nephrectomy and subsequently maintained on haemodialysis three times per week. Post-transplant progress was further complicated by asymptomatic CMV reactivation and transplant-associated thrombotic microangiopathy with large pericardial effusion requiring pericardiocentesis and anti-C5 therapy (eculizumab). These in conjunction with infection led to significantly delayed recovery and prolonged hospitalisation. Nevertheless, she achieved gradual clinical improvement and was discharged two and a half months later. Her haematological disease remains in complete remission with full donor chimerism and adequate graft function at day 100 post-transplant.

Results: A retrospective literature review was undertaken using PubMed and Google Scholar search for relevant studies assessing peri-stem cell transplant immunosuppression following previous solid organ transplants.[1–4] Key findings are summarised in Table 1. Long term survival is reported post SOT with low rates of solid organ rejection.[4] Higher graft failures were observed in renal transplant recipients compared to liver transplants.[2,3] There were no standardised recommendations for conditioning regimen, donor type or stem cell sources. Variable GvHD/solid organ graft rejection prophylaxis were documented mostly consisting of two different immunosuppressive agents including PtCy and cyclosporine combination which was utilised in our patient without significant impact on outcomes.

Table 1: HSCT post SOT study summary

Studies	Study design and participants	Immunosuppressive therapies	Outcomes
Basak et al. 2015[2]	Retrospective study; n = 28 (kidney 12; liver 13; heart 3); donor types: MRD 12, MUD 5; MMUD 3, haploidentical 5.	CSA/MTX (n=12); CSA/MMF (n=5); Tacro/MMF (n=5); other/unknown (n=6).	SOGF: 33%; OS: 40% overall (kidney 42%, liver 51%) at 60 months post-AlloSCT.
Jang and Hsu. 2024[1]	Case series; n = 3 (liver 1, kidney 1;, heart 1); graft sources: cord blood 1; haploidentical 2.	PtCy/MMF/Tacro (n=2); Tacro/MMF (n=1).	OS from HSCT: 13 months (heart); 27 months (liver); 43 months (kidney).

Shinohara et al. 2019[3]	Retrospective study; n = 22; type of transplant AlloSCT 17 (kidney 9; liver 7); donor types: MRD 12, MUD 5.	Calcineurin inhibitor in all; steroids (n=13); MTX (n=10); MMF (n=8); ATG (n=4).	OS: 41.7% at 5 years post-AlloSCT; renal rejection in 3 patients.

AlloSCT: allogeneic stem cell transplantation; ATG: antithymocyte globulin; CSA: cyclosporine; HSCT: haematopoietic stem cell transplant; MMF: mycophenolate mofetil; MMUD: mismatched unrelated donor; MRD: matched related donor; MUD: matched unrelated donor; MTX: methotrexate; OS: overall survival; PtCy: post-transplant cyclophosphamide; SOGF: solid organ graft failure; Tacro: tacrolimus.

Conclusions: We present our experience of AlloSCT for ALL in a deceased-donor renal transplant recipient. This case highlights the risk of solid organ graft failure and rejection and importance of careful consideration of appropriate IST peri-engraftment. Standardised guidelines in current literature are limited and further studies are required to improve outcomes in this challenging and unique population.

Schleswig-Holstein, Kiel, Germany, [7]University Hospital Tuebingen, Tuebingen, Germany, [8]University Medical Center Hamburg-Eppendorf, Hamburg, Germany, [9]University Hospital Carl Gustav Carus, Dresden, Germany, [10]University Hospital Bonn, Bonn, Germany, [11]Hannover Medical School, Hannover, Germany, [12]University Clinic Heidelberg, Heidelberg, Germany, [13]University Hospital Regensburg, Regensburg, Germany, [14]Medical University of Innsbruck, Innsbruck, Austria, [15]Klinikum Nuernberg, Nuernberg, Germany, [16]Otto-Von-Guericke University, Magdeburg, Germany

Background: Bridging therapy is the treatment after leukapheresis but before CD19-directed chimeric antigen receptor T cell (CAR-T) infusion. If and what bridging is utilized represents the physician's choice and depends on previous treatment, disease characteristics, and drug availability.

Methods: We retrospectively analyzed patients treated between January 2019 and May 2025 across 16 German and Austrian centers. Bridging choices were grouped as No-Bridging, radiotherapy, ancient (Pixantrone, CHOP-variants), intensive (e.g., R-DHAP, R-MATRIX), R-gemcitabine/oxaliplatin (R-GemOx), sequential, R-Polatuzumab (R-Pola), or R-Pola-Bendamustine (Pola-BR). Bridging efficacy was assessed before lymphodepletion by Lugano criteria. The primary endpoint was progression-free survival (PFS). Influence of Ann-Arbor stage, extranodal disease (END) status, ECOG, sex, and LDH-levels at bridging and at lymphodepletion on outcomes were determined by multivariate Cox regression analyses.

Results: 508 patients (384 DLBCL-NOS, 124 trFL) treated with Axi-cel (65.2%), Tisa-cel (25.4%), or Liso-cel (9.4%) were included. Sex distribution, median age, median prior lines of therapy, LDH or ECOG at lymphodepletion and bridging were well-balanced between the two groups. trFL had better 24m-PFS than DLBCL-NOS. Response to bridging predicted PFS after CAR-T in DLBCL-NOS with a 24m-PFS of 62.6% in patients who achieved CR, 44.6% for PR, 42.0% for SD and 21.8% for PD with no-Bridging patients at 50.2%. Patterns in trFL were less clear with similar PFS between SD and PD patients (grouped 24m-PFS of 40%) and no-Bridging/PR (grouped 24m-PFS 63%). LDH-elevation at bridging predicted poorer PFS for trFL and NOS. Because NOS included >3-times more patients, we performed granular subset analyses only for NOS. DLBCL-NOS with always normal LDH performed best (24mPFS 64.2%), whereas elevated LDH at bridging, at lymphodepletion, or both performed similarly poorly (mPFS 32.1%, 37.6%, 30.0%, $p < 0.001$). Neither delta-LDH nor fold-change of LDH grouped patient quartiles in response-reflecting PFS groups. Additionally, LDH-elevation and response were independent risk-factors. Of all bridging types, No-Bridging, radiotherapy, and Pola-BR had better (24mPFS 51.5%, 46.1%, 50.5%) and R-GemOx, sequential, R-Pola, intensive, and ancient worse 24m-PFS (31.4%, 31.0%, 31.3%, 36.3%). Because of their use in similar patients, we then compared the well-balanced R-GemOx with the Pola-BR group (except for relatively more women in R-GemOx (50% vs. 32.5%, $p=0.014$). Pola-BR resulted in improved survival compared with R-GemOx (24m-PFS: 50.5% vs. 31.4%, $p=0.004$). In multivariate analyses including ECOG, LDH, END (all at lymphodepletion) and LDH (before bridging), only bridging-LDH showed significantly worse bridging-dependent CAR-T outcome ($p = 0.005$).

Conclusions: Our dataset is limited by the retrospective nature including a possible bias that worse bridging outcome may prevent patients from CAR-T infusion. We found outcomes were distinct for trFL and DLBCL-NOS. In NOS, responses to bridging as well as any LDH-

elevation strongly and independently influenced outcomes. That any LDH>ULN was independent of LDH-reduction and of tumor response a strong risk factor for poor PFS, highlights disease biology as a driver of CAR-T failure. Though well-balanced, R-Gem/Ox was inferior to Pola-BR suggesting that choice of bridging matters for the outcomes after CAR-T which has previously been underappreciated.

OS06-02

MYELOABLATIVE IS NOT ALWAYS BETTER: DISMANTLING THE ONE-SIZE-FITS-ALL APPROACH TO HAPLOIDENTICAL CONDITIONING INTENSITY

Yosra Aljawai[1], *Denái Milton*[1], *Jeremy Ramdial*[1], *David Marin*[1], *Uday Popat*[1], *Partow Kebriaei*[1], *Portia Smallbone*[1], *Betul Oran*[1], *Yago Nieto*[1], *George Chen*[1], *Richard Champlin*[1], *Elizabeth Shpall*[1], *Rohtesh Mehta*[1]
[1]*MD Anderson Cancer Center, Houston, United States of America (the)*

Background: In haploidentical hematopoietic cell transplantation, the potent graft-versus-leukemia (GVL) effect challenges the historical superiority of myeloablative conditioning (MAC). While reduced intensity (RIC) and nonmyeloablative (NMA) regimens reduce toxicity, it remains unclear if they provide sufficient disease control across all age group. We aimed to define the optimal intensity across age-stratified disease groups.

Methods: We analyzed 5,143 adult patients using a publicly available CIBMTR dataset with acute myeloid leukemia (AML, n=2698 [52%]), acute lymphoblastic leukemia (ALL, n=1037 [20%]), or myeloproliferative neoplasm/ myelodysplastic syndromes (MPN/MDS, n=1408 [27%]) between 2017-2021. Age was stratified using clinically relevant, data-guided cut-offs tailored to each disease: AML (≤ 55 vs > 55 years), MPN/MDS (≤60 vs > 60 years), and ALL (≤ 40 vs > 40 years). Conditioning regimens were stratified into four groups, with MAC with total body irradiation (TBI) serving as the reference group for all analyses: MAC-no TBI, the most common NMA/RIC platform of fludarabine/ cyclophosphamide/ TBI (Flu/Cy/TBI), and a composite of all other RIC regimens (RIC/other). Our primary endpoint was overall survival (OS); secondary endpoints were relapse and non-relapse mortality (NRM).

Results: Notably, in multivariable analysis, OS was similar across all conditioning intensities and all subgroups, shifting the clinical focus entirely to the distinct trade-offs between relapse and NRM.
In younger patients, the reduction in NRM offered by RIC/NMA regimens was counterbalanced by higher relapse risk. In AML patients (≤55 years), Flu/Cy/TBI was associated with half the NRM risk (HR 0.50, p=0.017) but at the cost of nearly double the relapse risk (HR 1.98, p<0.001). Similarly, in ALL patients (≤40 years), the RIC/NMA platform was associated with reduced NRM (HR 0.22, p=0.046) but more than double the risk of relapse (HR 2.32, p=0.002). MDS/MPN (≤60 years) patients showed a similar trend, where Flu/Cy/TBI was associated with increased relapse (HR 1.90, p=0.057) but reduced NRM (HR 0.59, p=0.054). In young patients, RIC/all regimens showed comparable relapse and NRM rates across all disease, compared to MAC.
In contrast, in older cohorts, the trade-off favored de-escalation. In AML patients (>55 years), MAC-chemo was associated with higher risk of NRM (HR 2.16, p=0.003) without a significant difference in relapse. In ALL patients (>40 years), Flu/Cy/TBI was associated with half the risk NRM (HR 0.50, p=0.034) and comparable relapse rates to MAC. In MDS/MPN patients (>60 years), RIC/Other regimens were associated with reduced relapse (HR 0.31, p=0.002) with no difference in NRM, and Flu/Cy/TBI showed reduced relapse (HR 0.69, p=0.30) and NRM (HR 0.70, p=0.40) rates without statistical significance, compared to MAC.

Conclusions: Since OS is comparable across regimens, choice of conditioning intensity represents a strategic management of competing risks rather than a survival imperative. Our data characterize the specific relapse/NRM profile of each regimen by age and disease. Compared to MAC/TBI, RIC/other showed comparable relapse/NRM profile in younger patients across all diseases. While RIC/NMA was associated with comparable or superior outcomes in older patients across all diseases, challenging the notion that higher intensity equates to better outcomes and warrant a paradigm shift toward risk-adapted regimen selection.

Background: GATA2 deficiency is associated with a wide spectrum of disease, including immunodeficiency with increased risk of certain infections, bone marrow failure, and myeloid malignancies. Allogeneic hematopoietic cell transplantation (HCT) with myeloablative conditioning can reverse the hematologic manifestations; however, the conditioning carries considerable toxicity. Briquilimab is an anti-c-Kit/CD117 monoclonal antibody that clears host HSCs from the bone marrow niche with minimal toxicity. We report early outcomes of 11 patients transplanted on a Phase II HCT study (NCT05907746) using briquilimab with standard nonmyeloablative conditioning for GATA2 deficiency.

Methods: Patients with GATA2 deficiency and a hypocellular bone marrow without increased blasts and normal or low-risk cytogenetic abnormalities were eligible. All patients received briquilimab 0.6 mg/kg on transplant day (TD)-11 and total body irradiation 200 cGy on TD-1. HLA-matched donor recipients received fludarabine 30 mg/m^2 for three days (TD-4 to -2). Haploidentical related donor recipients received fludarabine 30 mg/m^2 for five days (TD-6 to -2) and cyclophosphamide 12.5 mg/kg for two days (TD-6, -5). Graft-versus-host disease (GVHD) prophylaxis consisted of cyclophosphamide (50 mg/kg on TD +3, +4), tacrolimus, and mycophenolate mofetil.

Results: Eleven patients with median age of 22 (range 13-28) years underwent HCT with follow-up of 3 to 24 months (Table 1). Indications for transplant included myelodysplastic syndrome (n=5), clonal monocytosis (n=1), bone marrow failure (n=2), severe infection (n=2), and was preemptive in 1. Patients received peripheral blood stem cells from matched sibling (n=3), 8/8 HLA-matched unrelated (n=6), and haploidentical related (n=2) donors. One patient had a flare of pre-existing cryptogenic organizing pneumonia (COP), and one patient had progression of *Mycobacterium abscessus* infection during conditioning. Otherwise, conditioning was well tolerated, and there were no infusion toxicities or serious adverse events attributed to briquilimab. Neutrophils and platelets engrafted at a median of 13 (range 12-17) and 17 (range 0-20) days post-HCT, respectively. One patient experienced secondary graft failure at TD+73 and was successfully retransplanted from a different donor with busulfan and fludarabine conditioning. Myeloid chimerism in the remaining 10 patients was 100% donor at all time points (TD+30, +60, +100, +180, +365); T cell donor chimerism increased over time and was 77% to 100% at last follow-up. All engrafted patients had normalization of peripheral blood cell counts, and day 100 and 1 year bone marrow biopsies demonstrated normal trilineage hematopoiesis with resolution of pre-existing abnormalities. There have been no cases of Grade II-IV acute GVHD, chronic GVHD, or viral reactivation. One patient developed asymptomatic COP between 6 and 12 months post-HCT that responded rapidly to steroids. The patient with pre-existing COP had improvement in lung disease post-HCT, and the patient with *M. abscessus* had resolution of infection. Four of five engrafted female patients have had return of menses. All patients are alive and well at last follow-up.

Table 1. Patient characteristics and transplant outcomes

Pt	Age at HCT (y)	GATA2-associated disease manifestations at baseline	Donor	Neutrophil engraftment (D)	Platelet engraftment (D)	Grade II-IV acute or chronic GvHD	Infections post-HCT	Other major post-HCT complications	Outcome
1	19	MDS with trisomy 8, *STAG2*variant	MRD	13	13	N	None	COP	Alive & well at 24 mos

2	13	MDS with severe neutropenia, *STAG2* variant, verrucae	MRD	12	0	N	None	None	Alive & well at 22 mos
3	26	Necrotizing fasciitis, disseminated HSV + HLH, HPV+ vulvar SCC, vulvar abscess	MMRD	14	17	N	Demodex folliculitis	None	Alive & well at 20 mos
4	23	Clonal monocytosis with *ASXL1* & *STAG2* variants, lymphedema	MRD	13	0	N	*E. coli* bacteremia	Self-limited hepatitis	Alive & well at 20 mos
5	24	Severe neutropenia	MUD	15	17	N	*E. faecalis* UTI	None	Alive & well at 18 mos
6	21	Disseminated Mycobacterium abscessus infection, trisomy 8	MUD	13	0	N	None	None	Alive & well at 18 mos
7	21	Severe neutropenia, *ASXL1* & *STAG2* variants, EBV, HSV, disseminated VZV	MUD	17	17	N	*Salmonella* enteritis	Drug-induced neutropenia	Alive & well at 17 mos
8	22	MDS with severe neutropenia, trisomy 8, *ASXL1* & *STAG2*	MUD	13	14	N	None	None	Alive & well at 12 mos

		variants, verrucae							
9	28	MDS with *ASXL1* & *STAG2*variants, extensive verrucae	MMRD	17	20	N	*S. mitis* bacteremia	None	Alive & well at 12 mos
10	24	Hypocellular bone marrow with megakaryocytic atypia	MUD	16	20	N	*E. coli* bacteremia	Secondary graft failure at Day +73	Alive & well 6 mos post-HCT#2
11	21	MDS with severe anemia, trisomy 8, *ASXL1*, *STAG2*, *DNMT3A*, *RUNX1* variants, COP	MUD	13	19	N	None	None	Alive & well at 3 mos

HCT=hematopoietic cell transplantation, GVHD=graft-versus-host disease, MDS=myelodysplastic syndrome, HSV=herpes simplex virus, HLH=hemophagocytic lymphohistiocytosis, HPV=human papillomavirus, EBV=Epstein Barr virus, HSV=herpes simplex virus, VZV=varicella zoster virus, SCC=squamous cell carcinoma, MRD=matched related donor, COP=cryptogenic organizing pneumonia, MMRD=mismatched related donor, MUD=matched unrelated donor, UTI=urinary tract infection

Conclusions: HCT with briquilimab-based nonmyeloablative conditioning resulted in sustained donor engraftment with full donor myeloid chimerism and minimal toxicity in patients with GATA2 deficiency. There may, however, be an increased risk of graft failure than with standard myeloablative conditioning.

Background: Allogeneic hematopoietic cell transplantation (allo-HCT) remains the only curative therapy for progressive bone marrow failure (BMF) in patients with Fanconi Anemia (FA). Given the DNA-repair defects in FA, genotoxic exposures with irradiation or busulfan can lead to substantial short- and long-term toxicity. In addition, a significant proportion of FA patients lack a fully matched sibling donor (MSD) or a suitably matched unrelated donor (MUD), creating an urgent need for expanded donor options.

Methods:

Figure 1: Trial Schematic

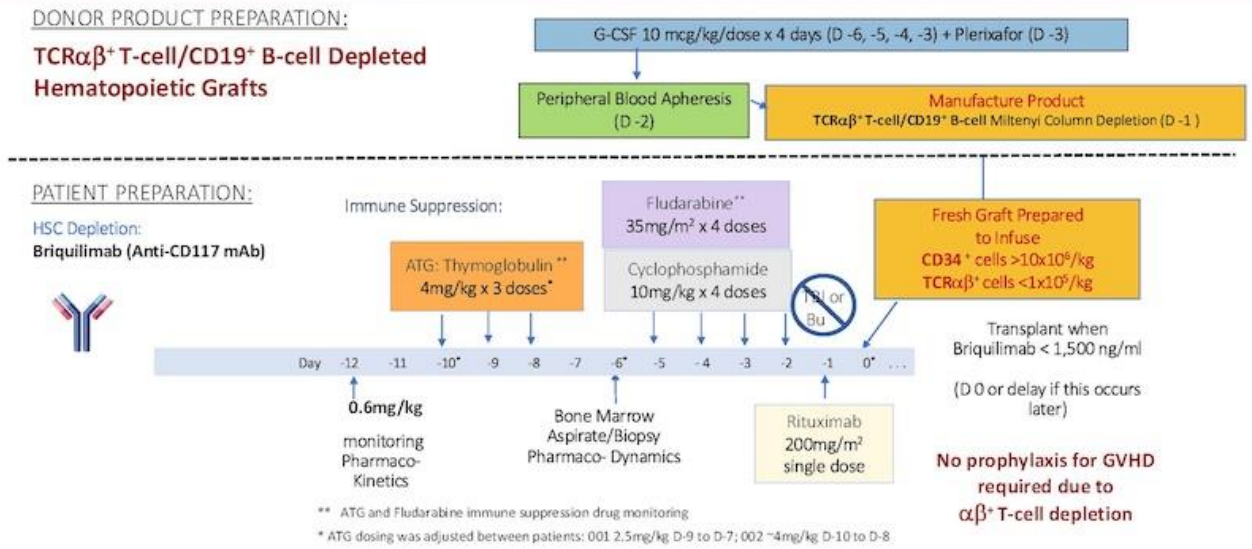

Figure 1: Treatment schema for transplantation of aB depleted-HSC grafts with Briquilimab, rATG, Fludarabine, Cyclophosphamide, and Rituximab immunosuppression and close PK monitoring of each drug.

We applied a prospective haploidentical donor transplant approach for patients with FA without MSDs with the dual goals of reducing genotoxic conditioning and minimizing GVHD

through TCRαβ+ T-cell/CD19+ B-cell depletion. We aimed to compare two conditioning strategies: (1) a regimen incorporating low-dose (200 cGy) total body irradiation (TBI) and (2) a busulfan- and irradiation-free antibody-based regimen that includes briquilimab, a CD117-directed monoclonal antibody that targets host hematopoietic stem cells. Both regimens also include rabbit anti-thymoglobulin (rATG), cyclophosphamide, fludarabine, and rituximab for immunosuppression, followed by transplantation with TCRαβ+ T-cell/CD19+ B-cell depleted grafts.

Methods: Patients with FA with BMF and without MSDs were eligible for allo-HCT with TCRαβ+ T-cell/CD19+ B-cell depleted hematopoietic grafts from MUD or haploidentical family donors with preference given to haploidentical family donors unless. All patient grafts contained ³ 10 x 10^6 CD34+ cells/kg and £ 1 x 10^5 TCRαβ+ cells/kg. Patients were treated on one of two conditioning protocols. In the cohort with TBI (n=9), patients received 200 cGy TBI combined with FA-standard immunosuppression with rATG, cyclophosphamide, fludarabine, and rituximab. In the antibody-based cohort (briquilimab, n=12), patients received briquilimab 0.6 mg/kg and the same immunosuppressive backbone (Figure 1). Kinetics of antibody clearance, engraftment, blood count recovery, and donor chimerism across multiple subsets (CD3, CD15, CD19, CD34, CD56) were assessed. Acute and Chronic GVHD was graded.

Results: A total of 21 patients with FA underwent haploidentical allo-HCT with TCRαβ/CD19-depleted grafts across the two conditioning protocols (9 TBI and 12 briquilimab cohorts) with follow up ranging from 6 months to 7 years. Briquilimab was well tolerated, with no infusion reactions or unexpected toxicities, and demonstrated predictable clearance to below threshold levels in all patients by the time of graft infusion. Engraftment kinetics were comparable between cohorts, with early recovery of full blood counts by Day +16 in engrafted patients. One patient in each cohort experienced primary graft failure. Among patients who engrafted, full and stable donor chimerism was achieved across evaluated subsets (CD3, CD15, CD19, CD34, CD56), with no meaningful differences between cohorts. No patient in either cohort developed grade III–IV acute GVHD. Immune reconstitution and performance status have been comparable in the 2 cohorts.

Conclusions: Haploidentical allo-HCT using TCRαβ/CD19-depleted grafts is feasible, safe, and effective in patients with FA, providing near-universal donor access with low rates of severe acute and cGVHD. Briquilimab-based, genotoxicity-sparing conditioning offers a compelling alternative to TBI- or busulfan-containing regimens, achieving reliable engraftment and outcomes comparable to a similar irradiation-based protocol. These findings support further development of antibody-based conditioning as a next-generation platform for FA and other bone marrow failure disorders.

OS06-05

EFFICACY OF A LOW-DOSE ATG-CONTAINING CONDITIONING REGIMEN FOR UMBILICAL CORD BLOOD TRANSPLANTATION IN SEVERE APLASTIC ANEMIA: A PROSPECTIVE, SINGLE-ARM CLINICAL TRIAL

Yue Wu[1,2,3], *Bingbing Yan*[1,2,3], *Kaidi Song*[1], *Baolin Tang*[1,2,3], *Xiaoyu Zhu*[1,2,3]
[1]*Department of Hematology, The First Affiliated Hospital of USTC, Division of Life Sciences and Medicine, University of Science and Technology of China, Hefei, China,* [2]*Anhui Provincial Key Laboratory of Blood Research and Applications, Hefei, China,* [3]*Blood and Cell Therapy Institute, Division of Life Sciences and Medicine, University of Science and Technology of China, Hefei, China*

Background: Antithymocyte globulin (ATG) is commonly used to enhance engraftment and prevent graft-versus-host disease (GVHD) in haploidentical hematopoietic stem cell transplantation (haplo-HSCT). However, its role in umbilical cord blood transplantation (UCBT) remains unclear and optimal ATG exposure is not well defined.

Methods: We conducted a single-center prospective clinical trial to evaluate the efficacy of a reduced-intensity conditioning regimen containing low-dose ATG in patients with severe aplastic anemia (SAA) undergoing UCBT (NCT06039436). The conditioning regimen consisted of fludarabine (200 mg/m^2), cyclophosphamide (120mg/kg) and total body irradiation/total bone marrow irradiation (400 cGy). In addition, rabbit ATG (2mg/kg) was administered on the first day of conditioning regimen before transplantation. Active ATG (aATG) concentrations were serially measured to explore the relationship between aATG exposure and clinical outcomes, including engraftment, acute GVHD (aGVHD), and viral infections.

Results: Twenty-four patients with a median age of 18.5 years (range, 2.0-45.0 years) were enrolled. The median follow-up for surviving patients was 376 days (range, 114-685). The baseline characteristics were shown in Table 1. The cumulative incidences of 42-day neutrophil engraftment and 60-day platelet engraftment were 91.7% (95% CI, 76.7%-98.6%) and 86.4% (95% CI, 60.1%-95.9%), respectively. The cumulative incidences of grade II-IV aGVHD, III-IV aGVHD and chronic GVHD (cGVHD) were 22.7% (95% CI, 10.2%-46.3%), 19.1% (95% CI, 7.6%-43.1%) and 12.1% (95%CI, 1.8%-32.8%), respectively. In 20 evaluable patients, pre-transplant aATG area under the curve (pre-UCBT AUC) was the best pharmacokinetic predictor of aGVHD based on receiver-operating characteristic (ROC) analysis (AUC 0.933; 95% CI 0.823-1.000). An optimal pre-UCBT AUC range (7.486-9.928 AU*d/mL) was associated with the lowest incidence of aGVHD without increasing viral infection risk (Figure 1). Patients within the optimal pre-UCBT AUC range (n = 9) had significantly lower cumulative incidence of grade II-IV aGVHD (0% vs. 45.5%, P = 0.024) and grade III-IV aGVHD (0% vs. 40.0%, P =0.039) compared to those outside the range (n = 11), with no significant differences in engraftment time, viral infections, cGVHD, GVHD-free relapse-free survival (GRFS), or overall survival (OS) (Figure 2).

Abbreviation: AUC, area under the curve; UCBT, umbilical cord blood transplantation; IST, immunosuppressive therapy.

Figure 1. Incidences of grade II-IV aGVHD and viral infection according to pre-UCBT aATG AUCs
Abbreviation: acute graft-versus-host disease (aGVHD), AUC, area under the curve; UCBT, umbilical cord blood transplantation.
Figure 2. Comparison of transplantation-related outcomes between the optimal pre-UCBT AUC group and non-optimal pre-UCBT AUC group.
Abbreviation: AUC, area under the curve; UCBT, umbilical cord blood transplantation

Figure 1

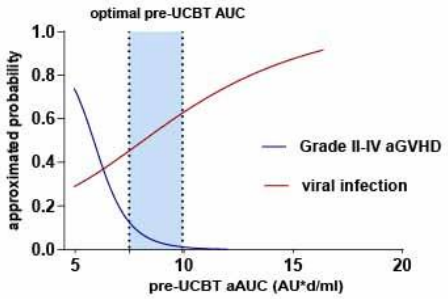

Figure 2

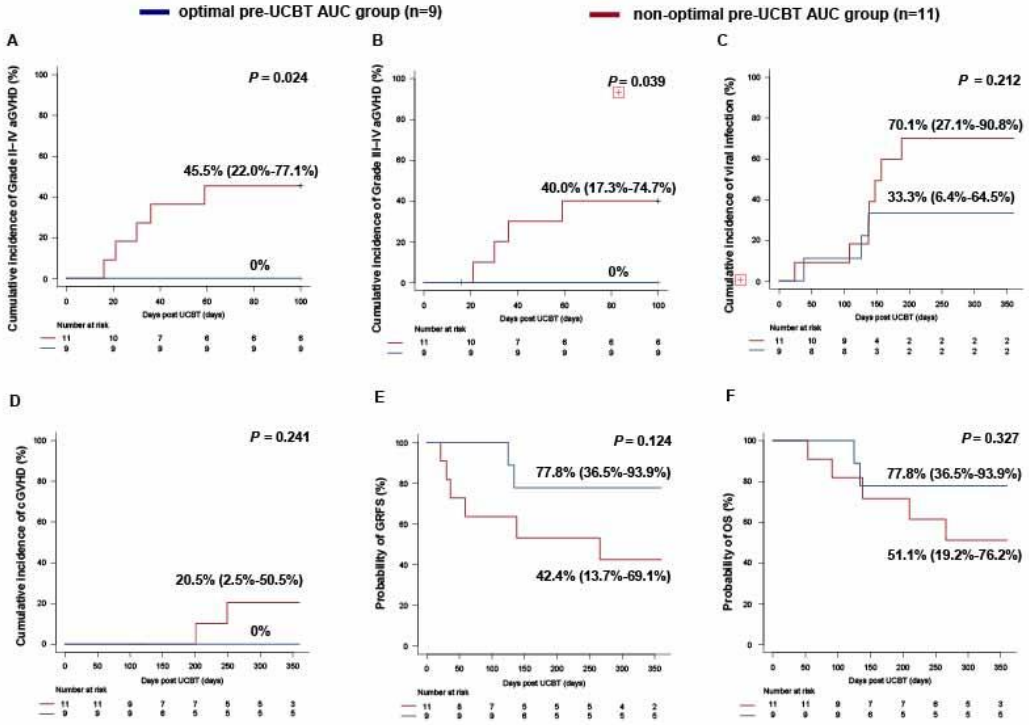

Conclusions: This study demonstrates that a low-dose ATG-containing conditioning regimen is effective and well-tolerated in SAA patients undergoing UCBT. Individualized aATG exposure monitoring may further optimize outcomes by minimizing GVHD without increasing infection risk.

TREOSULFAN MODEL INFORMED PRECISION DOSING FOR OPTIMIZED CLINICAL OUTCOME IN CHILDREN AT HIGH RISK FOR OVER- OR UNDEREXPOSURE UNDERGOING ALLOGENEIC HSCT FOR NON-MALIGNANT DISEASES

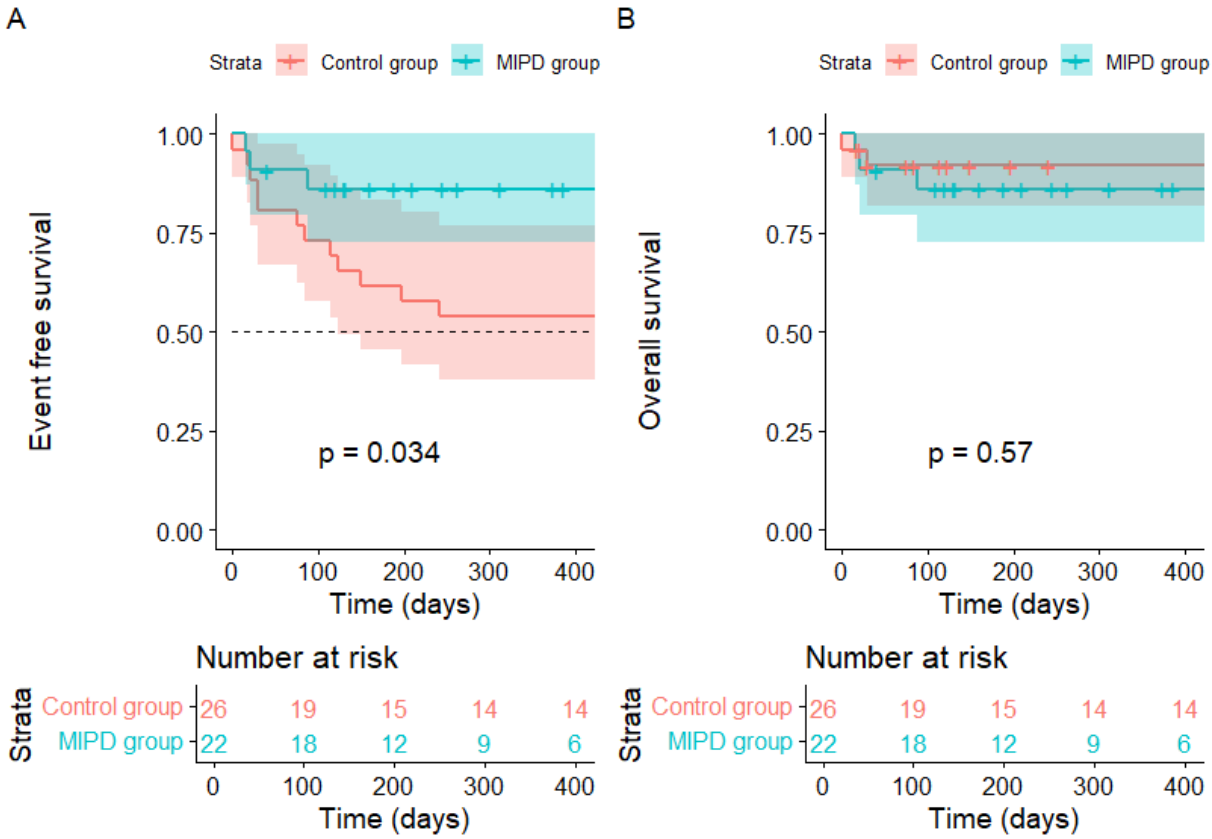
Federica Achini-Gutzwiller[1], M.Y. Eileen C. van der Stoep[1], Robbert G. M. Bredius[1], Arjan C. Lankester[1], ***Dirk Jan A.R. Moes***[1]
[1]*Leiden University Medical Center, Leiden, Netherlands (the)*

Background: Treosulfan-based conditioning regimens have been shown to provide high efficacy while presenting a favorable toxicity profile in children undergoing allogeneic hematopoietic stem cell transplantation (HSCT) for non-malignant diseases. Standardized treosulfan dosing based on body surface area results in excellent outcome in the overall cohort, but overexposure has been associated with higher mortality and underexposure correlated with an increased risk of graft failure(1). For optimizing exposure and clinical outcome, patients presenting with additional risk factors for higher pharmacokinetic (PK) and pharmacodynamic (PD) variability may benefit from model informed precision dosing (MIPD). However, no outcome data on children undergoing HSCT receiving treosulfan MIPD has been published yet.

Methods: In this pilot study, we included all children at high-risk for treosulfan over- or underexposure due to very young age at transplant (<1 year old), obesity, underweight or severe organ dysfunction undergoing HSCT for non-malignant diseases between 2022 and 2025 in Leiden, The Netherlands. Based on a limited sampling strategy of 3 measured concentrations and our previously developed PK model(2), we assessed the impact of treosulfan MIPD on event free survival (EFS) and overall survival (OS) by comparing the study group with patients selected according to the same high-risk criteria from our historical cohort transplanted in Leiden between 2011 and 2019(3). Log-rank test and cox proportional hazard survival analysis has been performed considering death and graft failure as events. Target cumulative area under the concentration versus time curve ($AUC_{0-\infty}$) was 4950 mg*h/L (+/- 10%).

Results: 22 children with a median age of 0.8 years at the time of HSCT (interquartile range [IQR] 0.4-2.4) have been included in the MIPD study group. The control group consisted of 26 children with a median age of 1.64 years (IQR 0.50-7.92) at transplant. Median $AUC_{0-\infty}$ after the first dose was 1854 mg*h/L (IQR 1604-2130) and 16 out of 22 children (73%) received a dose modification ranging from -55% to +32% to achieve target exposure. All study patients experienced sustained engraftment, no one needed a second HSCT at a median follow-up time of 8 months (IQR 4-15). 3 out of 22 patients (14%) died within the first 100 days post-HSCT due to severe preexisting infections. In the study group, OS and EFS at 100 days and 1 year post HSCT were both 86% (95% CI 73%, 100%). In the control group, EFS at 100 days and 1 year post HSCT was 73% (95% CI 58%, 92%) and 54% (95% CI 38%, 77%), respectively. OS in the control group at both 100 days and 1 year post HSCT was 92% (95% CI 82%, 100%). Survival analysis revealed significant improvement of EFS in the study group compared with the control group (p-value 0.034, Figure 1A). In contrast, no

significant difference between the groups has been found in OS analysis (p-value 0.57, figure 1B).



Conclusions: Our results support the use of treosulfan MIPD in children at high risk for hampered clinical outcome due to high PK/PD variability for optimizing EFS. Further research in larger cohorts is required to confirm these promising preliminary results.

Background: Survival of patients after allogeneic stem cell transplantation is adversely affected by two main factors, disease relapse and transplant related mortality (TRM). An ideal conditioning regimen would provide maximum disease reduction while causing minimal toxicity to non-haematopoietic tissues. Targeted radiotherapy delivered by a monoclonal antibody that preferentially targets haematopoietic organs has the potential to deliver high doses of radiation selectively to these tissues avoiding therapy related toxicity while maintaining effective disease eradication.

Methods: Forty-two patients due to receive allogeneic stem cell transplants for high risk haematological malignancies were entered into a Phase I/II study using antibody-targeted radiotherapy (ATRT) using an anti-CD66 monoclonal antibody radiolabelled with yttrium-90 (^{90}Y-besilesomab). Disease indications: Myeloma 22, AML/MDS 11, CML 5 and B-ALL 4, ages 20 - 68 years. All patients had initial dosimetry with the anti-CD66 radiolabelled with tracer activity of indium-111 (^{111}In-besilesomab), patient-specific internal dosimetry estimated from gamma-imaging and blood sampling. Whole-body gamma-camera images were taken 1 hour after infusion and 3 additional whole-body and SPECT(-CT) acquisitions between days 2 and 7. If imaging indicated favourable biodistribution patients received ^{90}Y-besilesomab fourteen days before the scheduled infusion of donor stem cells. On D -10 patients were admitted to start standard conditioning (fludarabine 30mg/m^2 D-7 to D-3, CAMPATH IH 10mg D -10 to D-8 (sibling) or D -6 (unrelated donor), melphalan 140mg/m^2 D - 2). Donor cells, sibling 9, unrelated donor 31, all PBSC. Immunosupression with ciclosporin A from D -1. Following transplant patients were managed according to standard procedures for the centres.

Results: There were no infusion related toxicities. Of the 42 patients that received ^{111}In-besilesomab, two had excessive hepatic uptake, excluded from receiving ^{90}Y-besilesomab and received a standard transplant. At the highest infused activity of ^{90}Y-besilesomab (45MBq/kg body weight) the mean BM radiation dose was 35Gy, range 18.1 - 40Gy (table 1). Of the 40 patients receiving ^{90}Y-besilesomab plus FMC all engrafted, median days to neutrophils >0.5 x 10^9/L D+17, plts >20 x 10^9/L D+18. D+30 chimerism >97% donor in all patients. Post-transplant adverse events (AE) and serious adverse events (SAE) were similar to those in patients receiving standard allogeneic transplants, no SAEs causally related to the ATRT. All patients achieved complete disease responses post transplant. Overall 19 patients (47.5%) remain alive with a median follow up of 216 months (range 19 - 258), median survival 155 months; 21 patients died, three transplant related causes (7.5%), four from unrelated causes (Alzheimers 1, trauma 1, secondary cancers 2), 16 patients relapsed (MM 10, AML 3,

ALL 2, CML-BT 1) with 14 relapse related deaths. Incidence of acute GvHD > grade 2 2.5% (n=1), chronic GvHD was seen in 2 patients (5%) and was limited. Three patients developed secondary cancers several years post transplant, one lung, one pancreatic and one with breast cancer who remains in remission. Nineteen patients remain in complete remission without serious long-term complications.

TOTAL MARROW AND LYMPHOID IRRADIATION WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE-BASED GVHD PROPHYLAXIS CONFERS FAVORABLE GVHD/RELAPSE-FREE SURVIVAL AND QUALITY-OF-LIFE IN PATIENTS WITH ACUTE MYELOID LEUKEMIA IN REMISSION

Anthony Stein[1], *Monzr M. Al Malki*[1], *Dongyun Yang*[1], *Haoyue Shan*[1], *Ibrahim Aldoss*[1], *Vaibhav Agrawal*[1], *Haris Ali*[1], *Idoroenyi Amanam*[1], *Ahmed Aribi*[1], *Andrew Artz*[1], *Brian Ball*[1], *Pamela Becker*[1], *Amanda Blackmon*[1], *Savita Dandapani*[1], *Chunhui Han*[1], *Leonardo Farol*[1,2], *Susanta Hui*[1], *Paul Koller*[1], *An Liu*[1], *Ryotaro Nakamura*[1], *Salman Otoukesh*[1], *Hoda Pourhassan*[1], *Vinod Pullarkat*[1], *Firoozeh Sahebi*[1,2], *Amandeep Salhotra*[1], *Karamjeet Sandhu*[1], *James Sanchez*[1], *Eileen Smith*[1], *Stephanie Yoon*[1], *Guido Marcucci*[1], *Stephen J. Forman*[1], *Joycelynne Palmer*[1], *Jeffrey Wong*[1]

Background: We have found that dose escalation of organ-sparing whole-body radiation using total marrow and lymphoid irradiation (TMLI) with chemotherapy results in favorable outcomes in patients with high-risk acute leukemia. In this study, we have combined TMLI 20 Gy with post-transplant cyclophosphamide (PTCy) and tacrolimus for patients with acute myeloid leukemia (AML) in first or second remission. Herein, we report interim results of this study on graft-versus-host disease/relapse-free survival (GRFS) including participants' quality of life.

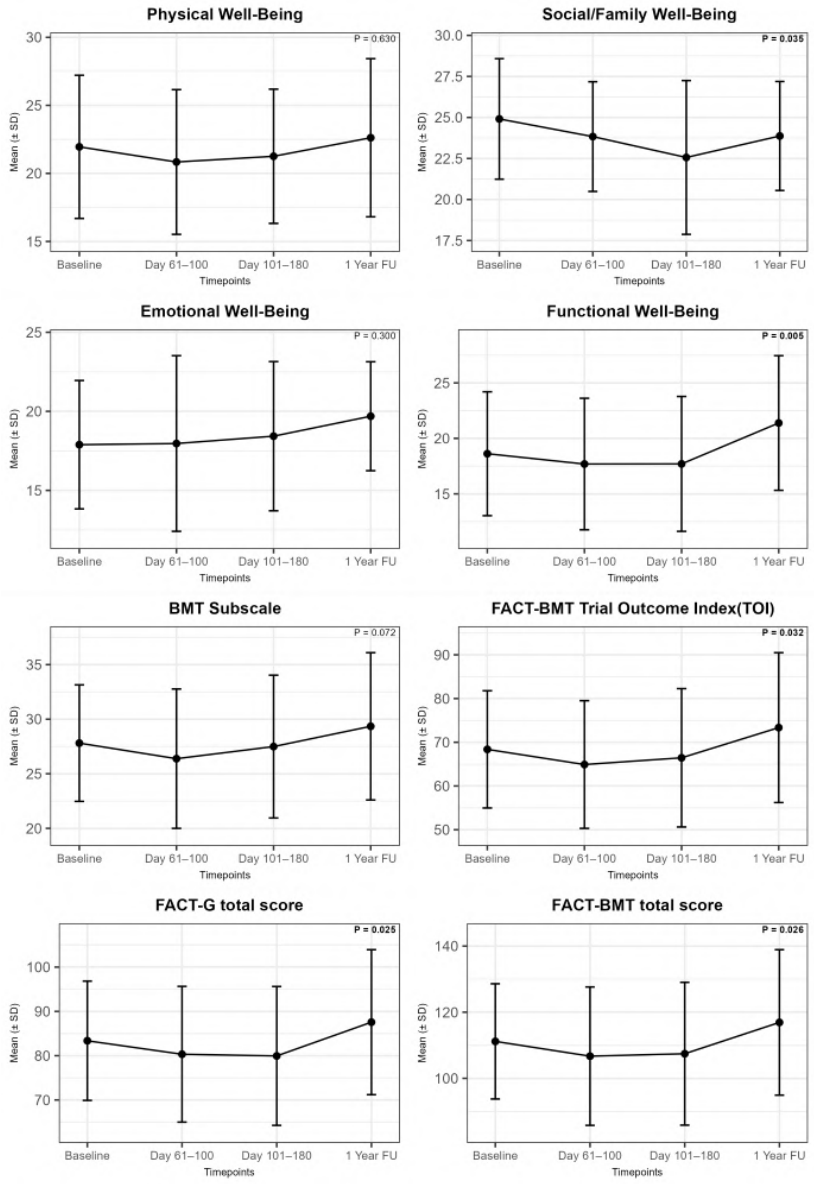
Methods: Between 03/2018 and 09/2024, we enrolled 43 patients with minimal residual disease–negative (by multicolor flow cytometry) AML in this single-center phase 2 trial, with a minimum follow up of 1 year for all patients. English- and Spanish-speaking patients were enrolled in the study and completed the Functional Assessment of Cancer Therapy – Bone Marrow Transplantation (FACT-BMT, Version 4) and the 36-Item Short Form Survey (SF-36) patient-reported outcomes assessments at baseline, day 61-100, day 101-180, and 1 year. A repeated measures ANOVA was used to evaluate the changes of the quality-of-life scores over time. All p values were 2-sided at a significance level of 0.05.

Results: Patient characteristics are reported in the Table. The 1-year GRFS rate was 67% (95%CI: 51-79%), overall survival (OS) 100%, progression-free survival (PFS) 88% (95%CI: 74-95%), relapse 12% (95%CI: 4-23%), and non-relapse mortality (NRM) 0%. The incidence of grade II-IV graft-versus-host disease (GVHD) was 9% (95%CI: 3-20%) and grade III-IV was 2% (95%CI: 0-11%). The incidence of chronic GVHD was 23% (95%CI: 12-37%), and moderate to severe GVHD was 7% (95%CI:2-18%).
Twenty-nine patients (67%) completed all timepoints in the FACT-BMT questionnaire. Social/family well-being improved at 1 year after a nadir at day 101-180 (p=0.035). Functional well-being was also improved at 1 year after a plateau at the previous timepoints (p=.005). Sums of subscales represented by the FACT-BMT Trial Outcome Index, FACT-G Total Score, and FACT-BMT Total Score were all enhanced at one year (see Figure for FACT-BMT outcomes). As assessed by SF-36, role limitations due to physical health (p=0.005) or due to emotional problems exhibited recovery at one year (p=0.025). Social functioning likewise was more favorable at one year (p=0.015).

	Total (N = 43)		Total (N=43)
Age at TMLI, Median (range)	41 (19-56)	HCT-CI	
ELN risk		0	31 (72.1%)
Favorable*	2 (4.7%)	1	8 (18.6%)
Intermediate	26 (60.5%)	≥2	4 (9.3%)
Adverse	15 (34.9%)		
Sex		KPS	

Female	24 (55.8%)	80	4 (9.3%)
Male	19 (44.2%)	90	32 (74.4%)
Disease status		100	7 (16.3%)
1st Remission	38 (88.4%)		
2nd Remission	5 (11.6%)	Donor	
		Related	17 (39.5%)
		Unrelated	26 (60.5%)

Table. Patient characteristics. *The two patients with favorable risk were in second complete remission.



Conclusions: At one-year post-transplantation, this study demonstrates an encouraging GRFS and preserved quality of life. We found that all patients engrafted, with low incidence of GVHD. The NRM rate of 0% highlights the safety of this regimen.

TREOSULFAN – BASED CONDITIONING IN ALLOGENEIC HEMATOPOIETIC STEM-CELL TRANSPLANTATION; LONG-TERM FOLLOW-UP

Avichai Shimoni[1], *Ronit Yerushalmi*[1], *Noga Shem-Tov*[1], *Ivetta Danylesko*[1], *Alexandra Tsynman*[1], *Abraham Avigdor*[1], *Arnon Nagler*[1]
[1]*Chaim Sheba Medical Center, Tel-Hashomer, Israel*

Background: Treosulfan was approved by the European Medicines Agency (EMA) in 2019 and more recently by the FDA for the use in the conditioning regimen for allogeneic hematopoietic stem-cell transplantation (HSCT). Prior studies have shown that Treosulfan is associated with strong anti-leukemia effect combined with relatively low rates of non-relapse mortality (NRM) and GVHD. However, there is limited data on long-term survival after Treosulfan- based conditioning and on the use of Treosulfan in diseases other than myeloid malignancies.

Methods: We have used the combination of fludarabine and treosulfan as the conditioning regimen for allogeneic HSCT in patients with various hematological malignancies, considered eligible for low to intermediate transplant conditioning intensity, over the last 20 years. Treosulfan dose (10-14gr/m^2 x3) was determined based on patient and disease characteristics. GVHD prophylaxis included cyclosporine and methotrexate or mycophenolate. ATG was added to unrelated donor HSCT.

Results: The study included 562 patients following their first HSCT, median age 57 years (range, 18-76). Diagnosis was AML (n=176), ALL (n=37), various lymphoproliferative diseases (n=185), MDS (n=166), others (n=8). The donor was an HLA-matched sibling (n=236), matched-unrelated (n=270), mismatched unrelated/ haploidentical (n=66). The median follow-up is 7 years (range, 0.4-20). The estimated 2- ,5- ,10- and 20-year overall survival (OS) rate is 54% (95%CI, 50-58), 42% (95%CI, 38-46), 38% (95%CI, 33-42) and 33% (95%CI, 26-39), respectively. The cumulative incidence of NRM is 22% (95%CI, 18-25), 28% (95%CI, 24-32), 30% (95%CI, 26-35) and 35% (95%CI, 29-42), respectively. The cumulative incidence of relapse mortality is 25% (95%CI, 21-28), 30% (95%CI, 26-34), 32% (95%CI, 28-35) and 33% (95%CI, 29-38), respectively. OS was significantly better in the last 10 years than in the previous 10 years, 5-year OS of 49% (95%CI, 31-43) and 34% (95%CI, 28-40), respectively (P=0.0001). This was mostly due to reduction of NRM, 5-year rate 23% (95%CI, 18-29) and 34% (95%CI, 28-40), respectively (P=0.004), while relapse morality was not significantly different, 28% (95%CI, 22-34) and 33% (95%CI, 27-39), respectively (P=0.20). Multivariate analysis identified advanced age (>60 years), HR 1.5 (1.18-1.91, P=0.009), and HSCT in the more recent period, HR 0.65 (0.50-0.82, P=0.009) as prognostic factors for OS. Outcomes were not significantly different across the various diagnoses. The incidence of acute GVHD grade II-IV, grade III-IV and chronic GVHD was 26%, 9% and 26%, respectively.

Conclusions: Treosulfan- based conditioning can allow promising long-term OS in patients with a variety of hematological malignancies. It is associated with potent anti-malignancy effect combined with relatively low NRM and GVHD rates. Long-term outcome analysis (up to

20 years) shows significant cure rate, although late events (beyond 2 years) are significant, underscoring the importance of long-term monitoring in assessing HSCT outcomes. HSCT safety is consistently improving over the last years.

REFINING THE TRANSPLANT CONDITIONING INTENSITY (TCI) INDEX BY INTEGRATING POST-TRANSPLANT CYCLOPHOSPHAMIDE: A RETROSPECTIVE ANALYSIS IN ALLO-HCT

Cristian Alberdi-Lema[1], *Jhonny Carranza*[2], *Jose Perez-Soler*[1], *Beatriz Garcia-Villaronga*[1], *Maria Suarez-Lledó*[2], *Esther Carcelero*[1], *Paola Charry*[2], *Laia Guardia*[2], *Berta Sole*[2], *Joan Cid*[2], *Miquel Lozano*[2], *Enric Carreras*[3], *Laura Rosiñol*[2], *Francesc Fernandez*[2], *Carmen Martinez*[2], *Montse Rovira*[2], *Maria Queralt Salas*[2]
[1]*Pharmacy Service, Division of Medicines, Barcelona, Spain,* [2]*Hematopoietic Cell Transplant Program, Barcelona, Spain,* [3]*Josep Carreras Foundation & Leukemia Research Institute, Barcelona, Spain*

Background: The Transplant Conditioning Intensity (TCI) index was developed standardize the evaluation of conditioning regimen intensity by classifying patients into low-, intermediate-, and high-intensity groups based on chemotherapy and radiotherapy doses to predict overall survival (OS) (Spyridonidis Et. Al. 2024). However, the TCI was created without considering post-transplant cyclophosphamide (PTCy), now widely used for GVHD prophylaxis at doses that add significant cytotoxic burden (40-50 mg/kg/day for two days). As this aspect may limit the applicability of the TCI in contemporary allo-HCT practice, we evaluated its performance in a large transplant cohort and developed a refined model incorporating PTCy exposure.

Methods: We included 538 patients who underwent allo-HCT at our institution between 2012 and 2024. GVHD prophylaxis evolved over time with the gradual adoption of PTCy, initially restricted to haploidentical transplantation and later extended to all donor types between 2016 and 2019. Since 2021, PTCy dose reduction to 40 mg/kg/day was implemented in 10/10 HLA-matched transplants.
Patients were retrospectively assigned to low-, intermediate-, and high-intensity categories according to TCI original definitions. A modified TCI score (nTCI) was defined by incorporating PTCy exposure, assigning 0.5 points for PTCy 40 mg/kg/day and 1 point for PTCy 50 mg/kg/day, corresponding to the weights used in the original TCI for equivalent doses of cyclophosphamide administered during conditioning. Patients were reclassified into nTCI categories using the same numerical thresholds as the original TCI. Baseline characteristics across TCI groups were compared, and predictive performance was evaluated for OS, non-relapse mortality (NRM), and cumulative incidence of relapse (CIR).

Results: Using the original TCI classification, 70 (13.0%), 422 (78.4%) and 46 (8.6%) patients were assigned to the high-, intermediate-, and low-intensity groups (Table 1).

Baseline characteristics differed across TCI categories with older patients more frequently receiving low or intermediate conditioning intensity regimens. As shown in Figure 1, no significant differences in OS (p=0.948), NRM (p=0.579) and CIR (p=0.272) were observed across TCI groups. Specifically, 2-year OS, NRM, and CIR were 81.7%, 17.2%, and 27.5% in the high-; 85.2%, 17.0%, and 31.0% in the intermediate-; and 88.8%, 13.4%, and 44.9 in the low-intensity group.
Subsequently, patients were reclassified according to the nTCI into high- 234 (43.5%), intermediate- 293 (54.5%), and low- (2.0%) intensity groups. Baseline characteristics again differed across categories, reflecting clinical practice in conditioning selection based on age, comorbidities, and disease characteristics. In contrast to the original TCI, the nTCI demonstrated good prognostic discrimination, with differences being observed in OS (p=0.005) and CIR (p=0.006) and no significant differences NRM (p=0.16), across nTCI intensity groups (Figure 1). Specifically, the 2-year OS, NRM, and CIR were 85.2%, 14.9%, and 26.2% for high; 82.1%, 18.6%, and 34.8% for intermediate; and 100%, 0, and 57.6% for low conditioning intensity group.

Conclusions: Pending of external validation, the TCI classification appeared insufficient for accurately predicting survival events based on accumulated toxicity specially in patient cohorts that contain transplant platforms with PTCy. Nevertheless, the incorporation of PTCy into the model, suggests improved stratification, risk adjustment, and predictive value.

Background: Allogeneic transplantation (HSCT) is a curative therapeutic option for high-risk AML. Undergoing HSCT while in CR1 is an important prognostic factor. Moreover, HSCT outcomes in patients (pts) receiving conventional GVHD prophylaxis also correlate with the number of induction courses needed to achieve CR1 (Loke J, Cancer 2024). However, whether it holds for HSCT with post-transplant cyclophosphamide (PTCy) is unknown.

Methods: The study aim was to compare transplantation outcomes in AML pts achieving CR1 after one *vs*. two inductions. HSCTs were performed between 2012-2022, and all pts received PTCy as GVHD prophylaxis. Statistical tests included a multivariate analysis (MVA).

Results: 677 pts (de novo-542, secondary-135) were included, 518 (77%) with 1 induction and 159 with 2 inductions. Median follow-up was 2.2 (range, 2-2.6) years, and the median year of transplant was 2020 (interquartile range [IQR], 2017-2021) with no significant difference between the two groups (p=0.14). Median pt age was 56.5 (IQR, 43.4-64.1)

years, and 58.8% were male, comparable between both groups (p=0.08 and p=0.93). The cytogenetic risk was categorized as intermediate (69.1% *vs.* 69.7%), adverse (25.8 % *vs.*27%), and favorable (5.1% *vs. 3.3%)*, in the 1 and 2 induction groups, respectively (p=0.65; data missing for 33 pts). Donors were haploidentical 65.6% *vs.* 69.2%; HLA matched sibling 9.3% *vs.* 11.3%; matched (10/10) unrelated 14.3% *vs.* 10.1%, and mismatched (9/10) unrelated 10.8 *vs.* 9.4%, respectively (p=0.46). PB grafts were the main stem cell source in 74.7 % and 71.7% of the pts, respectively (p=0.45). Myeloablative conditioning (MAC) was used in 46.3% *vs.* 53.5%, respectively (p=0.12). Day 30 ANC $\geq$0.5 x 10^9/L was 90.4% *vs*.91.1 % and day 60 platelet count $\geq$20,000/L was 87.3% *vs.* 86.5% for pts receiving 1 *vs.* 2 inductions, respectively. Day 180 acute (a) GVHD II-IV was 29.7% *vs.* 31.2 % and of III-IV it was 9.1% *vs.* 9.8%, respectively. The 1- y total and extensive chronic (c) GVHD was 29.8% *vs.* 34.2% and 11.3% *vs.* 16.1 %, respectively, with no significant difference between pts receiving 1 *vs.* 2 inductions. These data were confirmed by MVA. The 2-y relapse incidence (RI) was higher in pts receiving 2 inductions compared to those receiving 1 induction, 27% *vs.* 19.3%, HR = 1.75 (95% CI, 1.21-2.53, p=0.003). The 2-y overall survival 69% *vs.* 62.8%, GVHD-free, relapse-free survival 50.4% *vs.* 46,3%, leukemia-free survival 65% *vs.* 61.1% and non-relapse mortality 15.7% *vs.* 11.9% (Figure) did not differ significantly between pts receiving 1 *vs.* 2 inductions. These data were confirmed by MVA. The main cause of death was the original disease, 48.7% *vs.* 70.9% of the deaths, respectively.

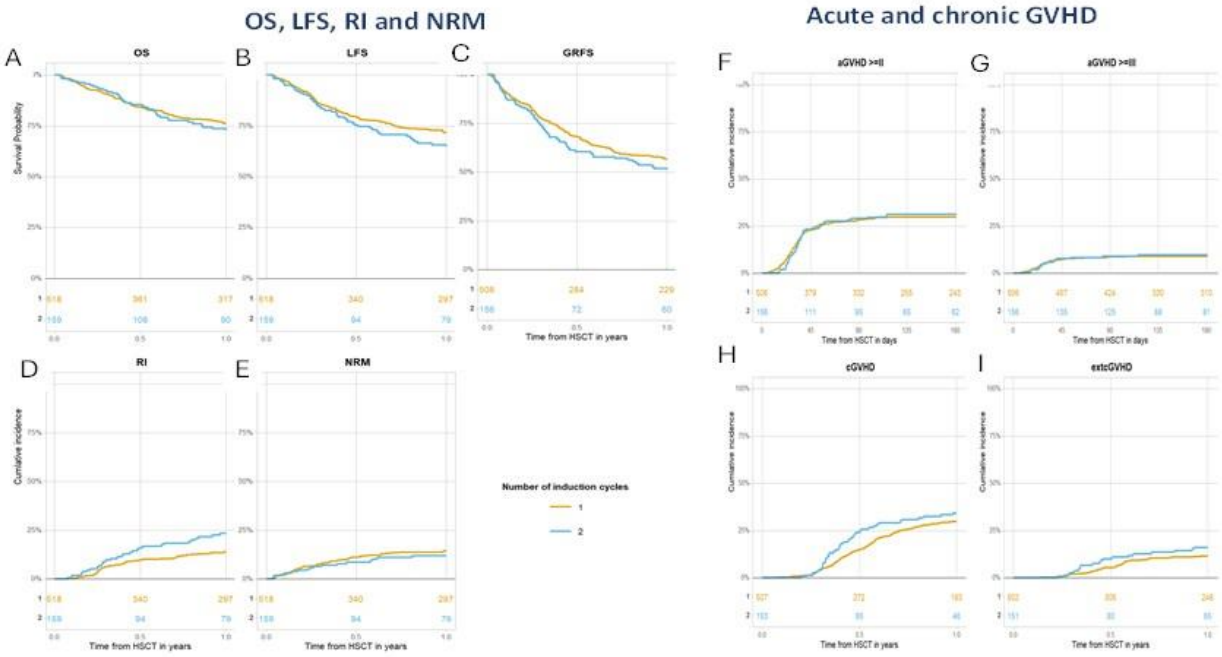

Figure Legend: Outcomes of HSCT with post-transplant cyclophosphamide (PTCy) in patients with AML achieving 1st CR after one versus two inductions: A. overall survival (OS), B. leukemia-free survival (LFS), C. GVHD free relapse free survival (GRFS), D. relapse incidence (RI), E. non-relapse mortality (NRM); F. acute GVHD grade II-IV (>=II) and G. III-IV (>=III); H. chronic GVHD total(cGVHD) and I. extensive (extcGVHD).

Conclusions:
In this registry-based retrospective analysis of HSCT for AML in CR1, achieved after one *vs*. two inductions, we observed similar transplantation outcomes other than for pts with a higher incidence of relapse achieving CR1 after 2 inductions. These data may indicate that in pts receiving PTCy as GVHD prophylaxis, the number of induction courses to attain CR loses its predictive value, which we previously observed in non-PTCy transplants, suggesting the uniqueness of PTCy biology.

Background: Optimizing graft-versus-host disease (GVHD) prophylaxis remains a key challenge to improve allo-HCT outcomes. In Europe, anti-thymocyte globulin (ATG) is widely used, while post-transplant cyclophosphamide (PTCy) is increasingly adopted, particularly for mismatched unrelated donors (MMUD). In matched related (MRD) and matched unrelated (MUD) allo-HCT, comparative studies of PTCy versus ATG have yielded conflicting results, preventing clear recommendations. We report a large national registry analysis to complement existing evidence.

Methods: We retrospectively analyzed SFGM-TC registry patients who underwent a first allo-HCT from MRD or MUD for acute myeloid leukemia (AML) or myelodysplastic syndromes (MDS) between 2014 and 2022. We restricted the analysis to reduced intensity conditioning (RIC) with peripheral blood stem cells (PBSC). GVHD prophylaxis consisted in: immunosuppressive agents (IS) alone (group NONE), PTCy with or without (+/-) IS (group PTCy), ATG +/- IS (group ATG), PTCy+ATG +/- IS (group PTCy+ATG). IS regimens included mainly calcineurin inhibitor (CNI) + antimetabolite (methotrexate or mycophenolate mofetil), or CNI alone.

Results: A total of 3702 patients were analyzed: group PTCy n=103, group ATG n=3340, group PTCy+ATG n=46 and group NONE n=213. The groups were comparable in age at allo-HCT, gender, disease type, remission status at transplant and HCT-CI score but differed significantly in transplant year, blood group compatibility, and RIC regimen. In addition, in the PTCy and PTCy+ATG groups, 14% of allo-HCT were performed without additional IS, compared to 0% in the other groups. In the NONE group, 65% of allo-HCT used MRD donors versus 45% in the remaining groups. These variables (except transplant year) were included as adjustment factors in multivariable analysis.
At day 100, all groups experienced similar cumulative incidence (CI) of grade ≥ II or grade III-IV acute GVHD (aGVHD). At 2 years, the CI of extensive chronic GVHD (ext cGVHD) was 9%, 7%, 15% and 2% in PTCy, ATG, NONE and PTCy+ATG groups respectively (p <0.001). In adjusted multivariable analysis, PTCy was associated with a significant reduction in grade III-IV aGVHD compared to ATG (HR 0.49, p=0.040). Regarding ext cGVHD, PTCy and ATG were both significantly superior to NONE. PTCy+ATG was not significantly different from other groups but the statistical power was limited by the small number of patients.
With a median follow-up of 16.6 months for the overall population, the 2-year OS, PFS and extGRFS were 59.8% [58.1 - 61.5], 53.8% [52.1 - 55.6] and 43.9% [42.2 – 45.6] respectively. These outcomes were not significantly influenced by donor type or by GVHD prophylaxis group in multivariable analysis.
The cumulative incidence of relapse (RI) and non-relapse mortality (NRM) at 2 years were similar between groups. An analysis of toxicity patterns and causes of death will be presented.

Conclusions: In this large retrospective cohort of MRD/MUD RIC allo-HCT for AML/MDS, PTCy significantly reduced severe aGVHD compared with ATG, while cGVHD, RI, OS, PFS, and

GRFS did not differ. These findings are consistent with previous reports and now await confirmation from ongoing randomized trials.

Background: Allogeneic stem cell transplantation (alloSCT) after remission induction remains the cornerstone for relapsed/refractory (R/R) or newly diagnosed (ND), adverse-risk acute myeloid leukemia (AML). We report the efficacy and safety of an investigational conditioning with alkylating agents, cytarabine, cladribine, hypomethylating agents, and venetoclax (ARCHIVE) in patients with ND adverse-risk, or R/R AML who proceeded to upfront alloSCT without remission induction.

Methods: We performed an observational, prospective, single-center study. Treatment regimens and data collection were approved by the Vilnius University Hospital Santaros Klinikos Hematology Board and the Vilnius Regional Biomedical Research Ethics Committee. The patients were 18 years or older, had AML or MDS/AML with >5% blasts and/or extramedullary disease, and were alloSCT-eligible.
ARCHIVE conditioning regimen (Picture 1) consisted of cytarabine 500 or 1000 mg/m^2, cladribine 5 mg/m^2 on days -8, -7, -6, -5, -4, venetoclax 600 mg/d and decitabine 20 mg/m^2 / azacitidine 75 mg/m^2 on days -8, -7, -6, -5, -4, -3, -2. The backbone alkylating agent was either busulfan (3.2 mg/kg on days -3 and/or -2) or melphalan (100 mg/m2 on day -2 in patients with previous busulfan exposure and/or *TP53*-mutated disease), whereas thiotepa was added to busulfan or melphalan in selected cases. Gilteritinib 120 mg/d was administered with ARCHIVE until day -2 in *FLT3*-mutated AML. Idarubicin or etoposide was

added on days -8 and -7 in selected cases. GVHD prophylaxis consisted of cyclophosphamide 40 mg/kg (days +3, +4), calcineurin inhibitor, and mycophenolate mofetil.
We collected baseline characteristics, CR+CRp rate at day +30, MRD negativity rate (by MFC and PCR), time-to-engraftment, grade 3-5 non-hematological toxicity (CTCAE v5.0), OS, and RFS.

Results: Thirty-two patients were enrolled, with their baseline characteristics summarized in Table 1.
Dose-escalated cytarabine (1000mg/m^2), additional Idarubicin/Etoposide, and Gilteritinib were used in 13% (4/32), 9% (3/32), and 13% (4/32), respectively. Thiotepa was added to busulfan/melphalan in 59% (19/32). Matched sibling, matched unrelated, mismatched unrelated, and haploidentical donors were used in 6% (2/32), 34% (11/32), 13% (4/32), and 47% (15/32), respectively.
The CR+CRp rate at day +30 post-alloSCT was 97% (30/31) with all responders successfully

engrafting. MRD negativity was achieved in 90% (26/29) of MRD-evaluable responders. The median time to neutrophil recovery was 17 (13-30) days after the stem cell infusion and 25 (19-38) days after the start of ARCHIVE.
The most common grade 3-5 toxicities were infectious complications (84%, 27/32) and mucositis (44%, 14/32). Adverse events of special interest were veno-occlusive disease (6%, 2/32), secondary graft failure (3%, 1/32), and grade 3-4 acute GVHD (16%, 5/32). Day 30 mortality rate was 6% (2/32).
At the data cut-off (2025-12-08), 26 patients are alive and in CR, with no confirmed relapses. Six patients died due to infectious complications (4), GVHD (1), and progressive disease (1). After the median follow-up of 6.5 months, the median OS and RFS were not reached, whereas the estimated 12-month OS and RFS were 77% and 85%, respectively.

Table 1. Baseline Characteristics

Characteristics	**Patients (N32)**
Female	59% (19/32)
Age (years), median (min-max)	58 (23-70)
ECOG 0-1	69% (22/32)
ECOG 2	31% (10/32)
AML	81% (26/32)
MDS/AML	19% (6/32)
ELN 2022 adverse risk group	81% (26/32)
*MECOM*r	25% (8/32)
*TP53*m	13% (4/32)
ELN 2022 Adverse karyotype	25% (8/32)
Newly diagnosed disease	16% (5/32)
Relapsed/refractory disease	84% (27/32)

1 prior treatment line	67% (18/27)
>1 prior treatment line	33% (9/27)
Prior Venetoclax	56% (15/27)
Prior *FLT3* inhibitors	7% (2/27)
Prior Revumenib	4% (1/27)
Prior alloSCT	22% (6/27)
Blast count % at baseline, median (min-max)	13 (0-70)

Conclusions: Upfront alloSCT with ARCHIVE conditioning demonstrates high antileukemic efficacy and manageable toxicity in patients with ND adverse-risk or R/R non-CR AML.

REJECTION PROPHYLAXIS IN AUTOLOGOUS GENE THERAPY PROTOCOLS: CHOOSING AN ALEMTUZUMAB DOSE

Nathan Jeffreys[1], *Sarah Brett*[2], *Claire Horgan*[1], *Oana Mirci-Danicar*[1], *Omima Mustafa*[1], *Ramya Hanasoge-Nataraj*[1], *Srividhya Senthil*[1], *Robert Wynn*[1]
[1]*Bone Marrow Transplant Unit, Royal Manchester Children's Hospital, Manchester, United Kingdom of Great Britain and Northern Ireland (the),* [2]*Department of Pharmacy, Royal Manchester Children's Hospital, Manchester, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Graft rejection is increasingly described in children with inborn errors of metabolism following haematopoietic stem cell gene therapy (HSCGT), as autologous T-cells reject the transgene protein and modified cells expressing the transgene protein product. There is evidence from primate studies that pre-transplant immune suppression with TBI

prevents such rejection, but TBI is clearly not suitable in clinical practice. We have proposed utilising alemtuzumab in place of TBI to promote recipient tolerance following HSCGT and thereby reduce graft rejection.
Alemtuzumab is an anti-CD52 monoclonal antibody used in transplant conditioning regimens to both prevent graft failure and acute graft-vs-host disease (aGvHD). Current protocols recommend dosage of 0.2mg/kg daily over 3-5 days (cumulative dose of 0.6-1mg/kg, capped at total dose 100mg). However, high exposure due to pharmacokinetic differences between patients is common and leads to delayed immune reconstitution and increased risk of viral reactivation and infection in the peri-transplant period. Locally, we have established a protocol utilising a dosage of 0.1mg/kg x 3 days (cumulative dose of 0.3mg/kg) on days -7 to -5 in matched related donor transplant in children with non-malignant disease to reduce side effects while preserving clinical efficacy. We report our experience utilising this lower dose within this cohort.

Methods: We performed a retrospective analysis of medical records at a single site (Royal Manchester Children's Hospital, UK) for patients aged 0 – 19 years who underwent first transplant for non-malignant indications between 01/01/2018 – 31/12/2024. Patients were included if they underwent matched related donor transplant and received 0.1mg/kg x 3 days alemtuzumab during the conditioning phase. Data collection included baseline characteristics, transplant characteristics and outcomes, presence of significant viral re-activation (positive result with viral copy number ≥1000), and immune reconstitution.

Results: 52 patients were identified during in the study period, who underwent transplant at a median age of 6.6 years (range: 0.2 to 18.7). The overall survival at 5-years was 90.3% (causes of death: pulmonary haemorrhage, n=2; parainfluenza pneumonitis, n=1; respiratory failure, n=1; TA-TMA, n=1).
Viral reactivation was not uncommon but there was no mortality from reactivated infection. Significant adenovirus reactivation occurred in 9/52 (17.3%), Epstein-Barr virus reactivation in 14/52 (26.9%), and cytomegalovirus reactivation in 17/52 (32.7%). There was no mortality in relation to viral reactivation for this cohort.
Immune reconstitution occurred promptly after transplant. The median absolute CD3 count (cells/μL) was 197 (range: 19-1225) at 3 months, 730 (range: 83-946) at 6 months, 1004 (range: 509-2765) at 9 months and 1452 (range: 395-2280) at 12 months. Acute GvHD of any grade was reported in 12/52 (23.1%) with only 1 patient experiencing GvHD of grade III-IV. There was no graft rejection.

Conclusions: Alemtuzumab at a dosage of 0.1mg/kg x 3 days is safe and well tolerated in this cohort. Immune suppression is adequate to prevent graft rejection, and immune reconstitution is sufficiently prompt to prevent virus-related mortality. We present our experience of such immune suppression in an ongoing, first-in-world clinical trial of HSCGT in MPSII, including in boys with demonstrable sensitisation to the transgene protein product.

Clinical Trial Registry: Not applicable.

VENETOCLAX-ENHANCED REDUCED-INTENSITY CONDITIONING IN ELDERLY PATIENTS WITH HIGH-RISK MYELOID MALIGNANCIES UNDERGOING ALLOGENEIC PERIPHERAL BLOOD STEM CELL TRANSPLANTATION: A PHASE II STUDY

Jie Gao[1], *Jun Yang*[1], *Yin Tong*[1], *Baoxia Dong*[1], *Jiahua Niu*[1], *Kun Zhou*[1], *Yu Cai*[1], *Liping Wan*[1], *Xianmin Song*[1], *Huiying Qiu*[1], *Chongmei Huang*[1]
[1]*Department of Hematology, Shanghai General Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China*

Background: Reduced-intensity conditioning (RIC) for high-risk acute myeloid leukemia (AML) and myelodysplastic syndromes (MDS) is associated with high relapse rates, and it remains unclear whether Venetoclax can enhance the efficacy of RIC in these patients undergoing allogeneic hematopoietic stem cell transplantation.

Methods: A prospective, single-arm, phase 2 trial enrolled patients with high-risk AML or MDS, who were aged ≥55 years and underwent allogeneic peripheral blood stem cell transplantation (allo-PBSCT). High-risk AML was defined as non-remission (NR) prior to transplantation, complete remission (CR) with measurable residual disease (MRD)-positive status, or adverse-risk disease according to the 2022 European LeukemiaNet (ELN) classification. High-risk MDS was defined as intermediate-2 or higher risk according to the International Prognostic Scoring System (IPSS), therapy-related MDS, or the presence of pathogenic mutations in *ASXL1, EZH2, RUNX1, SRSF2, U2AF1, STAG2, NRAS, ZRSR2*, or *TP53.*
All patients received venetoclax-enhanced RIC (VEN-RIC), which consisted of venetoclax, fludarabine, cytarabine, busulfan, and total body irradiation (TBI). Venetoclax was administered in an ascending dose regimen for patients with NR AML or untreated MDS: 100 mg on day -11, 200 mg on day -10, and 400 mg once daily from days -9 to -3. For all other patients, venetoclax was given at a dose of 400 mg daily from days -9 to -3. Fludarabine (30 mg/m²/d) was given from days -6 to -2, cytarabine (1 g/m² /d) from days -6 to -2, intravenous busulfan (3.2 mg/kg/d) on days -6 and -5, and TBI (3 Gy) on day -1.
The primary endpoint was 1-year progression-free survival (PFS), and secondary endpoints included overall survival (OS), graft-versus-host disease/relapse–free survival (GRFS), relapse, non-relapse mortality (NRM), graft versus-host-disease (GVHD), and safety.

Results: Fifty patients (median age 62) were enrolled, including 37 with AML and 13 with MDS. At a median follow-up of 14.9 months, the 1-year PFS was 72.5% (95% CI, 60.8–86.5%), with 1-year OS and GRFS rates of 73.8% (95% CI, 62.1–87.9%) and 56.9% (95% CI, 44.2–73.4%), respectively. The 1-year cumulative incidence of relapse was 16.8% (95% CI, 6.0–27.6%), while non-relapse mortality (NRM) was 10.6% (95% CI, 1.6–19.6%). Acute graft-versus-host disease (aGVHD) occurred in 22.9% (95% CI, 10.9%-34.8%) of patients within 180 days, with 1-year cumulative incidence of cGVHD at 25.8% (95% CI, 10.8%-40.8%). The 1-year cumulative incidence of CMV and EBV reactivation was 12.8% (95% CI, 3.3%-22.8%) and 47.9% (95% CI, 33.2%-61.9%), respectively.
Multivariable analysis showed that TP53 mutation was the strongest predictor of worse OS,

PFS, and GRFS, as well as higher relapse rates. A high Hematopoietic Cell Transplantation-specific Comorbidity Index (HCT-CI ≥3) and aGVHD were significantly associated with higher NRM. In subgroup analyses, patients aged 55–65 years had significantly better GRFS compared to those aged ≥65 year.

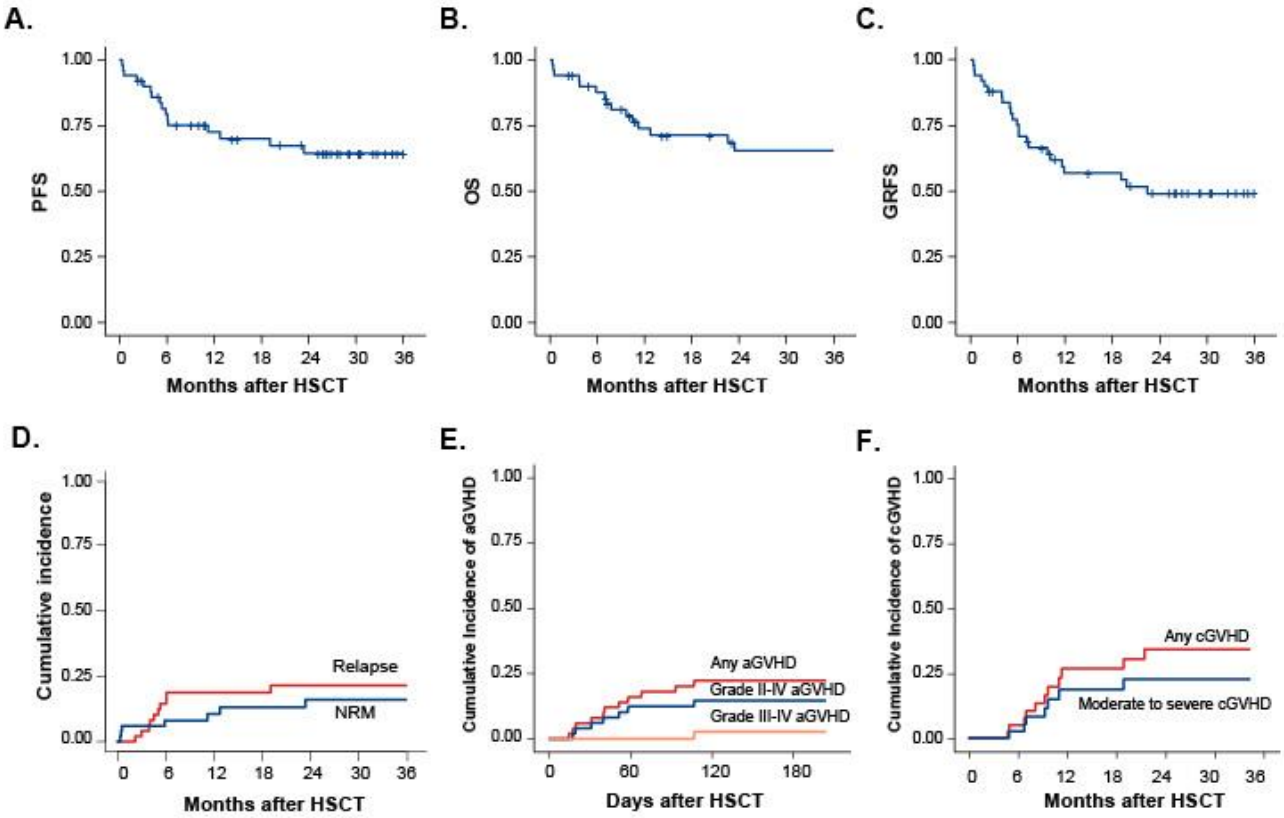

Figure: (A) PFS; (B) OS; (C) GRFS; (D) Relapse (red) and NRM (blue); (E) Acute GVHD by grade; (F) Chronic GVHD by grade.

Characteristics	N (%)

VENETOCLAX-AUGMENTED CONDITIONING REGIMENS IN ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR MYELOID NEOPLASMS: A SCOPING REVIEW AND EVIDENCE LANDSCAPE

*Mohammed Abdulgayoom[1], Amaal Gulied[1], Awni Alshurafa[1], Shehab F. Mohamed[2], Mohamed A. Yassin[1], **Afraa Fadul**[1]*
[1]National Center for Cancer Care and Research, Doha, Qatar, [2]National Canter for Cancer Care and research, Doha, Qatar

Background: Relapses remain a leading cause of treatment failure following allogeneic hematopoietic stem cell transplantation (allo-HSCT) for high-risk myeloid neoplasms. Venetoclax, a selective BCL-2 inhibitor with proven activity in acute myeloid leukemia (AML) and myelodysplastic syndromes (MDS), has emerged as a promising adjunct to conditioning regimens. However, its role in the transplant conditioning setting remains incompletely defined.

Methods: We performed a hybrid scoping review and evidence-mapping analysis in accordance with PRISMA-ScR guidelines to summarize published clinical experience and ongoing trials of venetoclax-augmented conditioning or sequential regimens prior to allo-HSCT. Systematic searches of PubMed/MEDLINE, Embase, Scopus, ClinicalTrials.gov, and major hematology conference proceedings (ASH, EHA) were conducted from inception through October 2025. Eligible studies included adult patients with AML or other myeloid neoplasms receiving venetoclax as part of conditioning. Outcomes of interest included engraftment, graft-versus-host disease (GVHD), relapse, non-relapse mortality (NRM), survival, and toxicity.

Results: Eighteen studies (20 reports) met the inclusion criteria, including nine published cohorts (n = 238 patients) and 11 ongoing registered trials. Published studies primarily enrolled patients with high-risk AML or MDS and incorporated venetoclax into myeloablative, reduced-intensity, or sequential FLAMSA-like conditioning backbones (Table 1). Venetoclax was administered at doses of 200–400 mg/day (occasionally up to 800 mg) for 3–14 days, most commonly in combination with busulfan–fludarabine-based regimens.
Engraftment occurred within expected timeframes, with median neutrophil recovery of 12–16 days and platelet recovery of 13–23 days. Acute GVHD rates ranged from 28–64%, with grade III–IV acute GVHD reported in 3–26%, while chronic GVHD occurred in 7–43%, predominantly mild to moderate. Relapse rates varied from 7–41%, and NRM ranged from 7–37%. One-year overall survival ranged from 63–84% (Figure 1). Venetoclax-associated toxicities were mainly infectious or mucosal; tumor lysis syndrome and veno-occlusive disease were rare.
Ongoing trials (n = 11) are predominantly phase I–II studies exploring venetoclax integration across myeloablative, reduced-intensity, and sequential platforms, with two randomized studies underway.
Table 1. Baseline Characteristics of Published Studies Evaluating Venetoclax-Augmented Conditioning before Allogeneic HSCT

*Values marked with an asterisk (*) denote single-patient ages.

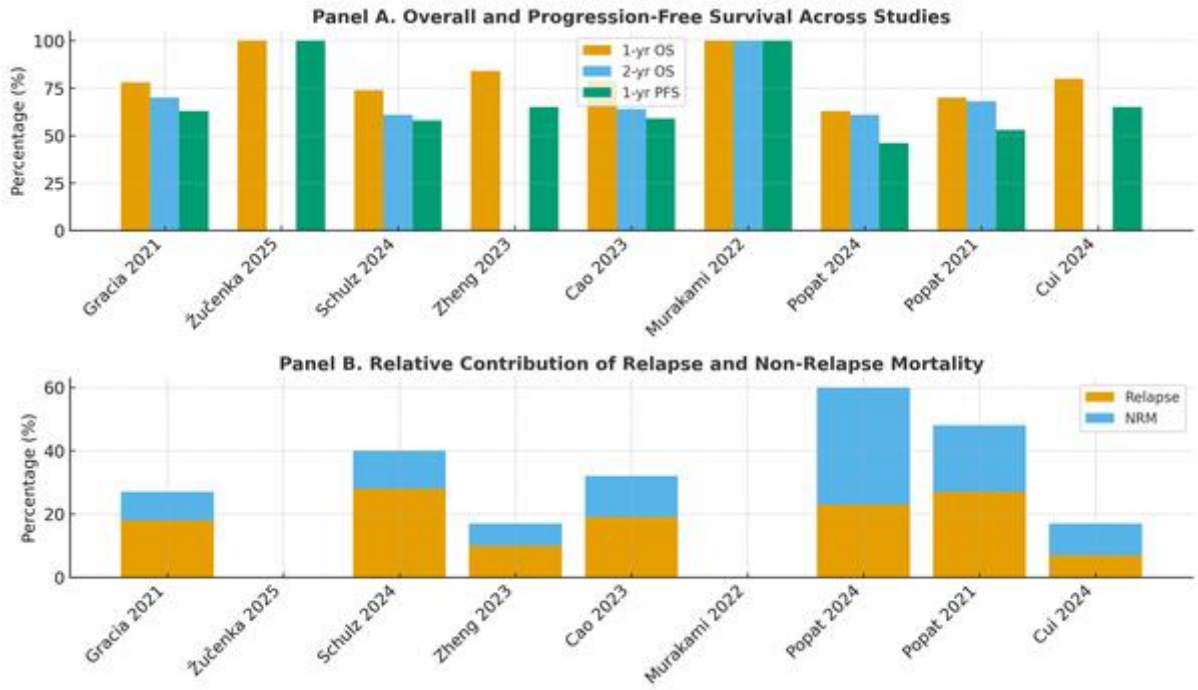

Figure 1. Transplant survival outcomes and mortality composition across included studies

Conclusions: Current evidence suggests that venetoclax-augmented conditioning regimens prior to allo-HSCT are feasible and generally well tolerated, with engraftment, GVHD, and survival outcomes comparable to contemporary transplant benchmarks in high-risk myeloid malignancies. Ongoing prospective and randomized trials will be critical to define optimal dosing, scheduling, and patient selection, and to clarify whether venetoclax-based conditioning improves disease control and post-transplant outcomes.

FLUDARABINE AUC EXPOSURE IS NOT PREDICTIVE OF MORTALITY IN THE CONTEXT OF FLUDARABINE BUSULFAN AND ATG CONDITIONED TRANSPLANTATION

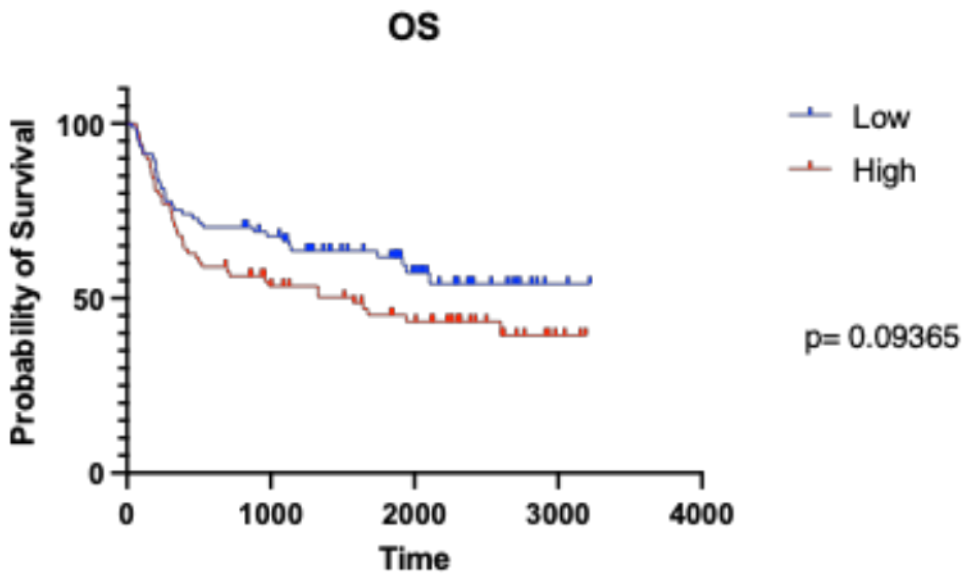
Alexander Glover[1], *Karina Harrington Edwards*[2], *Sarah Halligan*[1], *Christopher Fox*[2]
[1]*Nottingham University Hospital, Nottingham, United Kingdom of Great Britain and Northern Ireland (the),* [2]*Nottingham University, Nottingham, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Fludarabine (Flu) is a core component of allogeneic transplantation conditioning, providing lymphodepletion and reducing graft rejection risk. However,

conventional body-surface-area (BSA) dosing results in wide interpatient variability in drug exposure, measured as the area under the plasma concentration–time curve (AUC). Both high and low Flu exposure have been linked to increased non-relapse mortality (NRM), particularly in myeloablative or T-replete settings. We evaluated the association between Flu AUC and outcomes in patients receiving a uniform reduced-intensity conditioning (RIC) regimen of Flu/Busulfan/rabbit anti-thymocyte globulin (Flu/Bu/rATG), using a population pharmacokinetic (popPK) model to assess whether AUC-guided dosing could provide clinical benefit.

Methods: We retrospectively identified all patients with myeloid malignancies who received a Flu/Bu/rATG RIC allogeneic transplant at Nottingham City Hospital between January 2016 and September 2022. Conditioning consisted of Fludarabine 30 mg/m² (Day −9 to −5), Busulfan 3.2 mg/kg (Day −5 to −3), and rATG 2.5 mg/kg (Day −2 to −1). Fludarabine dose was reduced by 20% for patients with creatinine clearance 30–70 mL/min. Graft-versus-host disease (GVHD) prophylaxis included ciclosporin and mycophenolate mofetil. Fludarabine AUC was calculated using a validated population pharmacokinetic (popPK) model: AUC= (cumulative dose)/(((0.782 ×EGFR)+3.24)×((〖BW/70)〗^0.75)) (Langenhorst et al., 2019). The cutoff for fludarabine exposure was determined compared to median exposure. Kaplan-Meier logrank analysis was used to compare survival outcomes between the exposure groups. Multivariable Cox regression analysis was used to calculate the role of fludarabine exposure when adjusting for age, gender, donor type, HCT-CI score and diagnosis. The principal outcome measure was overall survival (OS) with secondary outcomes including progression free survival (PFS) and NRM.

Results: A total of 159 patients were included (median age 61 years; 55% male; median HCT-CI 2). Underlying diagnoses were AML (62%), MDS (18%), MPN (13%), and CML (8%). Matched sibling donors accounted for 20% and unrelated donors for 80%. Median follow-up was 68 months. Median Flu AUC was 31.8 mg·h/L (IQR 27.8–35.7), used as the exposure cutoff.
There was no significant difference in OS between the high- and low-exposure groups (p=0.09); median OS was 51 months in the high-exposure group and was not reached in the low-exposure group. One-year NRM was similar between groups (13.6% high vs 12.0% low). Maximally selected log-rank statistics did not identify an alternative AUC threshold predictive of OS. In multivariable Cox regression, Flu exposure category was not associated with OS. PFS was modestly superior in the low-exposure group (p=0.04), although this was not significant in the regression analysis. Given prior evidence linking high Flu exposure primarily to NRM rather than relapse risk, the clinical relevance of this isolated PFS difference remains uncertain.



Conclusions: In this single-centre cohort treated with homogeneous Flu/Bu/rATG RIC, we did not identify a Flu AUC threshold associated with increased NRM or inferior OS, contrasting with studies in myeloablative, T-replete or haplograft settings. These findings suggest that in RIC regimens incorporating rATG, optimising Flu exposure alone may not substantially influence outcomes. Further validation in external cohorts is needed before adopting AUC-guided Flu dosing in this context.

SUPERIORITY OF TBI-BASED COMPARED TO MELPHALAN-BASED CONDITIONING REGIMEN IN HAPLOIDENTICAL HEMATOPOIETIC STEM CELL TRANSPLANTATION: COMPARISON BETWEEN DIFFERENT APPROACHES OF TWO MAJOR PEDIATRIC TRANSPLANTATION UNITS

*Amadeus T. Heinz[1], **Tim Flaadt**[1], Philip Heesen[2], Tina Ganzenmüller[1], Sven Oberwegner[1], Franco Locatelli[3], Peter Lang[1], Pietro Merli[3]*
[1]University of Tübingen, Tübingen, Germany, [2]University of Zurich, Zurich, Switzerland, [3]Bambino Gesù Children's Hospital, Rome, Italy

Background: Transplantation of *ex vivo* α/β T- and CD19-depleted stem cell grafts has become an established approach for haploidentical stem cell transplantation (HSCT), particularly in the pediatric setting. Beyond graft manipulation, multiple transplant-related

variables influence clinical outcomes, including the conditioning regimen administered prior to graft infusion. Both chemotherapy-based and total body irradiation (TBI)-based regimens are commonly employed; we therefore aimed to compare their impact between two major transplant centers.

Methods: All consecutive paediatric patients undergoing HSCT for acute lymphoblastic T- or B-cell leukemia (ALL) or acute myeloblastic leukemia (AML) in Tuebingen, Germany and Rome, Italy, over the time span of 10 years (2010-2022) were analyzed.
A propensity scored full matching model including age, status at transplant, number of transplantations and minimal residual disease (MRD) at transplant, was calculated in order to dissect the role of conditioning regimen in determining the outcome of patients.

Results: Patients diagnosed with acute lymphblastic leukemia (ALL) or acute myeloblastic leukemia (AML) at a median age of 10.1 years underwent HSCT in Rome (n=225) or Tuebingen (n=70). Overall, patients treated in Rome presented with a more favorable risk profile, most undergoing first transplantation in complete remission, and received total body irradiation (TBI) as part of the conditioning regimen. In contrast, the majority of patients treated in Tübingen had an unfavorable risk profile, frequently undergoing second or subsequent transplantation for refractory disease, and received melphalan-based conditioning. In details, the majority of patients undergoing HSCT in Rome received the first transplantation (n=195/225, 87%) in complete remission (n=196/225, 87%), whereas in Tuebingen, many patients underwent the second or third transplantation (n=48/70, 69%), and n=26 patients transplanted in non-remission. For patients in first or second CR, 3-year event-free survival (EFS) was 75% (69-81; 95 CI) in Rome vs. 46% (27-76; 95 CI) in Tuebingen ($p<0.001$). The propensity scored matching model calculated was not reliable for AML patients as not enough matching pairs could be identified, while it was well applicable to ALL patients. The model included age, status at transplant, number of transplantations and minimal residual disease (MRD) at transplant, and showed that the type of conditioning regimen used (TBI- vs. Melphalan-based) was a highly predictive prognostic factor for EFS in ALL patients with a HR of 0.24 [0.10-0.57; 95 CI, $p=0.001$].

Conclusions: Matched-pair analysis of patients with comparable risk profiles demonstrated that a TBI-based conditioning regimen significantly improved event-free survival compared with a melphalan-based approach in children with ALL. Despite advances in haploidentical stem cell transplantation, survival outcomes remain suboptimal in ALL or AML patients with an unfavorable risk profile. In this high-risk subgroup, HSCT might be used as a platform for subsequent post-transplant interventions, such as immunotherapy with therapeutic antibodies or cellular therapy.

Disclosure: No conflicts of interest to disclose.

EFFICACY AND SAFETY OF MELPHALAN/TBI-BASED CONDITIONING REGIMENS (MCAC/TCAC) FOR AUTOLOGOUS HSCT IN ADULT ACUTE LYMPHOBLASTIC LEUKEMIA: A MULTICENTER, PROSPECTIVE COHORT STUDY

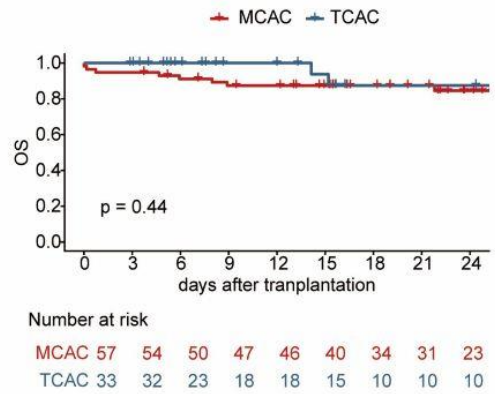
*Xinhui Zheng[1], **Jieya Luo**[1], Erlie Jiang[1], Xin Chen[1]*
[1]Institute of Hematology and Blood Diseases Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Tianjin, China

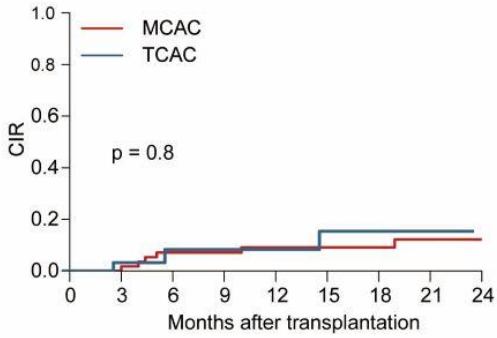
Background: Autologous hematopoietic stem cell transplantation (auto-HSCT) is a primary consolidation option for adult acute lymphoblastic leukemia (ALL) patients with sustained minimal residual disease (MRD) negativity, valued for its safety and donor independence. While traditional TBI-based conditioning is effective, its use is limited by poor accessibility and severe long-term toxicities. Consequently, we initiated a prospective, multicenter trial to evaluate a novel melphalan-based conditioning regimen for adult ALL undergoing auto-HSCT.

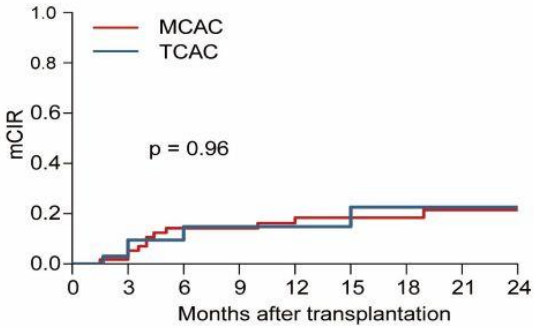
Methods: From Oct 2023 to Apr 2025, 90 B-ALL patients were enrolled, assigned based on TBI availability and patient preference. Eligibility required sustained MRD negativity (and complete molecular response for Ph+ patients) within three chemotherapy cycles. Exclusion criteria included CNS leukemia, extramedullary disease, ETP-ALL, Ph-like ALL, or T-ALL. The MCAC regimen comprised melphalan (70 mg/m², days -8, -7), cyclophosphamide (40 mg/kg, days -6, -5), and cladribine (5 mg/m²) plus cytarabine (2 g/m²) on days -4 to -2. The TCAC regimen used fractionated TBI (10 Gy total) followed by identical chemotherapy.

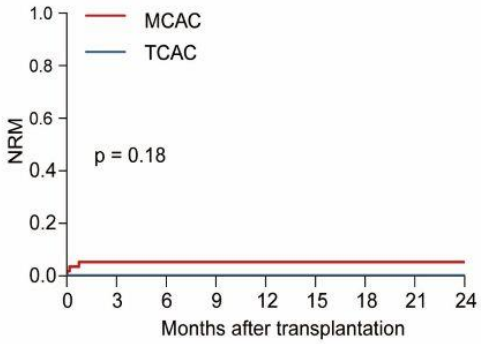
Results: A total of 90 adult ALL patients were enrolled, with 57 in the MCAC group and 33 in the TCAC group. The MCAC and TCAC groups were comparable at baseline, with no significant differences in age, sex, infused cell dose, disease type, or risk stratification. The median follow-up period was 16.5 months. Engraftment kinetics were comparable between the MCAC and TCAC arms, with a median time to neutrophil engraftment of 11 vs 12 days (p=0.3) and platelet engraftment of 17 vs 18 days (p=0.4), respectively.
At 18 months, survival outcomes were comparable between the MCAC and TCAC groups. The OS rate was 87% (95% CI, 79-97%) for MCAC vs 88% (95% CI, 73-100%) for TCAC (p=0.44). The cumulative incidence of relapse (CIR) was also similar at 9% (95% CI, 3-19%) vs 15% (95% CI, 3-36%) (p=0.8), as was molecular CIR at 18% (95% CI, 9-30%) vs 23% (95% CI, 7-44%) (p=0.96). Non-relapse mortality (NRM) was 5% (95% CI, 1-13%) in the MCAC group and 0% in the TCAC group (p=0.18).
In subgroup analysis, Ph+ B-ALL patients appeared to benefit more from the MCAC regimen (18-month mCIR: 19% vs 46%, p=0.24), while Ph- B-ALL patients seemed to favor the TCAC regimen (mCIR: 18% vs 0%, p=0.12); however, neither difference was statistically significant.
The incidence of Grade 3-4 toxicities during conditioning for MCAC versus TCAC group was: diarrhea (8 [14%] vs 0), hepatic dysfunction (2 [3.5%] vs 0), and oral mucositis (2 [3.5%] vs 1 [3%]). Other adverse events in MCAC group, included engraftment syndrome (4 [7%]), cardiac dysfunction (3 [5.3%]), and cerebral hemorrhage (1 [1.8%]). In TCAC group, notable events included engraftment syndrome (3 [9%]) and gastrointestinal bleeding (2

[6%]).









Conclusions: These preliminary findings suggest that the MCAC regimen appears to be a viable and safe alternative to TBI-based conditioning for auto-HSCT in adult ALL patients who achieve and sustain early MRD negativity. However, as enrollment in the TBI-based conditioning arm is not yet complete and the follow-up duration for both groups remains short, long-term efficacy and safety require further investigation.

COMBINATION OF 7.5 MG/KG ATG WITH BASILIXIMAB AS AN EFFECTIVE REGIMEN FOR PATIENTS WITH SEVERE INFUSIONAL SIDE EFFECTS IN HAPLOIDENTICAL HEMATOPOIETIC STEM CELL TRANSPLANTATION

Tingting Han[1], *Fengmei Zheng*[1], *Yuanyuan Zhang*[1], *Jun Kong*[1], *Zhengli Xu*[1], *Haixia Fu*[1], *Jing Liu*[1], *Chenhua Yan*[1], *Yuqian Sun*[1], *Meng Lv*[1], *Xiaodong Mo*[1], *Yifei Cheng*[1], *Lanping Xu*[1], *Xiaohui Zhang*[1], *Xiao-Jun Huang*[1], *Yu Wang*[1]
[1]*Peking University Peoples' Hospital, Beijing, China*

Background: The granulocyte colony-stimulating factor (G-CSF)/antithymocyte globulin (ATG)-based protocol is widely employed in haplo-hematopoietic stem cell transplantation (HSCT). However, ATG-associated severe infusional side effects(ISE) necessitates drug discontinuation, which cumulatively increases graft-versus-host disease (GVHD) risk. Accordingly, at our center, any patient that with severe ISE during the ATG course, the ATG dosage was reduced to 7.5 mg/kg and basiliximab was added.

Methods: To evaluate the efficacy and safety of this regimen in patients with ATG associated severe ISE compared to a control group (patients without severe ISE) administered the classical protocol (ATG 10 mg/kg). We conducted a single-center, retrospective, case-pair cohort study included 544 consecutive patients diagnosed with hematological malignancies that underwent haplo-HSCT at the Peking University People's Hospital between January 2023 and December 2024. Among them, 30 patients received 7.5 mg/kg ATG combined with basiliximab. Propensity score matching (PSM) ratio using nearest-neighbor matching was used to minimize the impact of potential confounders, matching 90 patients who underwent haplo-HSCT with ATG 10 mg/kg. Ultimately, 120 patients were included in the study.

Results: Till 18 September 2025, the median follow-up time was 485 days (range: 21–962) post-HSCT. Cumulative incidences of grades I–IV and II–IV acute GVHD were comparable between the two groups (23.3±7.8% vs. 26.7±4.6%; 6.7±4.6% vs. 14.4±3.7%). Similarly, the 1-year cumulative incidences of moderate-to-severe chronic GVHD (13.8±6.6% vs. 8.0±2.9%), did not differ significantly between the two groups.
One patient in the ATG 7.5 mg/kg + CD25 group did not achieve white blood cell (WBC) engraftment, and one patient in the ATG 10 mg/kg group also failed to achieve WBC engraftment. The cumulative incidence of platelet engraftment on day 100 were similar between the two groups (83.3±7.4% vs. 93.3±2.8%), with median engraftment times of 15 and 13 days post-HSCT, respectively. The 1-year cumulative incidences of relapse (6.9±4.9% vs. 14.8±3.8%), The 1-year cumulative incidences of TRM (16.7±6.9% vs. 12.2±3.4%) and the cumulative incidence of Cytomegalovirus and Epstein-Barr virus viremia at 180 days post-HSCT did not differ significantly between the two groups. At 1 year post-HSCT, the probabilities of overall survival and disease-free survival, were 79.7% vs. 80.4% and 76.4% vs. 72.9% for the ATG 7.5 mg/kg+CD25 and ATG 10 mg/kg groups, respectively.

Conclusions: Overall**,** the combination of 7.5 mg/kg ATG with basiliximab represents a feasible and effective protocol for treating patients who develop severe ISE during ATG treatment.

FROM PBPK TO BEDSIDE: VIRTUAL TWIN–GUIDED FLUDARABINE DOSING IN PEDIATRIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Mourad Mseddi[1], *Christa Nath*[2,3], *Khalil Ben Hassine*[1], *Vid Mlakar*[1], *Yvonne Gloor*[1], *Fanny Gonzales*[1,4], *Chakradhara Rao S. Uppugunduri*[1,5], *Youssef Daali*[4], *Steven Keogh*[2], *Marc Ansari*[1,4]
[1]*University of Geneva, Geneva, Switzerland,* [2]*The Children's Hospital at Westmead, Westmead, Australia,* [3]*University of Sydney, Camperdown, Australia,* [4]*University Geneva Hospitals, Geneva, Switzerland,* [5]*Regional Cancer Center JIPMER, Puducherry, India*

Background: Fludarabine is a key lymphodepleting agent in conditioning regimens before hematopoietic stem cell transplantation (HSCT). Yet, its pharmacokinetics show marked interpatient variability in children, contributing to suboptimal exposure–outcome relationships despite body surface area–based dosing. Physiologically based pharmacokinetic (PBPK) virtual twin (VT) approaches allow integration of patient-specific physiology, including renal function and protein binding, and may support model-informed precision dosing (MIPD) in pediatric HSCT.

Methods: A whole-body PBPK model for fludarabine and its main metabolites (fludarabine-hypoxanthine and fludarabine triphosphate) was developed in PK-Sim® using literature-derived physicochemical and pharmacokinetic data, and optimized with a middle-out strategy in adult HSCT cohorts. The model was then scaled to pediatrics by implementing age-dependent physiological changes and validated against published pediatric concentration–time data, including intracellular triphosphate levels. For VT simulations, individual virtual twins were generated for a subset of pediatric HSCT patients receiving intravenous fludarabine, by replacing population PK-Sim® default values with observed values such as renal function (estimated or measured glomerular filtration rate, eGFR/nGFR), hematocrit, and serum protein concentrations via a plasma protein scale factor (PPSF). Model performance was assessed by comparing predicted and observed total and unbound plasma $AUC_{0-->24h}$ using mean and geometric mean fold error (MFE, GMFE), absolute average fold error (AAFE), proportions of predictions within predefined fold-error ranges, Deming regression, and Bland–Altman analyses.

Results: In adults and external pediatric datasets, the PBPK model captured fludarabine and metabolite disposition across dose levels, with most observed concentrations and AUCs falling within the 0.8–1.25 bioequivalence bounds, and urinary excretion consistent with reported renal elimination. In the pediatric VT cohort, the demographics-only model slightly underestimated exposure but already achieved acceptable accuracy, with approximately 90% of $AUC_{0->24h}$ values for total and unbound fludarabine concentrations within a two-fold range of observed data and AAFE below 2.0. Informing the VT model with PPSF improved prediction of total plasma exposure, whereas incorporating measured nGFR better reflected true renal clearance; the combined PPSF and nGFR-informed VT model yielded the lowest bias, and

most favorable MFE (about 0.91 and 0.88 for total and unbound compartments, respectively), with Deming regression slopes closest to unity and minimal Bland–Altman bias. In contrast, models simultaneously informed by PPSF, hematocrit, and GFR did not further enhance accuracy and sometimes increased variability.

Conclusions: This PBPK-based VT framework reliably predicts individual fludarabine exposures in pediatric HSCT patients across age groups, supporting its use in selecting initial doses and refining conditioning regimens. Among the tested configurations, the PPSF and nGFR-informed VT model offers the best balance between accuracy and bias for both total and unbound fludarabine and is therefore the preferred model to retain for VT-guided MIPD in this setting. Implementation of this approach in clinical practice could help target exposure windows associated with improved HSCT and cellular therapy outcomes, ultimately contributing to safer and more effective conditioning in children.

A SIMULATED PK/PD INVESTIGATION OF RATG, FLUDARABINE, AND THIOTEPA IN HAPLO-IDENTICAL TRANSPLANT FOR SICKLE CELL DISEASE; A VANDERBILT GLOBAL HAPLO-IDENTICAL BMT LEARNING COLLABORATIVE (VGC^2) ANALYSIS

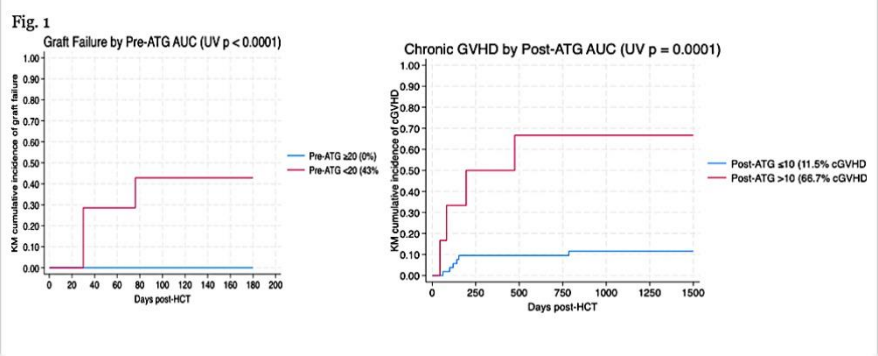
Kanayo Nwankwo[1], James Connelly[2], Haley Hawkins[2], Adetola Kassim[2], Hemalatha Rangarajan[3], Janel Long-Boyle[4], ***Jaap-Jan Boelens***[1]
[1]Memorial Sloan Kettering Cancer Center, New York, United States of America (the), [2]Vanderbilt University Medical Center, Nashville, United States of America (the), [3]Nationwide Children's Hospital, Columbus, United States of America (the), [4]University of California, San Francisco, San Francisco, United States of America (the)

Background: Outcomes of haplo-identical hematopoietic cell transplant (haplo-HCT) for sickle cell disease (SCD) are promising in adults, with no graft failure (GF) and low rates of

chronic graft-versus-host disease (cGvHD) (Blood, 2024). However, outcomes in participants <18 years are markedly worse, with GF occurring in 15–25% and cGvHD in up to 30% of pediatric patients. We hypothesized that variability in conditioning agent exposure (pharmacokinetics, PK) between weight cohorts correlates with these clinical differences.

Methods: SCD patients on the VGC2 haplo-HCT protocol were included. They received the reduced-toxicity conditioning including rabbit anti-thymocyte globulin [rATG], Thiotepa [TT], Fludarabine, and 200cGy TBI. GVHD prophylaxis consisted of post-HCT cyclophosphamide (PTCy), sirolimus, and mycophenolate mofetil. rATG, TT, and Fludarabine exposures were simulated using validated population-PK models on the InsightRx platform. Main outcomes were GF and moderate/severe cGvHD. Based on cohort distributions and published data, we evaluated Pre-HCT rATG exposure) <20 vs ≥20 AU·day/mL and post-HCT rATG exposure ≤10 vs >10 AU·day/mL. Cumulative incidence was estimated using Kaplan–Meier failure curves with univariate log-rank tests.

Results: 59 patients were included (8 participants <18 years); median age was 23 years (range 8–52). Three patients (all<18 years) experienced GF, and 10 total developed moderate/severe cGvHD. Median pre-HCT rATG exposure was 25 AU·day/mL (range 9.94–36.7) while median post-HCT rATG exposure was 5.39 AU·day/mL (range 0.289–16.2). Combined thiotepa + TEPA exposure was median 54.1 mg·h/L (range 36.2–73.2). Median fludarabine exposure was 21.7 mg·h/L (range 18.8–36.3). Patients with pre-HCT rATG exposure of < 20 AU·day/mL had a 180-day GF rate of 43% (3 out of 7), compared to 0% (0 out of 52) with pre-HCT rATG-exposure ≥20 AU·day/mL (p<0.0001) (Fig.1 Right). All GF events occurred in the low-exposure group and were associated with negligible donor CD3 T-cell chimerism (median 0%, range 0–15%). Conversely, patients with pre-HCT rATG exposure ≥20 AU·day/mL, achieved high chimerism (median 100%; range 27%-100%). Patients with post-HCT rATG exposure >10 had a 66.7% (4/6) cGVHD rate, compared to 11.5% (5/53) in those with post-HCT rATG exposure ≤10 (p=0.0001; Fig. 1Left). Although exposures to TT/TEPA and fludarabine were highly variable, in this small cohort of 59, exposures were not related to the outcomes of interest.



Conclusions: This preliminary analysis suggests that pre-HCT rATG underexposure is associated with GF, while post-HCT rATG overexposure is associated with cGVHD. Inadequate recipient immune-ablation, and interference of rATG with alloreactive T-cell depletion by PTCy might be the cause for this. A larger dataset, potentially including patients from the BMT-CTN 1507 trial, is needed to confirm these findings. Model-based dosing of rATG and possibly also

TT and Fludarabine (targeting to optimal exposures), might improve the outcomes and needs to be tested in a prospective trial.

ASSOCIATION BETWEEN BUSULFAN EXPOSURE AND OVERALL SURVIVAL AND TOXICITY IN HAPLOIDENTICAL HAEMATOPOIETIC STEM CELL TRANSPLANT WITH MYELOABLATIVE CONDITIONING – A PROSPECTIVE, MULTICENTRE ANALYSIS

Annabelle Robinson[1], *Christa E. Nath*[2], *Karim Ibraham*[1], *Steven Keogh*[2], *Ashish Bajel*[3], *David Ritchie*[3], *John Kwan*[4], *David Gottlieb*[4], *Nada Hamad*[1], *Matthew Greenwood*[5], *John Moore*[1]
[1]*St Vincent's Hospital, Sydney, Australia,* [2]*Cancer Centre for Children, The Children's Hospital at Westmead, Westmead, Australia,* [3]*Royal Melbourne Hospital, Melbourne, Australia,* [4]*Westmead Hospital, Sydney, Australia,* [5]*Royal North Shore Hospital, Sydney, Australia*

Background: Busulfan(Bu) is an alkylating agent used in myeloablative conditioning (MAC) for haematopoietic stem cell transplant (HSCT). Bu has highly variable pharmacokinetics (PK) and there is currently no consensus regarding the optimal target range, particularly in the haploidentical setting (haplo-HSCT). To the best of our knowledge, this is one of the first prospective studies exploring outcomes associated with Bu exposure in adult patients undergoing busulfan-fludarabine MAC prior to haplo-HSCT.

Methods: This prospective subgroup analysis was derived from the phase 2 study of peripheral blood haplo-HSCT (ANZHIT-1 study), conducted between 2015 and 2020.[1] Patients from four centres with Bu PK assessment were included. Standard conditioning comprised intravenous fludarabine and Bu 3.2 mg/kg on days −5 to −2. In a subset of 10 patients, the day -5 was given as 1.6 mg/kg divided over D−5 and −4, with PK monitoring guiding Bu dose adjustment commencing on day−3. Bu area-under-the-concentration–time curves ($AUC_{0-\infty}$), calculated using trapezoidal rule, were available for the first dose in 28 patients and for both first and last doses in 18 patients. Clearance (CL) was calculated as dose/AUC, and cumulative AUC (cAUC) as total Bu dose divided by average CL (first and last day). Paired Wilcoxon test compared CL between days 1 and 4. Kaplan–Meier survival

analysis and multivariate Cox regression assessed the impact of Bu cAUC above versus below the median (79.7 mg/L·h) on outcomes.

Results: 28 patients with haematological malignancies (median age 40 years) were included. At a median follow up of 686 days, (range 76–1522 days), 5 experienced TRM within 1 year due to chronic GvHD(2), acute GvHD, VOD, and graft failure. There were 2 deaths secondary to relapse and 1 death due to multiorgan failure.
Median Bu AUC was 18.9 mg/L.h(IQR:15.9–22.7) on day 1 and 20.4 mg/L.h(IQR:19.1–23.5) on day 4; a significant decrease (median 14%) in CL was observed (p<0.005). Median cAUC was 79.7mg/L.h overall for 18 patients who had AUC measured after the last dose. Dose reductions (median −24%) in 13 patients maintained AUC despite declining CL with no adverse effect on outcomes. Median days to chimerism was 50; median donor cells 100%. cAUC above or below 79 mg/L.h was associated with a median of 46 and 54 days to chimerism respectively. Two graft failure and two (of 3) VOD cases occurred with cAUC >79.7 mg/L·h despite Bu dose reduction on day -2. Mean OS was 3.96 years and longer with Bu cAUC >79.7 mg/L·h (3.96 vs 2.69 years; p = 0.151). Mean DFS was 3.6 years. In multivariate analysis, higher cAUC tended to have a protective effect on OS (HR 0.214, 95% CI 0.04 – 1.2, p =0.078). Graft failure predicted worse OS, TRM and DFS (p< 0.05).

Conclusions: In haplo-HSCT, higher Bu cAUC was associated with a trend to longer mean survival time, however was associated with VOD. Larger studies are required to define the optimal AUC target and clarify the impact of Bu exposure on outcomes in haploidentical HSCT.

Disclosure: Nothing to declare.

LONG-TERM FOLLOW-UP WITH TREOSULFAN BASED CONDITIONING REGIMEN IN HEMATOLOGICAL MALIGNANCIES: A SINGLE CENTER EXPERIENCE

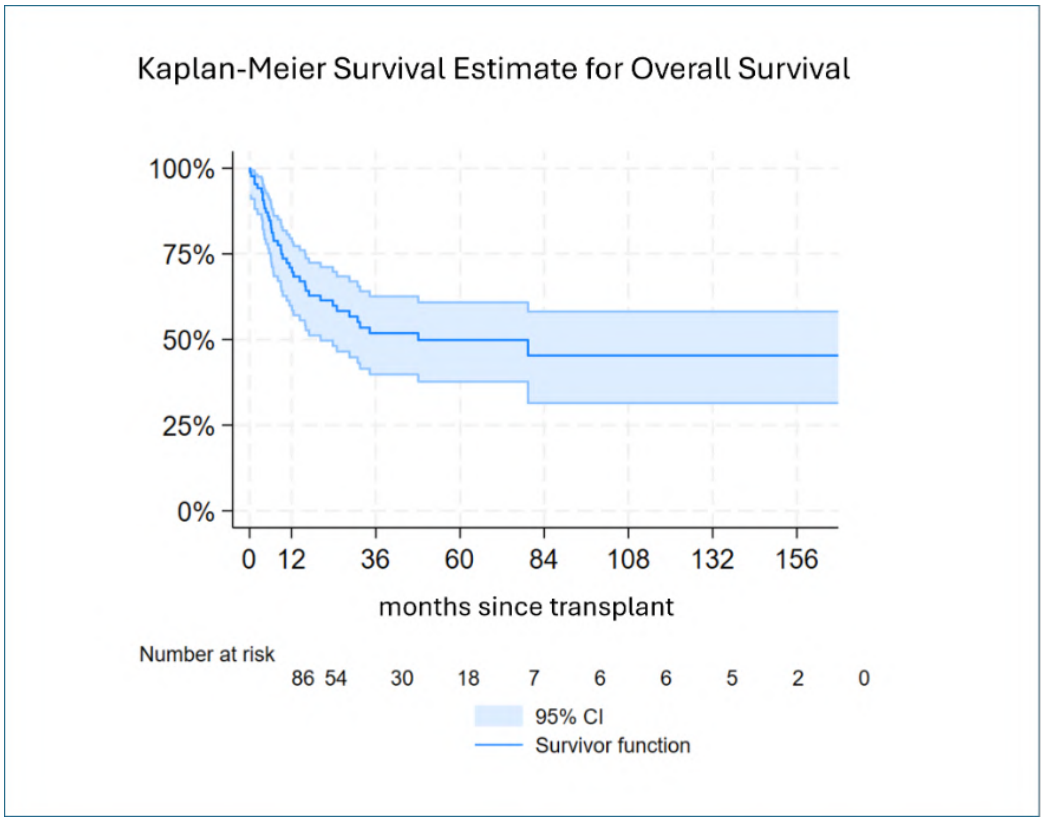
Martina Salvatori[1], Walter Barberi[1], Nadia Lopez[1], Marco Antonacci[1], Renata Celia[1], Biancamaria Mandelli[1], Ursula La Rocca[2], ***Anna Paola Iori***[1]
[1]Sapienza University of Rome, Rome, Italy, [2]Italian National Institute of Health, Rome, Italy

Background: Treosulfan is increasingly used in conditioning regimen for allogeneic hematopoietic stem-cell transplantation (HSCT) due to its myeloablative activity and immunosuppressive effect with low toxicity. Its favorable toxicity profile supports its use for malignant and non-malignant indications, including in older or frail patients. Evidence from real-world clinical practice, especially in adult populations, remains limited and heterogeneous.

Methods: We conducted a monocentric retrospective analysis of adult and pediatric patients who underwent HSCT at our center between 2006 and 2024. All patients received treosulfan-based conditioning (total dose 30–42 g/m²) plus fludarabine. Graft Versus Host Disease

(GvHD) prophylaxis was administered following institutional protocols. Outcome parameters analyzed were engraftment, acute and chronic GvHD, non-relapse mortality (NRM), relapse incidence, overall survival (OS), and disease-free survival (DFS). Statistical analyses were performed using STATA 19.0. OS and DFS were estimated using the Kaplan–Meier method, and NRM with cumulative incidence analysis.

Results: A total of 90 patients (50 males and 40 females) underwent HSCT, with a median age at transplant of 57.5 years (range 4–75). Treosulfan was administered at a total dose of 14 g/m² in 66 patients, 12 g/m² in 18 patients, and 10 g/m² in 6 patients, according to patient-specific characteristics. The analysis included 86 patients who had complete data available. Underlying diseases, patients' stratification according to HCT comorbidity index, stem cell sources and donor type are detailed in Table 1. GvHD prophylaxis was administered considering donor type and institutional protocols, as reported in Table 1. Neutrophils and platelets engraftment occurred at a median of 20 (IQR 18-24 days) and 24 days (IQR 18-33 days), respectively. The cumulative incidence of acute III-IV grade GvHD was 34.9%: grade III-IV aGVHD was observed in 8% of patients. The cumulative incidence of chronic GvHD was 12.8%. Veno-occlusive disease (VOD) occurred in two patients, one of whom had pre-existing portal hypertension due to myelofibrosis. We observed 1-year NRM of 19.8%; the relapse incidence was 10.5%. OS at 1, 3 and 5 years after HSCT was 71%, 51%, and 50% respectively. DFS at 1 year and 5-year post transplant were 58% and 41% respectively.



Charateristics	value n (%)
Diagnosis	
AML	57 (66.2%)
MDS	13 (15.3%)
MPN	14 (16.5%)
Other	2 (2.3 %)
Comorbidities (HCT-CI / Sorror Index)	
Low risk	7 (8.1%)
Intermediate	42 (48.8%)
High risk	22 (25.6%)
Missing	15 (17.5)

Acute GvHD	30 (34.9%)
Grade III-IV aGVHD	7 (8.1%)
Chronic GVHD	11 (12.8%)
Moderate-severe cGvHD	7 (8.1%)

Conclusions: This study is the longer monocentric real-world experience with treosulfan-based conditioning. In this study, we confirm that treosulfan offer a manageable safety profile, characterized by low organ toxicity and favorable engraftment kinetics. This is particularly beneficial for older or frail patients, where reduced toxicity is a priority. One-year OS and DFS rates align with previously reported clinical trial data. These findings reinforce the role of treosulfan as a versatile conditioning agent and highlight the need for further

prospective studies to better define its optimal indications and long-term benefits in real-world clinical practice.

HAPLOIDENTICAL HCT IN ADULTS WITH A NON-TBI CONDITIONING REGIMEN: A 10-YEAR SINGLE-CENTER COHORT

Hercules Amorim Mota Segundo[1], João Paulo de Vasconcelos Leitão[2], Beatriz Stela Gomes De Souza Pitombeira Araujo[2], Karine Sampaio Nunes Barroso[2], Livia Andrade Gurgel[2], Rafael da Nóbrega de Alencar[2], Lucas Freire Castelo[2], ***Fernando Barroso Duarte***[1,2]
[1]Universidade Federal do Ceará, Fortaleza, Brazil, [2]Hospital Universitário Walter Cantídio, Fortaleza, Brazil*

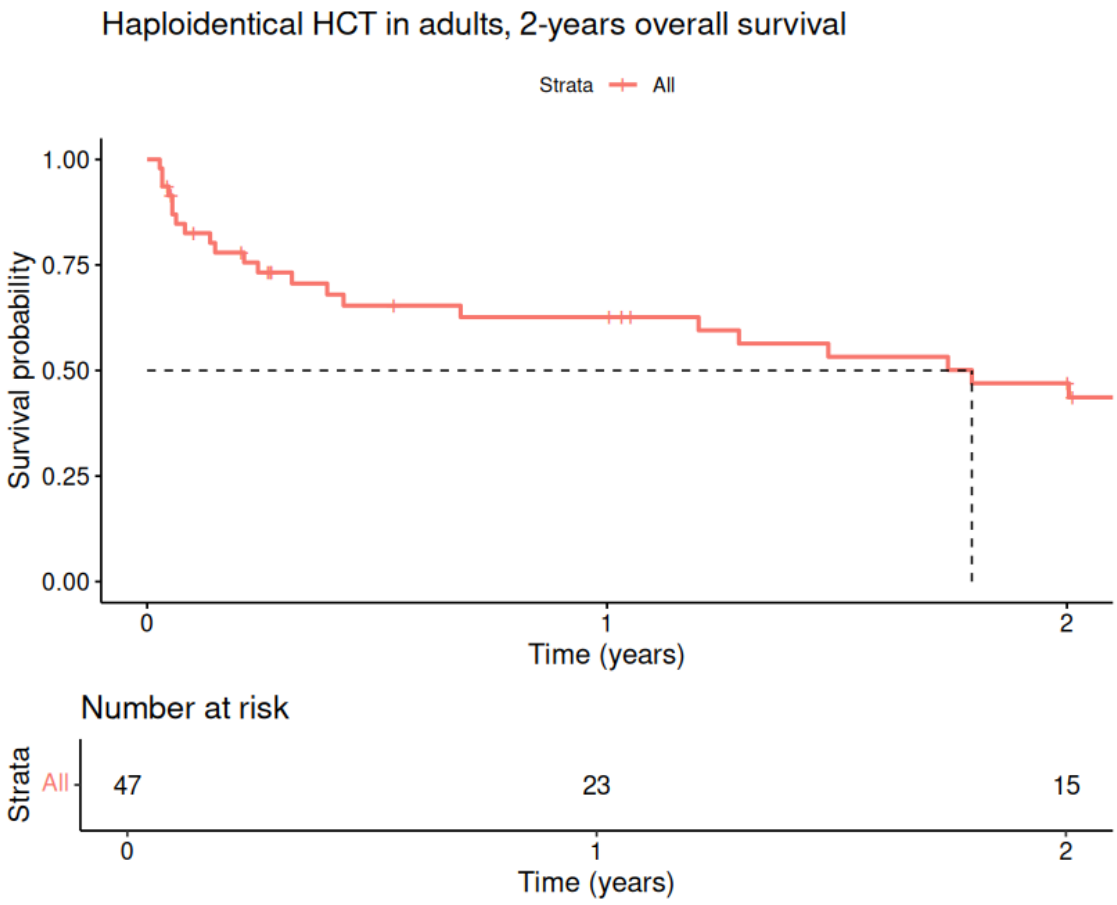
Background: The use of haploidentical donors has enabled hematopoietic cell transplantation (HCT) for a larger number of patients with hematologic malignancies. Total body irradiation (TBI) is widely used in conditioning regimens for this donor type. However, its availability is limited in resource-constrained regions.

Methods: We conducted a descriptive analysis of data regarding haploidentical allogeneic transplants performed in adults aged 18 years or older between 2016 and 2025, indicated for hematologic malignancies, at a university hospital in Northeast Brazil. Survival analysis was performed using the Kaplan-Meier method in R software (version 4.4.2).

Results:

During this period, 47 haploidentical transplants were performed. Acute myeloid leukemia was the most common indication (n = 19), followed by acute lymphoblastic leukemia (n = 16). Peripheral blood was the predominant stem cell source (n = 46). All patients received a conditioning regimen containing busulfan and fludarabine. GVHD prophylaxis consisted of cyclosporine, mycophenolate mofetil, and post-transplantation cyclophosphamide (PTCy). The 1-year and 2-year overall survival (OS) rates for this cohort were 63% and 47%, respectively. Median survival was 1.8 years.

Regarding the older adult subgroup, 14 transplants were performed during this period in patients 50 years or older, with ages ranging from 53 to 66 years. Most received HSC from offspring (n = 12) and siblings (n = 2). Regarding conditioning intensity, 11 transplants utilized reduced-intensity conditioning (RIC). The most frequent severe toxicities (grade 3 or 4) were mucositis (n = 7), hepatic toxicity (n = 2), and vomiting (n = 2). The median time to neutrophil and platelet engraftment was 16 and 21 days, respectively. Two patients developed sinusoidal obstruction syndrome (SOS), progressing to death. Transplant-related mortality (TRM) occurred in 21% of cases (n = 3). Overall survival was 79% at 1 year and 67% at 2 years. Median survival was 2.1 years. Causes of death were relapse (n = 3), SOS (n = 2), infection (n = 1), and secondary malignancy (n = 1).



Conclusions: Haploidentical allogeneic transplantation remains a viable curative option for adults. Non-TBI conditioning regimens may facilitate the procedure in resource-limited regions, in addition to avoiding potential toxicities associated with irradiation.

Disclosure: Nothing to declare.

CLADRIBINE WITH TOTAL BODY IRRADIATION AS A STRATEGY TO OPTIMIZE CONDITIONING REGIMEN IN AML AND MDS: A PROSPECTIVE STUDY OF THE POLISH ADULT LEUKEMIA GROUP

Malgorzata Sobczyk-Kruszelnicka[1], *Wlodzimierz Mendrek*[1], *Monika Dzierzak-Mietla*[1], *Anna Karkosz*[1], *Iwona Mitrus*[1], *Magdalena Głowala-Kosińska*[1], *Andrzej Smagur*[1], *Wojciech Fidyk*[1], *Agata Chwieduk*[1], *Paulina Borzdziłowska*[1], *Sławomir Blamek*[1], *Tomasz Czerw*[1], *Sebastian Giebel*[1]

[1]Maria Skłodowska-Curie National Research Institute of Oncology Gliwice Branch, Gliwice, Poland

Background: Allogeneic haematopoietic stem cell transplantation (allo-HCT) is a standard of care for patients with acute myeloid leukemia (AML) and for intermediate or high-risk myelodysplastic syndrome (MDS). Studies from the the Polish Adult Leukemia Group (PALG) have demonstrated that adding cladribine to induction therapy increases the chances of achieving complete remission and improves overall survival. Both cladribine and Ara-C enhance Ara-CTP levels in leukemia blasts; however, only cladribine exhibits direct cytotoxic and hypomethylating effects, which accounts for the observed differences in efficacy.

Methods: The CLARA study is a project funded by the Medical Research Agency. The aim of this study is to analyze the efficacy and safety of a conditioning regimen combining cladribine with total body irradiation (TBI).
The analysis included 40 patients, with a median age of 45 years (range: 21–60). Patients received allo-HCT from either siblings (15 patients) or unrelated donors (25 patients). The conditioning regimen involved cladribine administration from days -8 to -4, followed by TBI (4Gy in once-daily fractions) from days -3 to -1. Immunosuppressive therapy was based on the donor type: CNI + Mtx + ATG for HLA-matched donors, and PTCy + Tak + MMF for HLA-mismatched donors. Peripheral blood was the stem cell source.

Results: The current median follow-up is 22 (1-43) months. The analysis includes only patients who have been followed for at least 1 year. The 12-month probability of progression-free survival (PFS) and overall survival (OS) was 78% (± 7%). Eight patients died, seven of whom the first 6 months after allo-HCT. The causes of death were as follows: relapse (6 patients), infection complications (1 patient), and other complications (1 patient). For 14 patients, the two-year post-transplant follow-up period has not yet been completed. Grade 3 of acute GvHD was observed in 5 patients, and no cases of grade 4 were reported. Severe chronic GvHD was observed in 3 patients.

Conclusions: The myeloablative conditioning regimen consisting of TBI combined with cladribine may contribute to improved outcomes following allo-HCT for patients with AML and MDS.

IMPACT OF TMLI VERSUS TBI CONDITIONING ON TOXICITY, OUTCOMES, AND RELAPSE IN ALLOGENEIC STEM CELL TRANSPLANTATION FOR ACUTE LYMPHOBLASTIC LEUKEMIA

María Panizo-Inogés[1], *Belén Villacres*[1], *Adriana Martinez-Lage*[1], *Almudena Beneto*[1], *Andrea Urtasun*[1], *María Rodríguez-Ruiz*[1], *Sara Villar*[1], *José Rifón*[1]
[1]Clínica Universidad de Navarra, Pamplona, Spain

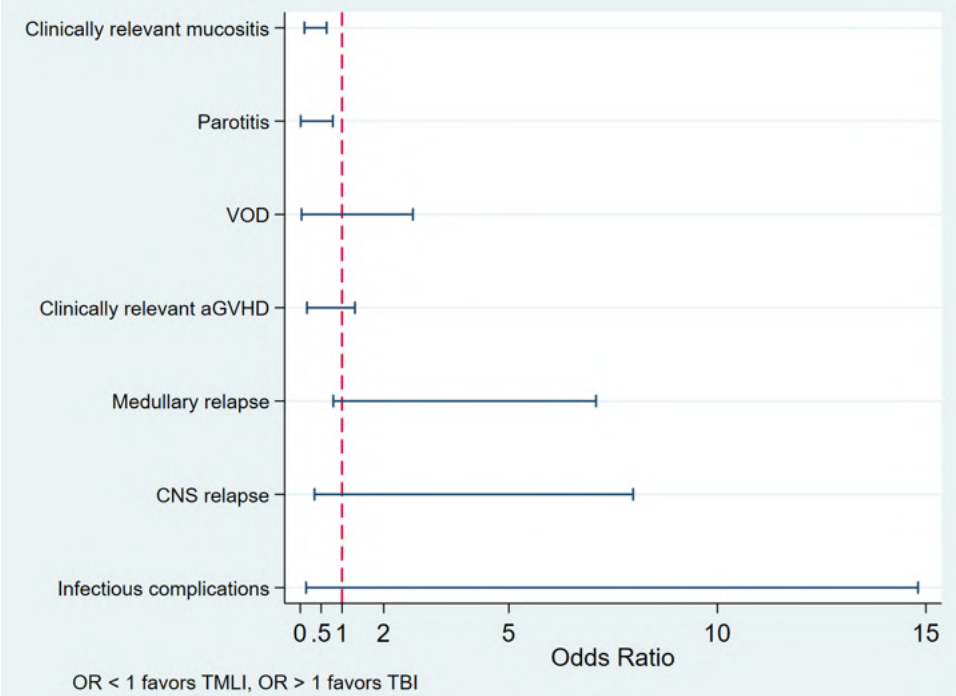
Background: Allogeneic stem cell transplantation (allo-SCT) is the standard consolidation therapy for patients with high-risk B-cell acute lymphoblastic leukemia (B-ALL) in first complete remission (CR1), for standard-risk patients with detectable minimal residual disease (MRD), and for those achieving second or subsequent remissions. Conventional conditioning regimens typically combine fludarabine or cyclophosphamide with total body irradiation (TBI).Total marrow and lymphoid irradiation (TMLI) is an innovative approach that limits toxicity compared to TBI by maximizing the preservation of healthy organs, without compromising antileukemic efficacy. The objectives were to compare the safety and relapse outcomes of TMLI versus TBI at 12 Gy dose as conditioning regimens for allogeneic stem cell transplantation in patients with B-ALL.

Methods: A retrospective study was conducted, including 90 patients with B-ALL who underwent allogenic hematopoietic stem cell transplantation at the Clínica Universidad de Navarra between September 2019 and May 2025. All patients were followed-up for a minimum of 6 months, and relevant clinical and laboratory data were collected. Data analysis was performed using STATA (StataCorp LP).

Results: The median age was 19 years-old (range 5-52) and the cohort included 39 children. 96% of the patients received post-transplant cyclophosphamide as GVHD prophylaxis. Mucositis was observed in 70% and 82% of patients in the TMLI and TBI groups, respectively. Patients receiving TMLI had a significantly lower risk of relevant mucositis (grade≥2) compared to those receiving TBI (OR 0.25, 95% CI 0.10–0.63, p<0.01). TMLI was also associated with a significantly lower risk of parotitis compared with TBI (OR 0.10, 95% CI 0.01–0.78, p=0.03). No cases of radiodermatitis were observed in the TMLI group, in contrast to the TBI group, resulting in a statistically significant difference (p=0.03). No cases of transplant-associated thrombotic microangiopathy (TA-TMA) occurred neither in the TMLI group whereas 4 cases (7%) were observed in the TBI group; however, the difference in incidence between the groups was not statistically significant (p=0.3). Sinusoidal obstruction syndrome (SOS) occurred 3% in TMLI group vs 10% in TBI group without significant association. The incidence of clinically relevant acute graft-versus-host disease (aGVHD) (grade ≥2) was lower in the TMLI group (20% vs 35%) although no association was found (p=0.14). Pulmonary function at 3 months showed no significant differences in overall toxicity (OR 0.93, p=0.88) or diffusion capacity decline (DLCO median: -15.2% TMLI vs -28.4% TBI; p=0.71). Trends toward greater declines in FEV1 (-7.01% vs -2.45%, p=0.11) and FVC (-6.28% vs -1.88%, p=0.07) were observed in TBI, without statistical significance. DLCO impairment was the most frequent pulmonary toxicity in both groups, suggesting early alveolar-capillary compromise, with comparable 3-month pulmonary risk. No association was observed between the use of TMLI and medullary or CNS relapse (OR 2.37, 95% CI 0.79–7.09 and OR 1.66, 95% CI 0.34–7.98 respectively).

	Total (n=90)	TMLI (n=30)	TBI (n=60)	p value
Age (years) (median, range)	19 (5-52)	22 (5-49)	17 (6-52)	0.01

Sex, n (%) Male Female	 59 (66) 31 (34)	 23 (77) 7 (23)	 36 (60) 24 (40)	0.1
Karnofsky-Lansky, n (%) 100 ≤90	 86 (96) 4 (4)	 30 (100) -	 56 (93) 4 (7)	0.3
HCT-CI, n (%) 0-1 ≥2	 64 (71) 26 (29)	 23 (77) 7 (23)	 41 (68) 19 (32)	0.4
Disease status, n (%) CR1 ≥CR2 SD PD	 33 (37) 51 (57) 3 (3) 3 (3)	 13 (43) 16 (53) 1 (3) -	 20 (33) 35 (59) 2 (3) 3 (5)	0.6
Donor type, n (%) MSD MUD MMUD Haploidentical	 3 (3) 16 (18) 16 (18) 55 (61)	 2 (7) 10 (33) 7 (23) 11 (37)	 1 (2) 6 (10) 9 (15) 44 (73)	<0.01
Source, n (%) Peripheral blood Bone marrow	 88 (97) 2 (3)	 30 (100) -	 58 (97) 2 (3)	0.6
EASIX score pre-conditioning, (median, IQR)	0.56 (0.33-0.97)	0.61 (0.42-0.86)	0.52 (0.32-0.97)	0.6



Conclusions: TMLI emerges as a safe radiation modality, with potentially lower rate of complications compared to TBI and no more relapses. However, further studies with larger sample sizes are needed to confirm these findings. Long-term follow-up is essential to better assess the safety profile and efficacy of this new modality.

OUTCOMES OF ALLOGENIC HAEMATOPOIETIC STEM CELL TRANSPLANTATION USING POST-TRANSPLANT CYCLOPHOSPHAMIDE: A 5 YEAR SINGLE CENTRE EXPERIENCE

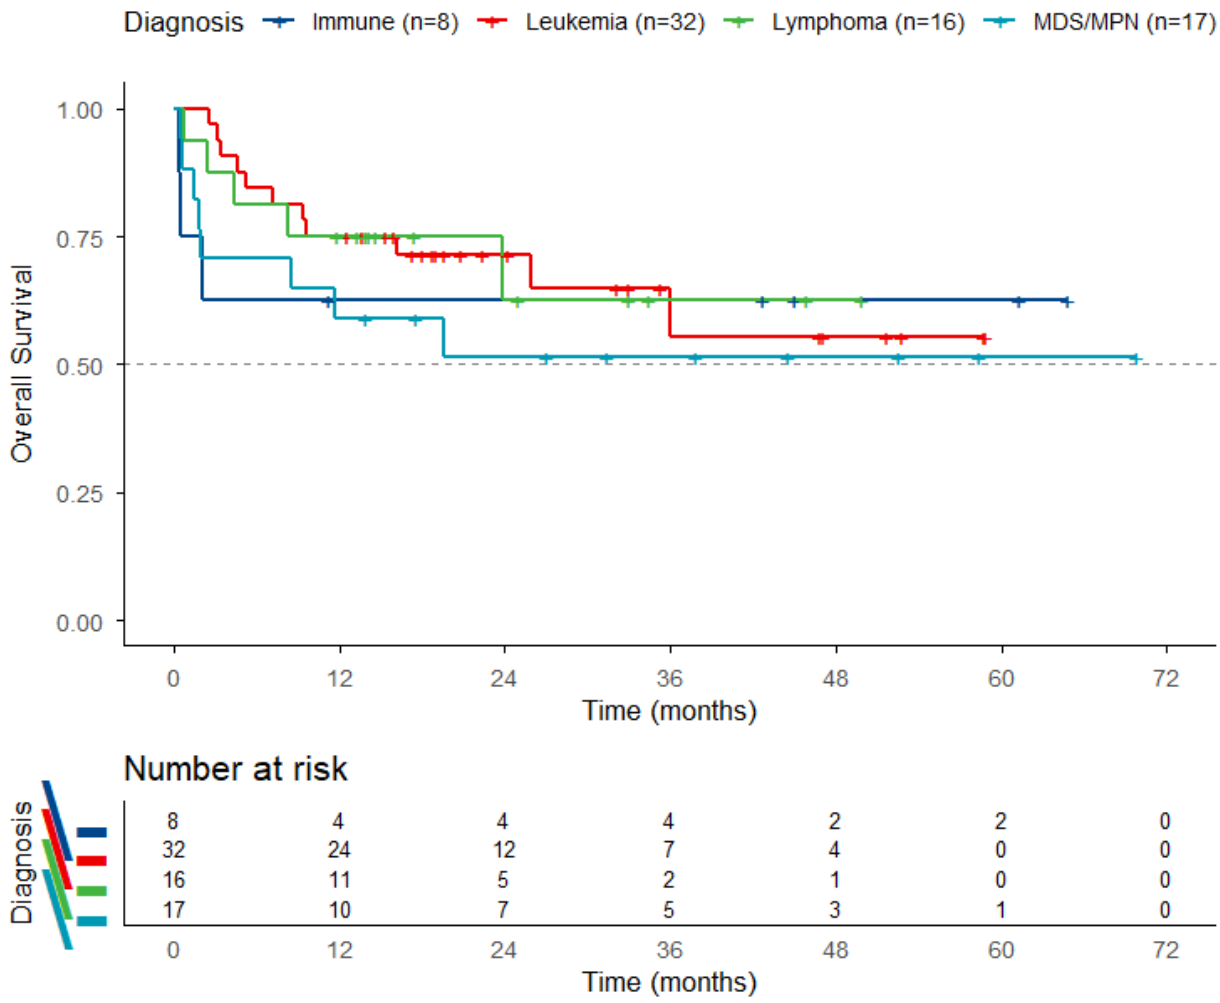
Yashashree Gupta[1], *Nuno Borges*[1,2], *Erin Hurst*[1], *Amy Publicover*[1], *Louise Duncan*[1], *Laura Jardine*[1,2], *Venetia Bigley*[1,2], *Matthew Collin*[1,2]
[1]*Newcastle upon Tyne, NHS Foundation Trust, Newcastle upon Tyne, United Kingdom of Great Britain and Northern Ireland (the),* [2]*Newcastle University, Newcastle upon Tyne, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Post-transplant cyclophosphamide (PTCy) has become a widely adopted strategy for T-cell depletion and graft-versus-host disease (GVHD) prophylaxis in both haploidentical and unrelated donor transplant settings. We conducted a retrospective analysis

to evaluate transplant outcomes, toxicities, infectious complications, and GVHD incidence in patients who received PTCy at our institution.

Methods: All patients who underwent allogeneic haematopoietic stem cell transplantation with PTCy between January 2020 and December 2024 were included. Clinical data were reviewed for demographics, underlying disease, transplant characteristics, survival outcomes, relapse, non-relapse mortality (NRM), infectious and non-infectious complications, chimerism, graft failure, and acute and chronic GVHD.

Results: A total of 73 patients were analysed (median age 54 years, 23 female/50 male). Underlying diagnoses included leukaemia (n=32: AML 23, ALL 5, CML 4), lymphoma (n=16), MDS/MPN (n=16), myeloma (n=1), and immune disorders including aplastic anaemia (n=8). 53 patients received haploidentical transplants and 20 received unrelated donor grafts.
All patients developed neutropenic sepsis; 38 (52%) had culture-proven bacterial infections, 2 had fungal chest infections, 33 (45.2%) patients had viral reactivations. Non-infectious complications included haemorrhagic cystitis (n=4), veno-occlusive disease (n=4), and cardiac events (n=5). Median time of neutrophil and platelet engraftment was 18 and 28 days respectively.
Acute GVHD occurred in 29 (39.5%) patients (median onset day 28), predominantly involving the skin (n=28). Cumulative incidence of grade 3 acute GVHD was 12.3% (8 skin, 2 GI, 1 liver). Chronic GVHD developed in 27 (36.9%) patients (13 mild, 9 moderate, 5 severe) with a median onset at day 210. Thirty patients (41%) did not develop any form of GVHD. Of the 48 patients alive at 1 year post HSCT, 8 patients had chronic GVHD and 4 of these were on systemic treatment.
Graft failure occurred in 7 (9.5%) patients. At 3 months, whole blood donor chimerism was >95% in 46 patients and <95% in 16; it was not assessable in 11 due to early mortality. 48 (65.7%) patients were alive 1 year post HSCT. Median total lymphocyte count was 1.47 $x10^9$/L ,CD4 +T cell count was 324 and CD8 +T cell count was 479 at 1 year.
At a median follow-up of 17 months (0–69), 46 (63%) patients were alive and 27(37%) had died. Relapse occurred in 13 patients, and 15 experienced NRM. 12 (16.4%) patients died within day 100 post-transplant due to infective complications. Of these 1 patient each has stage 3 gut GVHD, CMV colitis, HHV6 CNS infection and VOD along with concomitant sepsis. 54.7% patients were GVHD free and relapse free at 1 year.



Conclusions: PTCy-based GVHD prophylaxis in our cohort was associated with acceptable rates of acute GVHD and manageable chronic GVHD. Infectious complications, particularly bacterial sepsis and viral reactivation remained frequent. Overall survival and outcomes were consistent with contemporary PTCy-based transplant data. Further prospective evaluation is warranted to optimize infection prevention and reduce non-relapse mortality.

Disclosure: We have no disclosures.

FLUDARABINE PLUS TREOSULFAN CONDITIONING FOR OLDER AND COMORBID PATIENTS BEFORE ALLOGENEIC HSCT - A RETROSPECTIVE ANALYSIS IN A REAL-WORLD COHORT

Hanna A. Knaus[1], *Christina Schüller*[1], *Julia Cserna*[1], *Lina Z. Rüsing*[1], *Margit Mitterbauer*[1], *Axel Schulenburg*[1], *Werner Rabitsch*[1], *Hildegard Greinix*[1], *Philipp Wohlfarth*[1]
[1]*Medical University of Vienna, Vienna, Austria*

Background: Reduced-intensity conditioning (RIC) regimens, such as fludarabine/treosulfan (Flu/Treo), offer promising outcomes for older or comorbid patients undergoing allogeneic hematopoietic stem cell transplantation (HSCT). This study evaluates the efficacy and safety of Flu/Treo in an AML cohort at the Medical University of Vienna, comparing our findings to those reported in Beelen et al. (Am. J. Hematol. 2022).

Methods: In our retrospective, IRB approved study we included all AML patients who received Flu/Treo-based HSCT between 2020 and 2024 at our institution. Baseline characteristics and outcomes including overall survival (OS), relapse, non-relapse mortality (NRM), and graft-versus-host disease (GvHD) were recorded. Outcomes were assessed by plotting Kaplan-Meyer curves and evaluated against data from Beelen et al.. Moreover, multivariate COX-regression analyses were computed to identify significant predictors of outcomes.

Results: Our final study included 138 AML patients. Sixty-seven percent received Flu/Treo30 (treosulfan 10 g/m² for 3 days, fludarabine 30 mg/m² for 5 days), consistent with Beelen's cohort, while other regimens included Thio5Treo30Flu (16%), Thio10Treo30Flu (14%), and TreoFluCy (4%). The median follow-up was 15 months (range 8–24 months). Detailed baseline characteristics are provided in the table below.One-year OS was 81% (CI 74–88), two-year OS was 73% (CI 65–81), and three-year OS was 68%. Compared to Beelen's cohort, our Flu/Treo30 subgroup (n=92) had similar 2-year OS (75% vs. 71%) and 3-year OS (69% vs. 67%). Cox regression identified acute GvHD as a significant predictor of poor OS (HR 2.78, p = 0.01). HCT-CI ≥3 trended towards poorer OS, though not statistically significant (HR 2.24, p = 0.069). NRM at 1 year was 9.4%, at 2 years 12.5%, and at 3 years 15.6% (Beelen: 14.2% at 3 years). Relapse rates were 17.3% at 1 year, 19.3% at 2 years, and 27% at 3 years (Beelen: 25.9% at 3 years). Acute GvHD by day 100 occurred in 24%, lower than Beelen's cohort (52%). Chronic GvHD at 2 years was 14% in our cohort versus 18% in Beelen et al.

F/U [mo]	15 [8, 24]

Conclusions: Flu/Treo conditioning demonstrated favorable survival, low relapse, and NRM, and reduced rates of acute and chronic GvHD in older, comorbid AML patients. Acute GvHD was a significant predictor of poor survival, and HCT-CI ≥3 showed a trend toward worse outcomes, though not statistically significant. These findings support Flu/Treo as an effective and well-tolerated RIC regimen in a real-world setting, confirming its potential as a viable option for elderly or high-risk AML patients. Our results, consistent with Beelen's study, further advocate for Flu/Treo as a standard regimen in clinical practice for high-risk AML patients undergoing HSCT.

Malagola[1]
[1]*Unit of Blood Diseases and Bone Marrow Transplantation, Department of Clinical and Experimental Science, University of Brescia, ASST Spedali Civili di Brescia, Brescia, Italy*

Background: Allogeneic hematopoietic stem cell transplantation (allo-HSCT) remains a potentially curative therapeutic option for patients with malignant hematologic disorders. Conditioning regimens traditionally rely on Busulfan-based protocols, whose efficacy is well established but often limited by toxicity. Treosulfan has more recently emerged as a promising alternative to Busulfan in Reduced-Intensity Conditioning (RIC) regimens, particularly for elderly or frail patients, with a potentially more favorable therapeutic profile.

Methods: We retrospectively analyzed 316 patients aged 18-75 years undergoing allo-HSCT between March 2006 and December 2023 at our Istitution. All patients received conditioning regimens containing either Busulfan or Treosulfan. In order to improve the accuracy of the comparative analysis and reduce cohort heterogeneity, the study was restricted to patients who received exclusively RIC regimens, mainly for myeloid malignancies: by doing so, we aimed to minimize confounding factors related to variations in toxicity and myeloablative intensity. Overall survival (OS) and graft-versus-host disease-free, relapse-free survival (GRFS) were estimated using Kaplan-Meier analysis. The cumulative incidence of relapse, global GVHD, acute/chronic GVHD and non-relapse mortality (NRM) were assessed using the Gray's test for between-group analysis. Multivariate analysis for OS was performed using the Cox proportional hazards regression model.

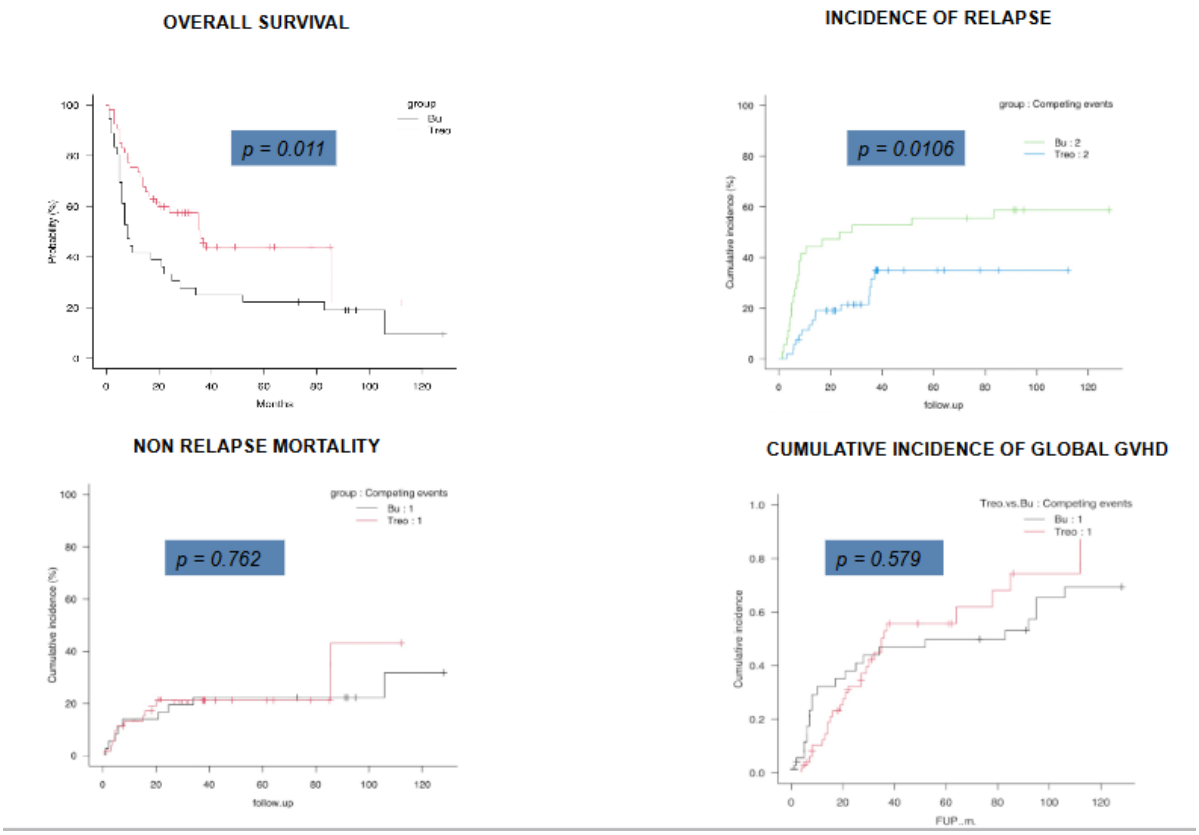
Our analysis included 90 patients (median age 65.4 years, range 18.6-74) who received a RIC conditioning including Fludarabine-Treosulfan (10 g/m2 for 3 days; FT10) in 54(60%) and Fludarabine-Busulfan(FB2) in 36(40%) patients, respectively (table 1).The main diagnosis was a myeloid disease (74.4%). Donors were matched related donors (MRDs) in 40% of cases, haploidentical (4.4%) or unrelated donors (55.6%). Peripheral blood was the main stem cell source.
Treosulfan-based conditioning was associated with significantly improved OS compared with Busulfan. Median OS was 8 months (95% CI: 6–22) in the Busulfan group versus 36 months (95% CI: 16–not reached) in the Treosulfan group (p = 0.011). GRFS duration was approximately four times longer in the Treosulfan group; however, despite this clinically meaningful difference, the comparison did not reach statistical significance (p = 0.247). In the Treosulfan group, the median GRFS was 34.9 (95% CI: 12.9–85.6) vs 7.9 months. Non-relapse mortality(NRM) did not differ significantly between groups (p = 0.762). By contrast, the Treosulfan cohort exhibited a significantly lower cumulative incidence of relapse (p = 0.0106), suggesting enhanced disease control. Rates of acute GVHD (grade II–IV), chronic GVHD and overall GVHD showed no statistically significant differences (p = 0.145, p = 0.525 and p = 0.579, respectively), despite differences in the temporal pattern of onset, confirming a comparable risk of GVHD associated with both regimens (figure 1). Multivariate analyses supported these findings, confirming Treosulfan as an independent predictor of improved OS without added immunologic complications .



Conclusions: Treosulfan-based conditioning demonstrated a favorable balance between efficacy and safety, showing significantly longer overall survival and a reduced risk of relapse compared with Busulfan, while maintaining similar rates of NRM and GVHD. Despite inherent methodological limitations including its retrospective design and cohort heterogeneity,these findings support Treosulfan as a valid and potentially useful option, particularly within reduced-intensity conditioning settings.

Disclosure: Nothing to declare.

COMPARISON OF CARMUSTINE-, LOMUSTINE-, AND NITROSOUREA-FREE CONDITIONING REGIMENS FOR AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION IN LYMPHOMA: RESULTS FROM THE BRAZILIAN REGISTRY

*Abrahao Hallack Neto[1], Vanderson Rocha[2], Eliana Miranda[3], Antonio Macedo[4], **Fernando Barroso**[5], Nelson Hamerschlak[6], Carmem Bonfim[7], Mary Flowers[8], Afonso Vigorito[3]*
[1]Juiz de Fora Federal University, Juiz de Fora, Brazil, [2]Sao Paulo Univesity, Sao Paulo, Brazil,

[3]Campinas State University, Campinas, Brazil, [4]Minas Gerais Militar Police Hospital, Belo Horizonte, Brazil, [5]Fortaleza Federal University, Fortaleza, Brazil, [6]Hospital Israelita Albert Einstein, Sao Paulo, Brazil, [7]Duke University, Durham, United States of America (the), [8]Fred Hutchinson Cancer Research Center, Seattle, United States of America (the)

Background: Background: Conditioning regimens (CT) for autologous hematopoietic cell transplantation (auto-HCT) in lymphoma commonly include carmustine (e.g., CBV, BEAM). When carmustine is unavailable, lomustine (e.g., LEAM) is often used as an alternative. In Brazil, intermittent shortages of both agents have prompted the use of additional nitrosourea-free regimens.

Methods: Methods: We analyzed adult patients with lymphoma in complete remission who underwent auto-HCT in Brazil between 2008 and 2023 and were reported to the CIBMTR/Brazilian Registry (HCTBR). Patients were grouped according to conditioning exposure: carmustine-based, lomustine-based, or nitrosourea-free. Endpoints included disease-free survival (DFS), overall survival (OS), and early non-relapse mortality (3-month NRM). Multivariable Cox and competing-risk models adjusted for baseline clinical differences. Subgroup analyses by lymphoma subtype were performed.

Results: Results: A total of 669 patients were included: Hodgkin lymphoma (HL, n=302), large B-cell lymphoma (LBCL, n=191), and mantle cell lymphoma(MCL, n=176). CT exposure comprised carmustine-based (n=279), lomustine-based (n=216), or nitrosourea-free (n=174) regimens. Estimated 5-year DFS was similar across groups (61%, 57%, and 57%, respectively). In multivariable analysis, CT type was not significantly associated with DFS, OS, or NRM. Older age at transplant was independently associated with inferior DFS ($p<0.0001$) and OS ($p<0.0001$), and higher NRM ($p<0.0001$). Compared with HL and MCL, patients with LBCL had worse DFS ($p<0.0001$) and OS ($p=0.02$). By diagnosis, 5-year DFS was 75% for HL, 57% for MCL, and 44% for LBCL. In subgroup analyses, CT type did not influence outcomes within any lymphoma subtype.

Conclusions: In this large national cohort, outcomes after auto-HCT for lymphoma were comparable across carmustine-, lomustine-, and nitrosourea-free conditioning regimens, supporting their interchangeability when specific agents are unavailable.

Disclosure: We have no conflict of interest to declare for this study.

FLUDARABINE AND TREOSULFAN MYELOABLATIVE CONDITIONING LEADS TO HIGH OS AND LOW NRM

Chiara Bernardi[1], *Amandine Pradier*[2,1], *Anne-Claire Mamez*[2], *Federica Giannotti*[2], *Sarah Morin*[2,1], *Yan Beauverd*[2], *Thomas Longval*[2], *Maria Mappoura*[2], *Sarah Noetzlin*[2], *Evgenia Laspa*[2], *Marie Maulini*[2], *Sarah Perdikis-Prati*[2], *An Do*[2], *Carmen de Ramon Ortiz*[2], *Boris Bours*[2], *Giulia Schiavini*[2], *Federico Simonetta*[2,1], *Stavroula Masouridi-Levrat*[2], *Yves Chalandon*[2]
[1]Department of Pathology and Immunology, Faculty of Medicine, University of Geneva,

Geneva, Switzerland, [2]Division of Hematology, Department of Oncology, Geneva University Hospitals, Geneva, Switzerland

Background: Myeloablative conditioning regimens based on fludarabine and treosulfan (FT14) are emerging as a safe, reduced toxic alternative to busulfan-based regimens for patients with myeloid disorders undergoing an allogeneic hematopoietic stem cell transplantation (allo-HSCT). However, real world data of this preparative regimen remain limited.

Methods: Here we report clinical data from a single center cohort in Geneva including 62 adult patients who underwent an HSCT for an hematological disorder after FT14 conditioning regimen (Fludarabine 30 mg/m2/d for 5 days and treosulfan 14 g/m2/d for 3 days), between 2019 and 2025.

Results: Overall, 62 patients were included in this retrospective study (38 with AML, 14 with MDS, and 10 with other hematological diseases). The median age at transplant was 44.5 years (range 20–63), with a median follow-up of 27 months. The majority of stem cell sources were peripheral blood stem cells (98%). Donors included sibling donors (19%), matched unrelated donors (44%), haploidentical donors (32%), and mismatched unrelated donors (5%). DRI score was low in 10%, intermediate in 74%, and high in 16% of patients. EBMT score distribution was: 1 (3%), 2 (27%), 3 (45%), 4 (18%), and 5 (7%).
At 2 years, overall survival (OS) was 85% (95% CI 75.9–95.2%), and progression-free survival (PFS) was 82.6% (95% CI 73.2–93.2%). The 2-year graft-versus-host disease-free, relapse-free survival (GRFS) was 67.8% (95% CI 56.7–81%). The 2-year cumulative incidence of relapse was 15.4% (95% CI 7.1–26.6%), while non-relapse mortality (NRM) was 1.6% (95% CI 0.1–7.6%). The cumulative incidence of grade II–IV acute GvHD at day +100 was 21% (95% CI 11.8–31.8%), and the 2-year cumulative incidence of moderate/severe chronic GvHD was 15.9% (95% CI 8.1–26.7%).

Conclusions: Our study confirms the favorable safety profile and efficacy of FT14 conditioning. Patients treated with this regimen demonstrated excellent survival, low relapse rates, and low mortality. Relapse remained the main cause of death after transplant in our cohort. Long-term toxicity requires further follow-up. Prospective randomized studies are warranted to further validate these findings.

CLINICAL STUDY OF THE TBFPTCY REGIMEN AS A CONDITIONING REGIMEN FOR ALLOGENEIC TRANSPLANTATION IN MYELOID MALIGNANCIES

Ping Zhang[1], *Lieguang Chen*[1], *Yongcheng Sun*[1], *Kaihong Xu*[1], *Shanhao Tang*[1], *Lixia Sheng*[1], *Xiao Wu*[1], *Huiling Zhu*[1], *Jiaping Wang*[1], *Guifang Ouyang*[1]
[1]*The First Affiliated Hospital of Ningbo University, Ningbo, China*

Background: Thiotepa has historically been used more frequently in conditioning regimens for umbilical cord blood transplantation, often combined with total body irradiation. It has also been part of regimens such as TBC (with busulfan and cyclophosphamide), TBM (with busulfan and melphalan), or TBF (with busulfan and clofarabine). Previous studies suggested that conditioning regimens containing thiotepa yielded suboptimal outcomes in myeloid neoplasms. Fludarabine, as a conditioning agent, has been increasingly used in reduced-intensity conditioning regimens in recent years, aiding in engraftment and immune reconstitution. The PTCY regimen, a classic method for in vivo T-cell depletion, is widely used in Western countries and is gradually gaining traction in China. To identify the most suitable conditioning regimen and dosage for older patients with myeloid malignancies, we designed a regimen combining the TBF conditioning regimen with PTCY. The related clinical study has been registered on the Chinese Clinical Trial Registry website.

Methods: Inclusion criteria: Patients aged 50 years or older with myeloid malignancies (including AML and intermediate/high-risk MDS suitable for transplantation), with an HCT-CI score < 2, and an ECOG score < 2. Patients with other types of acute leukemia and frail patients were excluded. The regimen design was as follows: Thiotepa 5mg/kg on days -8 and -7; Fludarabine 30mg/m² on days -6 to -2; Busulfan 0.8mg/kg every 6 hours on days -6 to -4; Cyclophosphamide 25mg/kg on days +3 and +4. The study planned to enroll 30 patients, and interim enrollment of 16 patients has been completed.

Results: Among all patients, there were 9 with AML and 7 with intermediate/high-risk MDS. Among the AML patients, 8 were in CR pre-transplant and 1 had NR. Among the 7 intermediate/high-risk MDS patients, 1 received chemotherapy before transplant, while the others proceeded directly to transplantation. All patients achieved successful engraftment. The median time to neutrophil engraftment was 13 days, and the median time to platelet engraftment was 13 days. The projected 1-year overall survival (OS) rate is 68.8%. No relapse occurred in any patient, resulting in a 1-year cumulative incidence of relapse (CIR) of 0%. The CMV infection rate was 31.25% (5/16), and the EBV infection rate was 37.5% (6/16). The Aspergillus infection rate was 12.5% (2/16), the Gram-positive cocci infection rate was 6.25% (1/16), and the Gram-negative bacilli infection rate was 6.25% (1/16). The incidence of acute GVHD (aGVHD) was 37.5% (6/16), and the incidence of chronic GVHD (cGVHD) was 31.25% (5/16), including one case (6.25%) of severe cGVHD. The incidence of transplant-associated microangiopathy (TMA) was 25% (4/16).

Conclusions: In the currently enrolled cohort of 16 patients, the TBFPTCY regimen demonstrated good tolerability in patients with myeloid malignancies over 50 years old. The engraftment success rate was 100%, and the post-transplant relapse rate was 0%. Interim

analysis with a follow-up of 1-12 months (median 5.6 months) showed a projected 1-year OS of 70.6%. The main adverse reactions included post-transplant infections and TMA. These results suggest that this regimen may be an effective option for preventing relapse post-transplantation in high-risk myeloid malignancy patients who can tolerate more intensive chemotherapy.

COMPARISON OF TOTAL NODAL IRRADIATION (6.0-7.5 GY) VS LOW-DOSE TOTAL BODY IRRADIATION (2 GY) IN EX VIVO TCRAB-DEPLETED HAPLOIDENTICAL TRANSPLANTATION IN ADULTS WITH HEMATOLOGICAL MALIGNANCIES

*Yin Teng Koh[1], **Liang Piu Koh**[1], Victor Ling[1], Michelle LM Poon[1], Lip Kun Tan[1], Joanne Lee[1], Hui Rong Han[1], Balamurugan Vellayappan[1]*
[1]National University Cancer Institute, Singapore, Singapore, Singapore

Background: Total Nodal Irradiation (TNI; 6-7.5 Gy) has been utilized in conditioning for *ex vivo* T-cell-depleted haploidentical hematopoietic cell transplantation (Haplo-HCT) to promote engraftment and to reduce graft rejection. Due to significant radiation-associated gastrointestinal (GI) toxicities, our institutional protocol was modified to substitute TNI with single-fraction, low-dose Total Body Irradiation (TBI; 2 Gy). This study compares the outcomes of these two radiation strategies.

Methods: We analyzed the outcomes of 109 patients (median age 54 years) who received Haplo-HCT with TCRαβ-depleted graft with CD45RA-depleted memory T-cell add-back (αβTCD+TMDLI) between 2017 to 2025. The conditioning regimen evolved from fractionated TNI (6-7.5 Gy in 3 fractions; n=22), to single-fraction TBI (2 Gy; n=87) from year 2000 onwards.

Results: All patients achieved sustained haematopoietic engraftment, with no difference in neutrophil or platelet recovery times. With a median follow-up of 20 months (range: 4-100), the low-dose TBI cohort demonstrated superior long-term outcomes: 5-year overall survival (82% vs. 36%, p<0.01), event-free survival (74% vs. 36%, p<0.01), and GVHD-free/relapse-free survival (84% vs. 32%, p<0.01). The cumulative incidences of grade II-IV acute GVHD, chronic GVHD, and relapse were comparable. However, the 2-year non-relapse mortality (NRM) was markedly lower with TBI (12% vs. 45%, p<0.001). TBI was also associated with significantly reduced severe mucositis (5% vs. 8%, p<0.01) and gastrointestinal toxicity (11% vs. 18%, p=0.002). On multivariable analysis, the use of TBI 2Gy (vs. TNI 6-7.5 Gy) was an independent favorable factor for NRM, OS, EFS, and GRFS. These survival benefits and the reduction in NRM remained significant after propensity score matching (21 patients per cohort).

Conclusions: In Haplo-HCT with αβTCD+TMDLI, substituting TNI with low-dose TBI (2 Gy) results in markedly improved survival outcomes and reduced non-relapse mortality, without compromising engraftment or efficacy. This regimen modification significantly lowers radiation-associated toxicity, enhances patient tolerability, and optimizes resource utilization, establishing low-dose TBI as the preferred conditioning component in this setting.

COMPARISON OF TREOSULFAN-THIOTEPA-FLUDARABINE VS FLUDARABINE-TREOSULFAN CONDITIONING FOR ALLOGENEIC HCT IN AML AND MDS: A SINGLE-CENTER RETROSPECTIVE EXPERIENCE

*Cecilia Anna Fidanza[1], **Fabio Serpenti**[1], Francesca Cavallaro[1], Nicola Cecchi[1], Kordelia Barbullushi[1], Maria Cecilia Goldaniga[1], Mariarita Sciumè[1], Elena Tagliaferri[1], Nicola Stefano Fracchiolla[1], Riccardo Mario Colombo[1], Francesco Onida[2,3], Francesco Passamonti[1,3], Giorgia Natascia Saporiti[1]*
[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy, [2]ASST Fatebenefratelli-Sacco, Milan, Italy, [3]University of Milan, Milan, Italy

Background: Conditioning regimen strongly influences allo-HCT outcomes, yet for treosulfan-based regimens in AML and MDS the optimal platform (single vs double-alkylator) and dose levels remain unclear. We compared fludarabine-treosulfan (FT) with thiotepa-treosulfan-fludarabine (TTF), and different treosulfan doses, to identify the regimen with the most favorable efficacy-toxicity balance.

Methods: Single-center retrospective analysis of 102 consecutive adults with AML, MDS, or MDS/MPN undergoing allo-HCT between 2016 and 2024. Conditioning was TTF (n=57) or FT (n=45). All patients received PBSC, across all donor types, and GvHD prophylaxis with ATG and/or PtCY, plus a calcineurin inhibitor and an antimetabolite. Primary endpoints were OS, PFS, EFS (including hematologic/molecular relapse, loss of donor chimerism or death), GRFS, cumulative incidence of relapse (CIR), and NRM.

Results: The FT group included older patients with higher-risk disease and lower performance status (*Table 1*). At 1 year, OS and PFS were 86% and 81% with FT vs 85% and 73% with TTF (both p>0.05). GRFS at 1 year was comparable (44% vs 56%, p>0.05). CIR at 1 year was significantly lower with FT (7% vs 20% with TTF; p=0.04). Median EFS was not reached with FT, whereas it was 52 months with TTF; 1-year EFS was 80% vs 61%, respectively (p=0.06).
Neutrophil engraftment occurred earlier with FT (median 13 vs 18 days with TTF; p<0.001). FT was also associated with less mucositis (any grade: 36% vs 61%; grade ≥3: 2% vs 28%; both p=0.01). Length of hospitalization tended to be shorter with FT (median 30 vs 36 days; p=0.08), while NRM was comparable (13% vs 8%; p=0.46).

Day-180 grade III–IV aGvHD rates were comparable (8% with FT vs 3% with TTF; p=0.40). In contrast, 1-year cGvHD incidence was higher in FT, both for any-grade (48% vs 19%) and moderate–severe forms (38% vs 6%; both p<0.05). Notably, median time to discontinuation of immunosuppression was significantly shorter after FT (127 vs 192 days; p=0.006). In multivariable analysis, the occurrence of cGvHD was independently associated with improved OS (HR 0.12; p=0.005) and PFS (HR 0.26; p=0.01). FT-based conditioning showed a trend toward reduced relapse risk (HR 0.30; 95%CI 0.08-1.1; p=0.07) and was independently associated with higher rates of any-grade cGvHD (HR 10.7; p<0.001). When comparing treosulfan dose levels (10, 12, and 14 mg/m² ×3), median survival and relapse rates were similar across groups. However, NRM was unexpectedly higher with Treo-10 compared with the other dose levels.

Table 1. Patients' and transplant characteristics	**TTF (N=57)**	**FT (N=45)**	**P**
Age at transplant, (median)	59 (24 – 74)	62 (29 – 74)	**0.04**
Sex (female): N (%)	26 (45.6%)	17 (37.8%)	0.5
Diagnosis: N (%) – AML/MDS/MDS-MPN	45 (78.9%) / 8 (14%) / 4 (7%)	31 (69%) / 13 (29%) / 1 (2%)	0.1
NGS: N (%) – Abnormal/available	21/22 (96%)	35/39 (97%)	>0.9
Karyotype: Abnormal, n (%)	18 (31.6%)	18 (40%)	0.5
Disease risk (ELN/IPSS): N (%) – High	16 (28.6%)	21 (46.7%)	**0.03**
Status at transplant (ELN 2022): N (%)			0.4
- CR1/CR≥2	28 (49%) / 15 (26.4%)	20 (44.4%) / 12 (26.7%)	
- PD/refractory	5 (8.8%)	1 (2.2%)	
- Upfront/stable disease	9 (15.8%)	12 (26.7%)	
Pre-transplant MRD	14 (25%)	7 (16%)	0.5
ECOG PS: N (%) ≥ 1	3 (5.3%)	16 (35.6%)	**<0.0**
HCT-CI: N (%) ≥ 3	24 (42.1%)	21 (46.7%)	0.8
Donor type: N (%)			0.1
- Sibling/Haploidentical	9 (15.8%) / 20 (35.1%)	7 (15.6%) / 7 (15.6%)	
- Matched/mismatch unrelated	21 (36.8%) / 7 (12.3%)	23 (51.1%) / 8 (17.8%)	
GvHD Prophylaxis: ATG / PtCY, n (%)	31 (54.4%) / 24 (42.1%)	26 (57.7%) / 16 (35.5%)	0.4

CMV status: R-/D+, n (%)	3 (5.3%)	8 (17.8%)	0.07
Median follow up (months)	30.6 (0.16 - 103.9)	12.1 (0.95 - 63.7)	**<0.0**

Conclusions: In this treosulfan-based series, FT and TTF provided comparable survival outcomes with low NRM and no graft failures. Despite being used in older, higher-risk, and less fit patients, FT was associated with lower toxicity (reduced mucositis and faster neutrophil recovery), with relapse rates at least comparable to TTF.
This favorable efficacy-tolerability profile was counterbalanced by a higher incidence of cGvHD, in the context of earlier immunosuppression discontinuation. Overall, FT emerges as a promising treosulfan platform, whereas the TTF regimen may be reserved for selected scenarios. Future work should aim to standardize immunosuppression tapering strategies, refine treosulfan dosing and better assess the long-term impact of cGvHD.

Disclosure: Nothing to declare.

IMLIFIDASE EFFICIENTLY ABROGATES THE EFFECT OF ATLG AND THYMOGLOBULIN ON T- AND NK-CELL VIABILITY AND FUNCTION

Claus-Philipp Maier[1,2], *Florian Heubach*[1], *Finn Trautner*[1], *Christina Parpoulas*[1], *Robert Bockermann*[3], *Latifa Zekri*[4,5,6], *Claudia Lengerke*[2,5], *Hendrik Rosewich*[1,7,8], *Rupert Handgretinger*[1], *Peter Lang*[1,5,6]
[1]*University Children's Hospital, Tuebingen, Germany,* [2]*Center for Internal Medicine, University Hospital, Tuebingen, Germany,* [3]*Hansa Biopharma, Lund, Sweden,* [4]*Clinical Collaboration Unit Translational Immunology, Center for Internal Medicine, University Hospital, Tuebingen, Germany,* [5]*Cluster of Excellence iFIT, University of Tuebingen, Tuebingen, Germany,* [6]*German Cancer Consortium (DKTK), Partner Site Tuebingen, Tuebingen, Germany,* [7]*University Children's Hospital, Göttingen, Germany,* [8]*German Center for Child and Adolescent Health (DZKJ), Partner Site Göttingen, Göttingen, Germany*

Background: ATLG (Grafalon) and Thymoglobulin are long-established agents in allogeneic hematopoietic stem cell transplantation (allo-HSCT), effectively preventing both graft rejection and graft-versus-host disease (GvHD). Using *ex vivo* TCRαβ/B-cell-depletion for GvHD prophylaxis in allo-HSCT, the main function of both agents is to prevent graft failure. In this context, high serum levels of ATLG/Thymoglobulin before transplant are beneficial, but hamper posttransplant immune recovery, potentially limiting the antileukemic activity of NK- and γδT-cells.
Imlifidase (Idefirix), an enzyme of *S.pyogenes*, hydrolyzes IgG in $F(ab')_2$ and Fc fragments. Therefore, using imlifidase straight before transplant may be effective in rapidly inactivating ATLG/Thymoglobulin.
Here, we analyze the potency of imlifidase to reduce ATLG/Thymoglobulin-mediated i.) T- and NK-cells lysis and ii.) inhibition of NK-cell function.

Methods: MACS-isolated $CD3^+$ T- and $CD56^+$ NK-cells from healthy donors were co-incubated (2h) with different concentrations of ATLG/Thymoglobulin alone or ATLG/Thymoglobulin pretreated with imlifidase (10 µg/ml) and assessed for Calcein release. Natural cytotoxicity of expanded NK (eNK)-cells (effectors, E) after preincubation (3.5h) with ATLG/Thymoglobulin alone or ATLG/Thymoglobulin pretreated with imlifidase was determined against K562 cells (targets, T) (E:T=10:1) in the presence of human AB serum as complement source.

Results: In the presence of 10 (100, 250, 500) µg/ml ATLG, lysis of freshly isolated Calcein-labeled T-cells (donors n=3) ranged between 0-5% (4-17%, 17-30%, 30-40%), whereas T-cell lysis was completely abrogated when incubated with ATLG pretreated with imlifidase. Compared to T-cells, exposing enriched NK-cells from identical donors (n=2-3) to the same ATLG concentrations resulted in higher lysis rates, ranging between 18-39% (44-87%, 60-87%, 69-93%) and dropping to 0-1.2% in the presence of corresponding doses of ATLG pretreated with imlifidase.
As with ATLG, Thymoglobulin-mediated T-cell lysis was also dose-dependent, reaching 0-8% (9-26%, 38-44%, 41-51%; donors n=3) in the presence of 2 (10, 100, 200) µg/ml Thymoglobulin. Lysis was markedly reduced to a maximum of only 2.3% using corresponding doses of imlifidase-pretreated Thymoglobulin. As observed with ATLG, Thymoglobulin (2, 10, 100, 200 µg/ml) induced stronger lysis of NK-cells (donors n=3) compared to T-cells, ranging from 14-24% (20-30%, 53-85%, 70-87%). Again, prior treatment of Thymoglobulin with imlifidase completely prevented lysis of NK-cells.
eNKs were generated by stimulation of PBMCs (donors n=4) with IL-2 (50-100 U/ml) and irradiated feeder cells (K562-mbIL15-4-1BBL). Lysis of K562 by untreated eNKs ranged from 60-93% and was reduced to 21-56% (0-12%) after eNK-cell incubation with 10 (100) µg/ml ATLG. However, lysis increased to 41-77% (26-62%) after preincubation with imlifidase-pretreated ATLG 10 (100) µg/ml. This effect was also true for Thymoglobulin. eNK-cell-mediated K562 lysis was decreased to 23-48% (32-45%, 7-30%, 3-20%) by pretreatment of eNKs with 2 (10, 100, 200) µg/ml Thymoglobulin, but reached 51-65% (44-68%, 32-58%, 21-55%) using imlifidase-cleaved Thymoglobulin.

Conclusions: Imlifidase markedly attenuates the impact of ATLG/Thymoglobulin on NK-cell function and abrogates ATLG-/Thymoglobulin-mediated cytotoxicity on T-/NK-cells. This effect of imlifidase is to be evaluated in a clinical study in the context of T-/B-cell-depleted allo-HSCT in order to determine whether pre-transplant application of imlifidase (e.g. on day-2) results in effective inactivation of ATLG/Thymoglobulin *in vivo* and thereby accelerates post-transplant immune reconstitution.

SALVAGE ALLOGENEIC STEM CELL TRANSPLANTATION FOR RELAPSED/REFRACTORY AML: CLADRIBINE-BASED INTENSIVE CONDITIONING VERSUS STANDARD MYELOABLATIVE REGIMENS

*Xiaoyu Lai[1,2,3], **Wenyi Wang**[1,2,3], Xiaolu Song[4,5], Lizhen Liu[1,2,3], Luxin Yang[1,2,3], Jimin Shi[1,2,3], Jian Yu[1,2,3], Yanmin Zhao[1,2,3], Yibo Wu[1,2,3], Lin Li[1,2,3], Yishan Ye[1,2,3], Jie Sun[1,2,3], Weiyan Zheng[1,2,3], He Huang[1,2,3], Yi Luo[1,2,3], Jianping Lan[4,5]*
[1]Bone Marrow Transplantation Center of The First Affiliated Hospital & Liangzhu Laboratory, Zhejiang University School of Medicine, Hangzhou, China, [2]Institute of Hematology, Zhejiang University, Hangzhou, China, [3]Zhejiang Province Engineering Research Center for Stem Cell and Immunity Therapy, Hangzhou, China, [4]Cancer Center, Department of Hematology, Hangzhou, China, [5]Zhejiang Provincial People's Hospital, Affiliated People's Hospital, Hangzhou Medical College, Hangzhou, China

Background: Salvage allogeneic hematopoietic stem cell transplantation (allo-HSCT) remains the sole potential curative therapy for patients with relapsed or refractory (R/R) acute myeloid leukemia (AML). The intensive conditioning regimen may contribute to improved long-term survival. However, the optimal conditioning regimen remains undefined. This study aimed to compare the clinical outcomes of patients with R/R AML receiving the Cladribine-based intensive regimen (CLAG) versus those receiving a standard Bu/Cy-based MAC regimen (BUCY).

Methods: This retrospective, dual-center study screened 127 patients with R/R AML who underwent salvage allo-HSCT at the Bone Marrow Transplantation Center of the First Affiliated Hospital, Zhejiang University School of Medicine, and Zhejiang Provincial People's Hospital between July 2016 and May 2025. We excluded individuals diagnosed with acute promyelocytic leukemia, or the myeloid blast phase of chronic myeloid leukemia. Consequently, 103 eligible patients were included and divided into the CLAG cohort (n=50) and the BUCY cohort (n=53). Cladribine-based regimen consisted of cladribine 5 mg/m2/day and high-dose cytarabine 2 g/m2/day for 3 days followed by Bu/Cy-based MAC regimen. Patients without grade II-IV acute graft versus host diseases (aGVHD) received one course of prophylactic donor lymphocyte infusion (pro-DLI) at about day +90.

Results: The median patient age was 42 years, and the majority of the cohort was diagnosed with de novo AML (90.3%), while the remaining 9.7% had AML secondary to myelodysplastic syndromes. Patients in the CLAG cohort presented with a significantly higher burden of pre-transplant bone marrow blasts compared to the BUCY group (median 15% vs 11%, P=0.002). Other baseline characteristics were balanced between the two cohorts. The two cohorts had comparable median times to neutrophil engraftment (13 days; P=0.946) and platelet engraftment (14 days; P=0.736). All patients achieved complete remission and full donor chimerism by day +30 post-HSCT.
With a median follow-up of 12.3 months, the median overall survival (OS) and disease-free survival (DFS) for the entire cohort were 16.9 months and 9.8 months, respectively. No significant differences between the CLAG and the BUCY cohorts were observed in long-term outcomes. The 1- and 2-year overall survival (OS) rates for the CLAG versus BUCY cohorts were 55.4% vs. 59.0% and 45.6% vs. 43.8%, while the corresponding cumulative incidence of relapse were 39.1% vs. 33.5% and 46.0% vs. 44.0% (all P>0.5). Multivariate analysis

identified high blast burden pre-transplant, rather than the conditioning regimen, as the independent risk factor for inferior 100-day survival (HR=15.5, P=0.03). However, the CLAG cohort exhibited higher 100-day NRM (14.0% vs. 1.9%, P=0.022).
In the entire cohort, 23.3% of patients received pro-DLI, with median time of 102 (range, 52-195) days post-HSCT. On landmark analysis at day+60, pro-DLI significantly decreased risk of 2-year relapse (23.5% vs 48.3%, P=0.047). OS was longer in the DLI cohort than the non-DLI cohort (median: 28.8 months vs 18.4 months).

Conclusions: This study demonstrated that a cladribine-based intensive regimen achieved comparable clinical outcomes to standard Bu/Cy MAC regimen in salvage HSCT for R/R AML, but may increase the risk of early NRM. Furthermore, for these patients, prophylactic DLI post-HSCT effectively reduced the risk of relapse, thus improving overall survival.

Disclosure: Nothing to declare.

B185

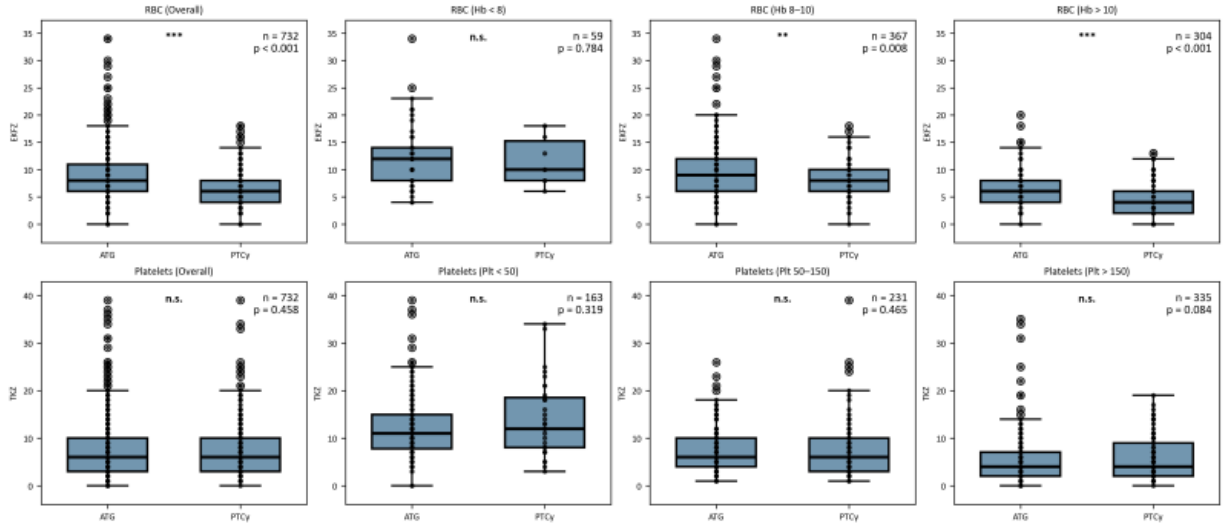
TRANSFUSION BURDEN UNDER ATG AND PTCY IN ACUTE LEUKEMIA PATIENTS RECEIVING ALLOGENEIC STEM CELL TRANSPLANTATION

Jette Luedersen[1], *Catherina Lueck*[1], *Ina Rudolph*[1], *Jochim Reinert*[1], *Franziska Marquard*[1], *Johanna Richter*[1], *Mathias Schaeferskuepper*[1], *Radwan Massoud*[1], *Max Wichmann*[1], *Maraike Harfmann*[1], *Gunnar Weise*[1], *Sofia Oechsler*[1], *Luisa Stegat*[1], *Silke Heidenreich*[1], *Evgeny Klyuchnikov*[1], *Nicolaus Kroeger*[1], *Francis Ayuketang Ayuk*[1]
[1]*University Medical Center Hamburg-Eppendorf, Hamburg, Germany*

Background: Hematopoietic stem cell transplantation (HSCT) requires T-cell depletion as part of graft-versus-host disease (GvHD) prophylaxis. The advantages and disadvantages of anti-thymocyte globulin (ATG) and post-transplant cyclophosphamide (PTCy) are widely discussed. However, data directly evaluating transfusion requirements associated with these approaches is lacking. We therefore conducted a retrospective analysis of transfusion needs in patients with acute leukemia undergoing allogeneic HSCT to assess and compare transfusion requirements under ATG- and PTCy-based GvHD prophylaxis.

Methods: We included all patients with acute leukemia (AML or ALL) who underwent allogeneic HSCT at our center between November 2015 and November 2025. Exclusion criteria were age <18 years, second or later HSCT, cord blood grafts, and cases not clearly assignable to ATG or PTCy. Baseline characteristics were generated using Python library *TableOne*. Group differences were assessed using non-parametric tests for continuous variables and chi-square–based tests for categorical variables. Primary endpoints were transfusion requirements from day −7 to day +30 and time to engraftment. Transfusion differences (red blood cell and platelet units) were evaluated using the Mann–Whitney U test. Mean values with 95% confidence intervals and medians were calculated descriptively. Transfusions per inpatient day were calculated for day −7 to day +30 or until earlier discharge. Additional predefined subgroup analyses were performed.

Results: A total of 878 patients were included, with 612 receiving ATG and 266 receiving PTCy. Red blood cell (RBC) transfusion requirements differed between groups, with higher RBC use in the ATG group (median 8 vs. 6, p <0.001), while platelet transfusions were comparable (6 vs. 6, p = 0.434). Among patients who were transfusion-dependent at the beginning of the peri-transplant phase (Hb < 8 g/dl; n = 59), RBC transfusion requirements did not differ between ATG and PTCy (median 12 vs. 10 units, p = 0.784). When adjusted for inpatient duration, ATG patients required more RBC units (0.28 vs. 0.18, p <0.001) and platelet units per hospital day (0.23 vs. 0.19, p <0.001), due to shorter inpatient duration (21 vs. 27 days, p <0.001).
Leukocyte engraftment occurred at a median of 11 vs. 16 days (p <0.001) and platelet engraftment (platelets 20 x10⁹/L) at 12 vs. 21 (p <0.001) days for ATG and PTCy.
Findings were similar in the AML subgroup (n = 762), showing higher RBC use with ATG (8 vs. 7, p = 0.004) but no differences in platelet transfusions (6 vs. 7, p = 0.345) while platelet engraftment occurred later with PTCy (12 vs. 22 days, p <0.001). Transfusions per inpatient day showed similar results regarding RBC units (0.28 vs. 0.22, p <0.001) but no difference in platelet units (0,23 vs. 0.22, p = 0.628).



Conclusions: Only RBC transfusion requirements differed significantly between ATG and PTCy groups, although the clinical relevance of this difference appears limited. Overall findings suggest that the transfusion burden between the two GvHD prophylaxis strategies may be more balanced than anticipated. The later engraftment observed after PTCy accompanied by a prolonged hospital stay may offset the more frequent but shorter duration of transfusion requirements under the application of ATG.

TOTAL BODY IRRADIATION, BUSULFAN, FLUDARABINE WITH POST-TRANSPLANT CYCLOPHOSPHAMIDE FOR PEDIATRIC ACUTE LYMPHOBLASTIC LEUKEMIA UNDERGOING HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION

Jae Won Yoo[1], *Suejung Jo*[1], *Seongkoo Kim*[1], *Jae Wook Lee*[1], *Nack-Gyun Chung*[1], *Bin Cho*[1]
[1]*Catholic Hematology Hospital, College of Medicine, The Catholic University of Korea, Seoul, Korea (the Republic of)*

Background: Total body irradiation (TBI)-based myeloablative conditioning is considered the standard of care for pediatric acute lymphoblastic leukemia (ALL) undergoing allogeneic hematopoietic cell transplantation (HCT); however, the optimal TBI dose has yet to be defined. To reduce radiation-related long-term toxicities while preserving antileukemic efficacy, we incorporated a conditioning strategy using 8-Gy TBI combined with busulfan and fludarabine, particularly in the setting of T-cell-replete haploidentical HCT with post-transplant cyclophosphamide (PTCy) for pediatric patients with high-risk or relapsed ALL in remission.

Methods: We retrospectively reviewed the outcomes of 36 patients (median age: 7.5 years, range, 1.3-17.8) with high-risk cytogenetics (n=6) or relapsed ALL (n=30) who underwent allogeneic HCT in complete remission (CR) between 2019 and 2025. Diagnoses included B-ALL in 31 patients, T-ALL in 2 patients, and mixed phenotype acute leukemia in 3 patients. Eight patients (22.2%) had a history of prior HCT. All patients received G-CSF-mobilized peripheral blood stem cell grafts from haploidentical family donors. The conditioning regimen consisted of 8-Gy TBI administered on days -8 and -7, followed by busulfan at 130mg/m^2/day on days -6 and -5 and fludarabine at 40mg/m^2/day on days -6 to -3. Graft-versus-host-disease (GVHD) prophylaxis included PTCy at 50mg/kg/day on days +3 and +4 in combination with cyclosporine.

Results: The median age at HCT was 12.9 years (range, 2.5-22.0 years). Disease status prior to HCT included first CR in 6 patients, second CR in 23 patients, and third CR in 7 patients. The median infused cell doses were as follows: total nucleated cells (TNCs) 20.4 x 10^8/kg, CD34+ cells 6.3 x 10^6/kg, and CD3+ cells 45.8 x 10^7/kg. Neutrophil and platelet engraftment were observed in all patients and all but one patient at a mean of 15 days and 27 days post-transplant, respectively. The 100-day cumulative incidences (CI) of grades II-IV and grade III-IV acute GVHD were 51.4.0±8.2% and 13.5±5.6%, respectively. Chronic GVHD developed in 10 of 36 patients (moderate, n=9; severe, n=1), with a 3-year CI of 29.7±8.5%, and no GVHD-related mortality was observed. With a mean follow-up of 36 months (range, 3-83 months), the estimated 3-year leukemia-free survival and overall survival rates were 81.3±7.1% (6/36) and 91.3±4.8% (3/36), respectively. These survival outcomes were comparable to those of our historical cohort who underwent matched donor transplantation with a conventional 13.2-Gy TBI and cyclophosphamide-based conditioning regimen.

Conclusions: An 8-Gy TBI-based myeloablative conditioning regimen combined with busulfan and fludarabine with PTCy prophylaxis resulted in encouraging survival outcomes in pediatric patients with high-risk or relapsed ALL undergoing haploidentical HCT in remission. Future studies from our institution will explore the applicability of this conditioning strategy in matched donor transplantation, with the aim of reducing long-term radiation-related toxicities.

'IMPROVING TRANSPLANT PLATFORMS': REAL-LIFE EXPERIENCE OF TREOSULFAN AS CONDITIONING FOR ALLO-HSCT IN AML AND MDS

*Raquel García-Talavera Hernández[1], Elena Herrero Ferrer[2], **María del Mar Perera Álvarez**[1], Leslie González Pinedo[1], Jorge Gayoso Cruz[1], Alejandro Morales Curbelo[1], Amagoia Ruiz Martín[1], Concepción Sánchez Chamizo[1], Minia Grobas Sebio[1], Carol Herrera Hernández[1], Natalia López Esteban[1], Mónica Betancor Pérez[1], José Antonio Moreno García[1], Guillermo Rodríguez Rodríguez[1], Luisa Guerra Domínguez[1], María Teresa Gómez Casares[1]*
[1]Hopital Universitario de Gran Canaria Doctor Negrín, Las Palmas de Gran Canaria, Spain, [2]Hospital Universitario Nuestra Señora de la Candelaria, Santa Cruz de Tenerife, Spain

Background: Conditioning for allogeneic hematopoietic stem cell transplantation (allo-HSCT) is a key part of the procedure. Age, comorbidities and, especially, the need for a second transplant make it difficult to use ablative regimens and increase morbidity and mortality. The use of treosulfan allows us to reduce toxicity while maintaining its antitumor effect.
The aim of our study is to report real-world experience with the use of treosulfan in conditioning for a-HPT in adult patients diagnosed with myelodysplastic syndrome (MDS) and acute myeloid leukaemia (AML).

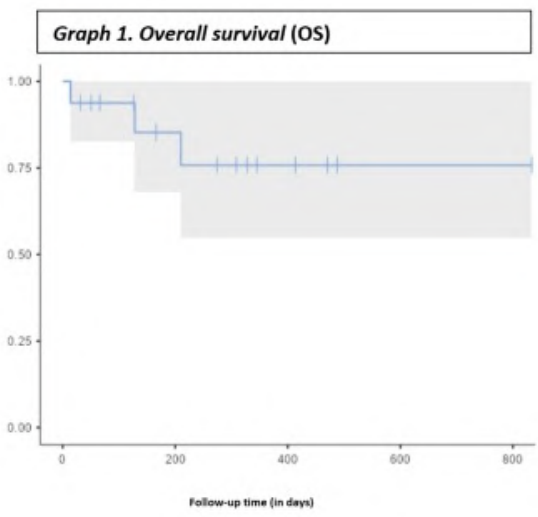
Methods: A retrospective observational study evaluating overall survival (OS), progression-free survival (PFS), toxic mortality (TMR), and the incidence of complications in all patients with AML and MDS who have received Treosulfan in the conditioning regimen for allogeneic HPT at our center from February 2023 to the present. Patients were selected based on their comorbidities and the need for a second allo-HSCT.

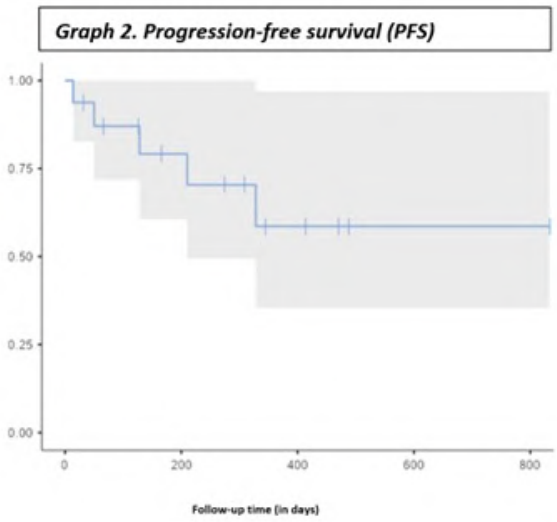
Results: Baseline characteristics are presented in Table 1. Eighteen patients were included, 62% with AML and 38% with MDS, mainly males (67%) with a mean age of 58 years (range 27–71). In 28% (5/18) an HLA-identical (HLA-i) donor was used, in 33% (6/18) an unrelated donor (URD) and in 39% (7/18) a haploidentical donor. Forty per cent of the series are second allogeneic transplants. More than half of the patients (56%) were in a situation of second CR or higher or refractoriness, and only 44% were in first complete response. Molecular alterations are described in Table 1, with the most frequent being RUNX1 (28%), DNMT3A (22%), and TP53 (16%).

Table 1. Characteristics.

Total	N= 18 patients
Average age	58 (27-71)
Gender Male Female	 12 (67%) 6 (33%)
Underlying disease AML MDS CML	 11 (62%) 6 (335) 1 (5%)
NGS/BM (AML/MDS) TP53 DNMT3A RUNX1 ASLX1 TET2/KRAS FLT3 NPM1	 2/1 2/2 2/3 1/1 1/1 1/0 1/0
Donor type HLAi DNE 10/10 DNE 9/10 Haploidentical	 5 (28%) 5 (28%) 1 (5%) 7 (395)
TPH ≥ 2	7 (39%)
Situation pre-TPH 1st CR 2nd CR pr > RR	 8 (44%) 7 (39%) 3 (17%)
Conditioning Treosulfan-Fludarabine (30 g/m2)	18 (100%)
EICR prophylaxis PTCy-Tacrolimus MTX-Tacrolimus	 16 (90%) 2 (10%)

All patients received ablative conditioning according to the Treosulfan 10 g/m² x 3 days (total dose of Treosulfan 30 g/m²) with Fludarabine regimen. Graft-versus-host disease (GVHD) prophylaxis was performed in 90% of patients with post-TPH Cyclophosphamide and Tacrolimus/Mycophenolate. No serious complications were reported during the procedure, and 22.2% of patients required some form of analgesia for muscle pain in the lower limbs. Sixty-two percent of patients developed acute GvHD, while only 10% developed grade III-IV GvHD. Twenty-eight per cent developed chronic GvHD, most (4/5) of which was mild to moderate. Two patients developed EVOH (11%); a second allo-TPH and a patient with tumor infiltration of the liver. Three patients (17%) developed IFI, all of whom were refractory. The SG was 75.8% at 2 years with an SLP of 58.6% and a median not reached. The MRT was 11.1% (2/18), exitus due to MAGIC III and IBMTR D cutaneous EICR and severe mucormycosis.





Conclusions: The conditioning regimen with Treosulfan demonstrated both efficacy in preventing disease relapse in high-risk patients (relapsed and refractory) and safety, allowing the inclusion of patients undergoing second transplants, older patients, and patients with comorbidities, without observing high rates of toxic mortality.

Disclosure: No conflict of interest.

P197

THIOTEPA, CYCLOPHOSPHAMIDE AND FLUDARABINE CONDITIONING REGIMEN FOR ADULT PATIENTS WITH NON-HODGKIN LYMPHOMA UNDERGOING ALLOGENEIC STEM CELL TRANSPLANTATION: IMPACT OF DONOR MISMATCH ON OUTCOME

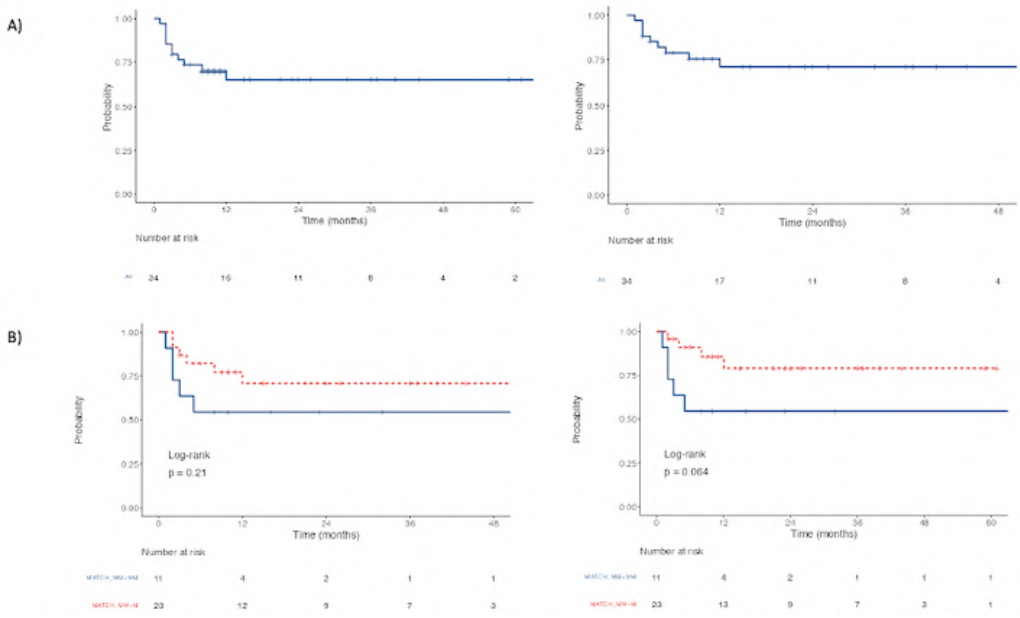
*Gabriele Facchin[1], **Massimo Moratti**[1,2], Marta Lisa Battista[1], Rosa Plos[1,2], Valeria Liotta[1,2], Gaia Tomadini[1,2], Antonella Geromin[1], Renato Fanin[1,2], Francesca Patriarca[1,2]*
[1]Azienda Sanitaria Universitaria Friuli Centrale (ASUFC), Udine, Italy, [2]University of Udine, Udine, Italy

Background: Allogeneic stem cell transplantation (HSCT) still represents a potentially curative option for patients with refractory/relapsed (RR) lymphoid malignancies. Modulation of conditioning intensity is crucial for disease control with acceptable toxicity. Thiotepa, Cyclophosphamide and Fludarabine (TCF) is a low-intensity conditioning (according to the new Transplant Conditioning Intensity Index) that has demonstrated excellent balance between safety and efficacy, even if data are still limited.

Methods: In this retrospective study we analyzed all 34 consecutive adult patients (pts) affected by lymphoid malignancies who underwent HSCT following TCF conditioning at our center between January 2019 and December 2024.

Results: Median age at transplant was 59 (35-74) years and 53% of pts were male. Baseline diagnoses were: 8 (23%) T-cell lymphomas, 6 (18%) DLBCL, 6 (18%) mantle cell lymphoma, 5 (15%) follicular lymphomas, 4 (11%) Richter syndrome and 5 (15%) other histology. Median number of lines before transplant were 3 (range 1-10); 8 (23%) pts received autologous stem cell transplant, 6 (18%) pts CAR-T (3 tisagenlecleucel, 1 brexucabtagene autoleucel, 1 axicabtagene ciloleucel) and 6 (18%) bispecific antibodies (4 glofitamab, 2 mosunetuzumab). Disease status at HSCT was complete remission (CR) in 53% of pts. Donors were matched unrelated in 19 (56%) pts, matched related in 4 (11%) pts, mismatch unrelated in 9 (26%) pts and haploidentical in 2 (6%). Overall, 25 (74%) pts received ATG as GVHD prophylaxis while 9 (26%) post-transplant cyclophosphamide (PT-Cy). Graft source was peripheral blood in all pts. Median infused CD34+ and CD3+ counts were 7,37 x10^6 cells/kg (3,20-10,5) and 18,8 x10^7 cells/kg (9,69-65,4), respectively. All pts engrafted. Median time for neutrophil and platelet engraftment was 14 (range 10–22) and 15 (range 11–34) days, respectively. With a median follow up of 11,5 (1-68) months, one-year progression-free survival (PFS), overall survival (OS) and graft-relapse free survival (GRFS) were 66%, 71% and 42% respectively (Figure 1A). Eight (23%) pts died due to transplant complications: 6/8 (75%) GVHD, 1/8 (12%) infections and 1/8 (12%) other. Only one pts died due to disease progression (1/34, 3%). A trend towards better one-year OS was observed in pts transplanted from matched donors compared with mismatch donors even if not statistically significative (79% vs 54%; p=0,064) while no differences in terms of 1-year PFS (p=0,21) were recorded (Figure 1B). Deaths due to complications were higher in mismatched group (45% vs 23%, p=0,037) while relapse rate was similar (36% vs 22%, p= 0,366).

Figure 1 A) PFS and OS global B) PFS and OS comparison between Matched and Mismatched donors HSCT



Conclusions: Our data highlight the efficacy of TCF conditioning for disease control in heavily pretreated lymphomas, with 1-year PFS and OS of 66% and 71% respectively. HSCT from mismatched donors had higher complications rate (mainly GVHD, despite the prevalent use of PT-Cy GVHD prophylaxis platform) and a tendency of lower 1-year OS.

Disclosure: Nothing to declare.

P198

ENGRAFTMENT KINETICS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION: IMPACT OF CONDITIONING INTENSITY AND EARLY POST-TRANSPLANT EVENTS

*Juliana Pardo Aljure[1], Juliana Castro[1], **Manuela Estrada-Schweineberg**[2], Federico Ramos-Marquez[2], Juan Camilo Vásquez[2], Stefania Pantoja[2], Paula Perez[2], Dana Taub Sánchez[1], Gabriel Ayala-Carrascal[3], Alejandra Melo[1], Mateo Gutierrez[1], Andrés Guerra[1], Laura Ortiz[2], Ana Maria Molano[2], Karen Chaves[2], Carmenza Camargo[2], Beatriz Wills[2], Guillermo Quintero[2], Claudia Agudelo López[2]*
[1]Universidad de los Andes, Bogotá, Colombia, [2]Fundación Santa Fé de Bogotá, Bogotá, Colombia, [3]Universidad Nacional de Colombia, Bogotá, Colombia

Background: Real-world data from resource-limited settings evaluating the impact of myeloablative (MYA) and reduced-intensity (RIC) conditioning on engraftment kinetics after hematopoietic stem cell transplantation (HSCT) remains scarce.

Methods: This single institution retrospective cohort study was conducted from 2022 to 2025, including adult patients undergoing conditioning regimens in the context of HSCT. Conditioning protocols were classified as MYA or RIC, and engraftment kinetics were analyzed using time to neutrophil and platelet recovery.

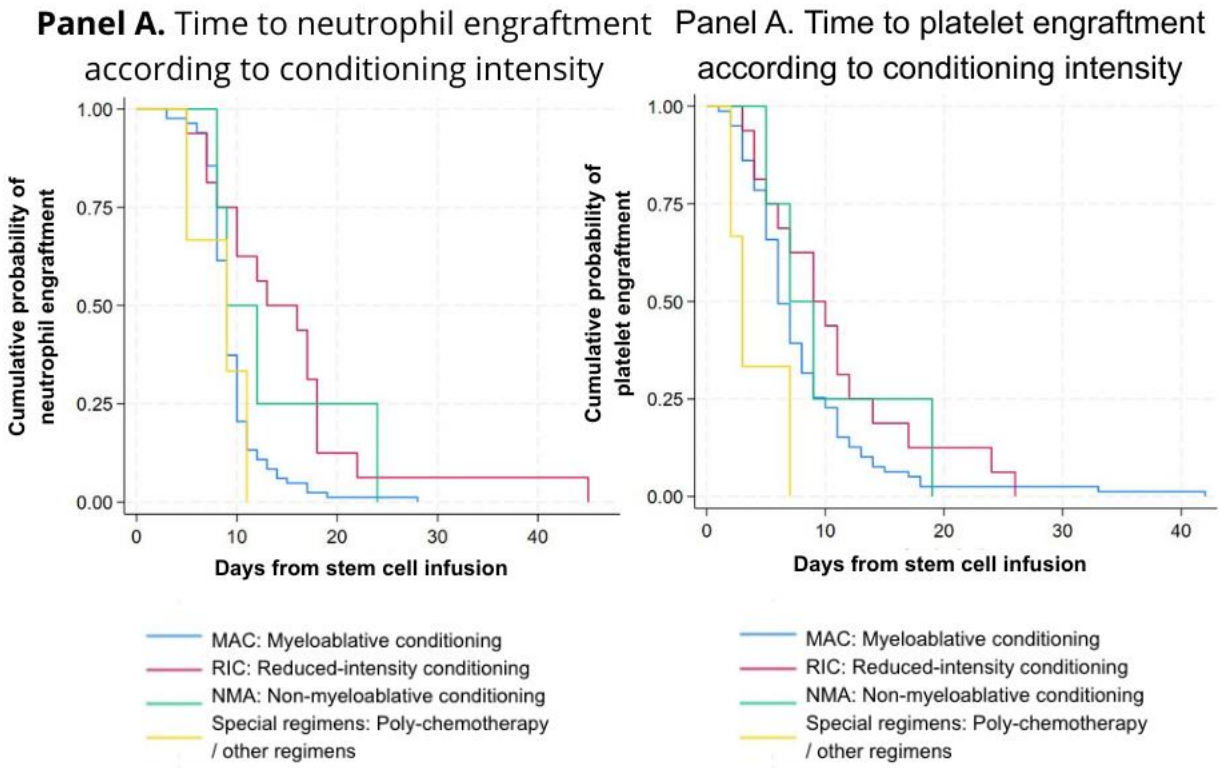
Results:

A total of 111 patients were included in the analysis, of whom 77.4% received myeloablative conditioning (MAC), 15.3% reduced-intensity conditioning (RIC), 4.5% received other non-myeloablative regimens (NMA) and 2.7% were treated with special regimens or poly-chemotherapy. Adverse events during conditioning were uncommon, with diarrhea occurring in 10 patients (9.1%) and emesis in 9 patients (8.2%). Late adverse events were more frequent, with mucositis observed in 43 patients (39.5%) and diarrhea in 79 patients (72.4%).

The most prevalent diagnosis was multiple myeloma (n=52, 46.85%), followed by mantle cell lymphoma (n=10, 9.01%) and acute myeloid leukemia (n=10, 9.01%). The mean time to neutrophil engraftment was 10.2 days (SD=5.4). Kaplan–Meier analysis showed significant differences in neutrophil engraftment kinetics according to conditioning intensity. Patients receiving myeloablative conditioning experienced earlier neutrophil engraftment compared with reduced-intensity conditioning (log-rank $p < 0.001$). In multivariable Cox regression analysis, higher CD34+ cell dose was independently associated with faster neutrophil engraftment (HR 1.005, $p = 0.014$). Other variables such as age and sex showed no significant association. Differences in engraftment kinetics were also observed according to donor type.

Mean time to platelet engraftment was 8.19 days (SD=6.27). Platelet engraftment kinetics showed greater variability across conditioning regimens. Although myeloablative conditioning appeared to be associated with earlier platelet recovery on Kaplan–Meier analysis, differences between regimens did not reach statistical significance (log-rank $p = 0.056$). This finding was consistent when comparing myeloablative versus reduced-intensity conditioning ($p = 0.13$).

Figure 1. Engraftment kinetics according to conditioning intensity



Protocol	Histology	Frequency
Abbreviated BEAM	Follicular lymphoma	4 (19.5%)
	Burkitt lymphoma	3 (14.29%)
	Mantle cell lymphoma	8 (38.1%)
BEAM	Mantle cell lymphoma	2 (100%)
Busulfan/Fludarabine/AMA	Acute myeloid leukemia	1 (100%)

Etoposide + carboplatin	Others	2 (100%)
Etoposide + carboplatin + melphalan	Others	1 (100%)
Fludarabine + melphalan	Acute myeloid leukemia	1 (100%)
Ifosfamide + carboplatin + etoposide (ICE)	Non-germinomatous germinal tumor	1 (100%)
Melphalan	Multiple myeloma	52 (92.86%)
	Hodgkin lymphoma	1 (1.79%)
	Amyloidosis	3 (5.36%)
Thiotepa + busulfan + fludarabine	Acute myeloid leukemia	3 (60%)
	Chronic myeloid leukemia	1 (20%)
	Acute lymphocytic leukemia	1 (20%)
Thymoglobulin	Non-malignant hematological diseases with bone marrow failure	1 (50%)
	Systemic sclerosis	1 (50%)
Thymoglobulin + cyclophosphamide	Non-malignant hematological diseases with bone marrow failure	1 (50%)
	Systemic sclerosis	1 (50%)

Conclusions: In this real-world cohort, conditioning intensity was a key determinant of neutrophil engraftment kinetics after HSCT, with myeloablative regimens associated with earlier neutrophil recovery compared with reduced-intensity approaches. Importantly, CD34+ cell dose emerged as an independent predictor of engraftment speed, underscoring the role of graft quality beyond conditioning intensity alone. In contrast, platelet engraftment showed greater heterogeneity and was not consistently influenced by conditioning intensity, suggesting that additional factors may modulate platelet recovery. Collectively, these findings emphasize the need for integrated optimization of both conditioning strategies and graft characteristics to improve early post-transplant outcomes in resource-limited settings where delays in engraftment may translate into increased morbidity and healthcare burden.

MYELOABLATIVE CONDITIONING FOR MYELOID MALIGNANCIES WITH THIOTEPA, BUSULFAN, FLUDARABINE WITH ANTI-THYMOCYTE GLOBULIN OR POST TRANSPLANT CYCLOPHOSPHAMIDE (TBF-ATG OR TBF-PTCY) - A SINGLE CENTRE EXPERIENCE

Alexander Bashford[1], *Jenny Byrne*[1], *Gerardo Errico*[1], *Yadanar Lwin*[1], *Alexander Glover*[1], *Tom Taylor*[1], *Catherine Grundy*[1]
[1]*Nottingham City Hospital, Nottingham, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Thiotepa-Busulphan-Fludarabine has been shown to be a highly effective myeloablative chemotherapy-only preparative regimen in patients with myeloid malignancies, avoiding the toxicities of TBI.

Methods: We analysed the outcomes of 36 consecutive patients who underwent allogeneic transplantation using the TBF backbone (Thiotepa 10 mg/m2; Busulphan 9.6mg/m2; Fludarabine 50mg/m2) at our centre. Those with HLA 10/10 matched sibling (n=4) or unrelated donors (n=17) received ATG 2.5 mg/kg on days -1 and -2 together with CSA and MMF from D-1 as GVHD prophylaxis (n= 21). Those with HLA 9/10 mismatched unrelated (n=4) or haplo-identical family donors (n=11) received PTCy (40 mg/kg on days +3 and +4) together with CSA and MMF from Day +5 (n=15).

Results: All patients received PBSC grafts with a median cell dose of 5.20 x 10^6 CD34+/kg. The median age in both ATG and PTCy groups was 35 years (17-51 yrs). The diagnoses were AML (n=16), MDS (n=4) and CML (n=4) in the ATG group and AML (n=13) and CML (n=2) in the PTCy group. The median haemopoietic comorbidity score was 0 in the ATG group and 1 in the PTCy group (range 0-6).
All patients engrafted, with a faster median time to neutrophil and platelet engraftment in the ATG group of 11 days (9-22 days) and 18 days (15-28 days), compared with 15 days (13-21 days) and 21 days (14-50 days) in the PTCy group. All patients in both groups achieved full donor chimerism at 1- and 3-months post-transplant.
All patients except one were EBV seropositive and one third were CMV seropositive. EBV reactivation requiring treatment occurred in 71% of TBF-ATG and 13% of TBF-PTCy patients whilst CMV reactivation required treatment in 14% of TBF-ATG and 20% of TBF-PTCy. BK virus haemorrhagic cystitis incidence was high requiring treatment in 33% of TBF-ATG and 40% of TBF-PTCy. There were 3 cases of VOD all in heavily pre-treated patients and one case of CRS in a haploidentical PTCy patient that required brief ITU admission for inotropic support.
At a median follow up of 24 months (5-70m) 30/36 patients (83%) are alive. In the TBF-ATG group 2y OS was 93% with 9.5% NRM at 2 years (2 infective deaths and 1 relapse) whilst in the TBF-PTCy group 2y OS was 70% with 0% 2y NRM, but 3 deaths from relapse (2 = AML and 1=CML-2CP). Acute GVHD Grade 2-3 occurred in 25% of the TBF-ATG cohort and 6% of the TBF-PTCy group with no cases of grade 4 aGVHD.

Conclusions: We conclude that the TBF platform is an effective strategy for patients regardless of donor type, with acceptable toxicity and relapse rates. We observed a higher risk of EBV reactivation in the ATG group as compared to the PTCy group likely due to slower immune reconstitution, and high symptomatic BK haemorrhagic cystitis in both groups as compared to other regimens. Although longer follow up is needed, these findings, together with the lower incidence of GVHD in the PTCy group, makes PTCy an attractive option for fully matched donors going forward.

Disclosure: Nothing to declare.

P200

FLUDARABINE AUGMENTED REDUCED INTENSITY CONDITIONING IMPROVES ENGRAFTMENT AND OUTCOMES IN ADVANCE CUTANEOUS T-CELL LYMPHOMA

Yashashree Gupta[1], *Erin Hurst*[1], *Amy Publicover*[1], *Louise Duncan*[1], *Laura Jardine*[1,2], *Venetia Bigley*[1,2], *Matthew Collin*[2,1]
[1]*Newcastle upon Tyne, NHS Foundation Trust, Newcastle upon Tyne, United Kingdom of Great Britain and Northern Ireland (the),* [2]*Newcastle University, Newcastle upon Tyne, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Advanced stage cutaneous T cell lymphoma (CTCL), including Mycosis fungoides (MF) and Sezary syndrome (SS) are rare, usually refractory with limited curative options. Allogenic HSCT offers potential cure and Reduced Intensity Conditioning (RIC) is recommended by the EORTC-CLTG and the NCCN . Although Stanford nonmyeloablative regimen (TSEB/TLI/ATG) is well tolerated, the slow and sometimes incomplete engraftment and higher rate of primary and secondary graft failure remain a major concern. In view of these concerns we incorporated fludarabine into conditioning regimen at our center. We report a 10 year experience of allo-HSCT in advanced CTCL, comparing outcomes across conditioning approaches.

Methods: A retrospective analysis was conducted of all patients who underwent an allo-HSCT for MF/SS at a tertiary UK centre from 2015 to 2025. Data collected included disease stage, remission status, prior treatments, conditioning regimens, engraftment kinetics, transplant complications, GVHD, donor chimerism and relapse.

Results: Nine patients with advanced-stage MF/SS (stages IIB–IVB) underwent allo-HSCT (7 MF, 2 SS). The median prior systemic therapies was 6(range 3-7). At transplant, 7 patients were in CR and 2 in PR. Median follow up was 11.6 months (range 1.2- 48.9).
3 patients received the Stanford protocol and 4 patients received institutional modified Stanford protocol incorporating fludarabine (60 mg/m2). One patient without a suitable MUD underwent HAPLO RIC transplantation. One patient with bulky nodal disease received LEAM/ATG.
TSEB/TLI/ATG RIC (n = 3)
2 patients developed non-neutropenic fever and one developed neutropenic sepsis. One had CMV reactivation. Two experienced grade 1–2 acute skin GVHD. 2 patients never dropped their neutrophils <0.5 x 10^9/L and 1 patient engrafted on day 11. Day-90 donor chimerism was <95%in one evaluable patient. All relapsed, including two within 30 days, one late relapse, they all subsequently died.
Modified RIC: TSEB/TLI/ATG/Fludarabine (n = 4)
Two patients had no acute complications, while two developed non- neutropenic fever. One had CMV reactivation. Three did not drop their neutrophils < 0.5 x 10^9/L and One engrafted on day 7. Three developed grade 1 skin GVHD. By day 90, two achieved full donor chimerism and two remained in mixed. There was no evidence of graft failure. Two patients remain in

sustained remission, while two relapsed at 3 and 13 months post HSCT. All remain alive at last follow up.
Other Regimens (LEAM/ATG and Haplo-RIC; n = 2)
Both experienced early bacterial sepsis with neutropenia. Engraftment occurred on days 11 (LEAM/ATG) and 15 (HAPLO RIC). Patient undergoing LEAM conditioning developed grade 2 gut and skin GVHD. Both patients remain in remission with full donor chimerism and are alive at last follow up.

Table 1: Patient Information

Number	Diagnosis	Stage	CLIPI Risk group	Number of prior treatments	Transplant conditioning	Transplant complications	Neutrophil Engraftment	GVHD	Donor Chimerism	Disease status	Days of relapse post HSCT	Alive/ Dead
1	MF	2B	High	3	TSEB+TLI+ ATG	Sepsis, CMV reactivation	Never <0.5x 10 9/L	No	NA	Relapse	19	Dead
2	MF	IV A	High	6	TSEB+TLI+ ATG	Sepsis	Never <0.5x 10 9/L	Grade 2 Skin	NA	Relapse	24	Dead
3	MF	2B	Intermediate	6	TSEB+TLI+ ATG	Neutropenic sepsis	Day 11	Grade 2 skin	<95	Relapse	262	Dead
4	SS	IV A	High	5	TSEB+TLI+ ATG+Flu	Psudomonas exit line site infection	Never <0.5x 10 9/L	Grade 1 skin	100	Remission	NA	Alive
5	MF	2B	Low	6	TSEB+TLI+ ATG+Flu	None	Never <0.5x 10 9/L	Grade 1	100	Relapse	397	Alive

								skin				
6	MF	IVA	High	3	TSEB+TLI+ATG+Flu	Neutropenic sepsis	Never <0.5x 10 9/L	No	<95	Relapse	105	Alive
7	MF	2B	Intermediate	4	TSEB+TLI+ATG+Flu	None	Day 7	Grade 1 skin	<95	Remission	NA	Alive
8	SS	IVB	High	7	HAPLO RIC	Neutropenic sepsis	Day 15	No	100	Remission	NA	Alive
9	MF	IVA	High	7	LEAM ATG	Neutropenic sepsis	Day 11	Grade 2 skin, Gut	100	Remission	NA	Alive

Conclusions: Incorporation of fludarabine to the TSEB/TLI/ATG RIC regimen improved donor chimerism and outcomes without increasing toxicity, no graft failures were observed. HAPLO-RIC and LEAM- based conditioning regimens were feasible alternatives for patients lacking matched donors or with bulky disease. Although limited by small sample size, these findings support further prospective evaluation of incorporation of fludarabine as a reliable conditioning strategy in advanced stage CTCL.

TREOSULFAN-BASED CONDITIONING REGIMEN IS ASSOCIATED WITH AN INCREASED RISK OF EARLY TOXICITY AND RELAPSE IN PATIENTS WITH HEMATOLOGICAL MALIGNANCIES

Ahlem Slama[1], Rihab Ouerghi[1], Insaf Ben Yaiche[1], Dorra Belloumi[1], Lamia Torjemane[1], Rimmel Kanoun[1], Anna Chabaan[1], Tarek Ben Othman[1], ***Nour Ben Abdeljelil***[1]
[1]*Service d'Hématologie et de Greffe, Centre National de Greffe de Moelle Osseuse, Tunis, Tunisia*

Background: Treosulfan-based conditioning has emerged as an effective myeloablative regimen associated with reduced non-relapse mortality (NRM).
The aim of our study was to evaluate the safety and efficacy of treosulfan-based conditioning in patients with hematological malignancies (HM) who underwent allogenic hematopoietic stem cell transplantation (allo-HSCT) from matched sibling donors (MSD).

Methods: Retrospective study conducted in all consecutive patients with HM who underwent allo-HSCT from MSD between 2019 and 2024. Conditioning regimens consisted on a combination of treosulfan- thiotepa and fludarabine (TTF) for lymphoid malignancies and treosulfan-fludarabine or cyclophosphamide (FT or TreCy) for myeloid malignancies. GVHD prophylaxis consisted on cyclosporine and short course of methotrexate+/- antithymocyte globulin (ATG). Stem cell sources were bone marrow (BM) or peripheral blood stem cells.

Results: Overall, 39 patients were included with a median age of 31 years (range, 7–53). Underlying diseases were acute lymphoblastic leukemia in 31% of cases and acute myeloblastic leukemia in 56% of cases. Before allo-HSCT, 59% of patients were in CR1, 28% ≥ CR2 and refractory disease in 2 patients. Stem cell source was BM in 95% of patients. Fifteen patients received TTF (38%), 44% TreCy and 18% FT. Nine patients (23%) received ATG in addition of the standard GVHD prophylaxis. During the early phase of conditioning, 30 patients (77%) developed grade III-IV mucositis, diarrhea (77%), vomiting (64%). Skin involvement was observed in 64% of patients, consisting of diffuse erythema. Among them 3 patients developed epidermal detachment. The skin biopsy, along with the pharmacovigilance investigation, supported a treosulfan-induced drug eruption. Engraftment was achieved in all cases, with median neutrophil engraftment on day +16 and platelet engraftment on day +23. Twelve patients (31%) developed grade II-IV acute GVHD with a median time of 17 days (range, 10-100), mainly with gastrointestinal involvement (n= 11). Chronic GVHD was observed in 15% of patients, with 2 cases of extensive form. CMV reactivation was observed in 28% of patients. After a median follow-up of 7 months (range, 1–21m), the 1-year OS and EFS were 78% and 51%, respectively. Relapse occurred in 23% of patients after a median time of 2 months (range: 1–14m). NRM occurred in 3 patients after a median time of 5 months (range, 2-7m), due to severe acute GVHD in 2 patients and infectious complication in 1 patient.

Conclusions: Our experience showed that treosulfan based conditioning regimen is associated with an increased risk of skin toxicity and early relapse. A pharmacokinetic study is probably required to optimize efficacy and minimize toxicity.

Disclosure: Nothing to declare.

P203

SUCCESSFUL ABTCR-DEPLETED HAPLOIDENTICAL HSCT AFTER MINIMAL TOXICITY CONDITIONING IN AN HEAVILY PRETREATED DOWN'S SYNDROME PATIENT WITH R/R BCP-ALL

Kateryna Venger[1], *Tristan Römer*[1], *Arend Stackelberg*[2], *Peter Lang*[3], *Andrej Lissat*[2], *Udo Kontny*[1]
[1]*Uniklinik RWTH Aachen, Aachen, Germany,* [2]*Charité – Universitätsmedizin Berlin, Berlin, Germany,* [3]*Universitätsklinikum Tübingen, Tübingen, Germany*

Background: Down's syndrome (DS) patients with ALL have a significantly worse outcome compared to their non-DS counterparts due to both higher relapse risk and higher treatment-related mortality. Profound sensitivity to conventional chemotherapy can limit treatment options in these patients in case of relapsed/refractory disease, and standard myeloablative conditioning before HSCT may not be applicable due to unacceptable toxicity risk.

Methods: We here present the case of a 20-year-old female DS patient with R/R BCP ALL who could successfully be salvaged by αβTCR-depleted haploidentical HSCT from her sister after conditioning with frontline ATG 20mg/kg x3, fludarabine 30mg/m^2 x4 and TBI 2Gy, complemented by posttransplant cyclophosphamide 25mg/kg d3+4, without further GVHD prophylaxis. Shortly before transplant, the patient was diagnosed with pulmonary aspergillosis, and antifungal treatment with isavuconazol was initiated.

Results: The transplant procedure was unexpectedly well tolerated, with rapid and sustained engraftment and achievement of MRD negativity on d+30. Prophylactic DLI were given from d+62, and venetoclax 50mg/d was preemptively reintroduced on d+64, after re-emergence of low-level MRD was noticed. Pulmonary aspergillosis completely resolved under continuous isavuconazol.

Conclusions: This case shows that heavily pretreated and highly vulnerable patients can successfully be salvaged with αβTCR-depleted haploidentical HSCT after minimal toxicity conditioning. Effective lymphodepletion with frontline ATG and posttransplant cyclophosphamide enabled rapid engraftment and made further GVHD prophylaxis dispensable. Low toxicity of this regimen allowed early initiation of prophylactic DLI and reintroduction of venetoclax for promoting antineoplastic efficacy. Invasive fungal infection at the time of transplant is not necessarily a contraindication for proceeding to RIC HSCT.

Disclosure: Nothing to declare.

P204

OUTCOME OF TREOSULFAN-FLUDARABINE CONDITIONING REGIMENS: A SINGLE CENTER EXPERIENCE

Elsa Masedu[1], *Stefano Bonfanti*[1], *Francesca Duca*[1], *Silvia Viola*[1], *Marilena Fedele*[2], *Paola Perfetti*[2], *Elisabetta Terruzzi*[2], *Andrea Aroldi*[2], *Elena Maria Elli*[2], *Carlo Gambacorti-Passerini*[2,1], *Matteo Parma*[2]
[1]*University of Milano Bicocca, Monza, Italy,* [2]*Fondazione IRCCS San Gerardo dei Tintori, Monza, Italy*

Background: Allogeneic hematopoietic stem cell transplantation (allo-HSCT) in elderly patients remains a clinical challenge due to frailty, comorbidities, and increased susceptibility to treatment-related toxicity. Treosulfan based regimens are a particularly promising option, providing robust myeloablation while maintaining a more favourable toxicity profile than traditional myeloablative treatments either in malignancies or in non-malignant disease. Despite this growing adoption, real-world data on treosulfan-based conditioning in elderly or frail patients remain limited and warrant further investigation.
The aim of this study was to collect real-world data on the feasibility, efficacy, and safety of treosulfan in a single-centre cohort.

Methods: We conducted a retrospective analysis of all patients aged ≥18 years old who received treosulfan-based conditioning in our Institution between 2021 and 2025. Treosulfan was administered in combination with fludarabine 200 mg/m² as immunosuppressive agent. Baseline demographics, disease characteristics, comorbidities and conditioning details were collected. Outcomes of interest included engraftment kinetics, transplant-related toxicity, infectious complications, acute and chronic graft-versus-host disease (GVHD), non-relapse mortality (NRM), relapse incidence, progression-free survival (PFS), and overall survival (OS).

Results: A total of 46 patients underwent allo-HSCT with a treosulfan-based conditioning regimen between 2021 and 2025. The median age at transplant was 65 years, but two patients were younger than 35. Standard treosulfan dosage was 10 g/m², increased to 14 mg/m² in selected patients.
Median engraftment time of neutrophil (≥ 0.5 × 10^9/L) and platelet (≥ 20 × 10^9/L) was 17 and 14 days respectively. Infectious complications occurred in 16 patients within the first 100 days, two had fatal outcome. Severe mucositis (grade ≥3) was recorded in only 7 patients. 19 patients (41%) presented acute or chronic GvHD: 8 were responsive to steroid treatment but 11 required a second-line therapy.
In the whole cohort median OS was 21 months, 6 patients died for relapse, 8 for non relapse mortality. Median PFS was 15 months; relapse occurred in 9 patients and 3 of them are still alive.
Two clinically relevant cases involved two young patients (35 and 20 years old): the first had AML associated with chronic bowel disease, and the second had MDS with del(7) cytogenetic abnormality secondary to Fanconi anemia. In these cases, treosulfan was chosen to reduce systemic toxicities while maintaining effective myeloablation. Both patients are alive, in complete remission, and free from GvHD after 10 and 48 months, respectively.

Conclusions: In this real-world cohort of predominantly elderly patients, treosulfan-based conditioning showed favorable engraftment kinetics, acceptable infectious morbidity, and a low incidence of severe mucositis. Notably, fewer than half of the patients developed GvHD, although 42% of these cases were steroid-refractory. OS and NRM were consistent with expectations for an elderly transplanted population.
These findings support the feasibility and tolerability of treosulfan-based conditioning in elderly or comorbid patients undergoing allo-HSCT. The inclusion of two younger patients with complex clinical backgrounds further highlights the regimen's adaptability in selected cases. Larger studies with longer follow-up are warranted to confirm these observations and to better define the optimal treosulfan dosing strategy across different patient subsets.

Disclosure: Nothing to declare.

P205

CONDITIONING WITH FLUDARABINE, CYTARABINE, VENETOCLAX, ETOPOSIDE FOR ALLOGENEIC STEM CELL TRANSPLANT IN PATIENTS WITH ACTIVE ACUTE MYELOID LEUKEMIA

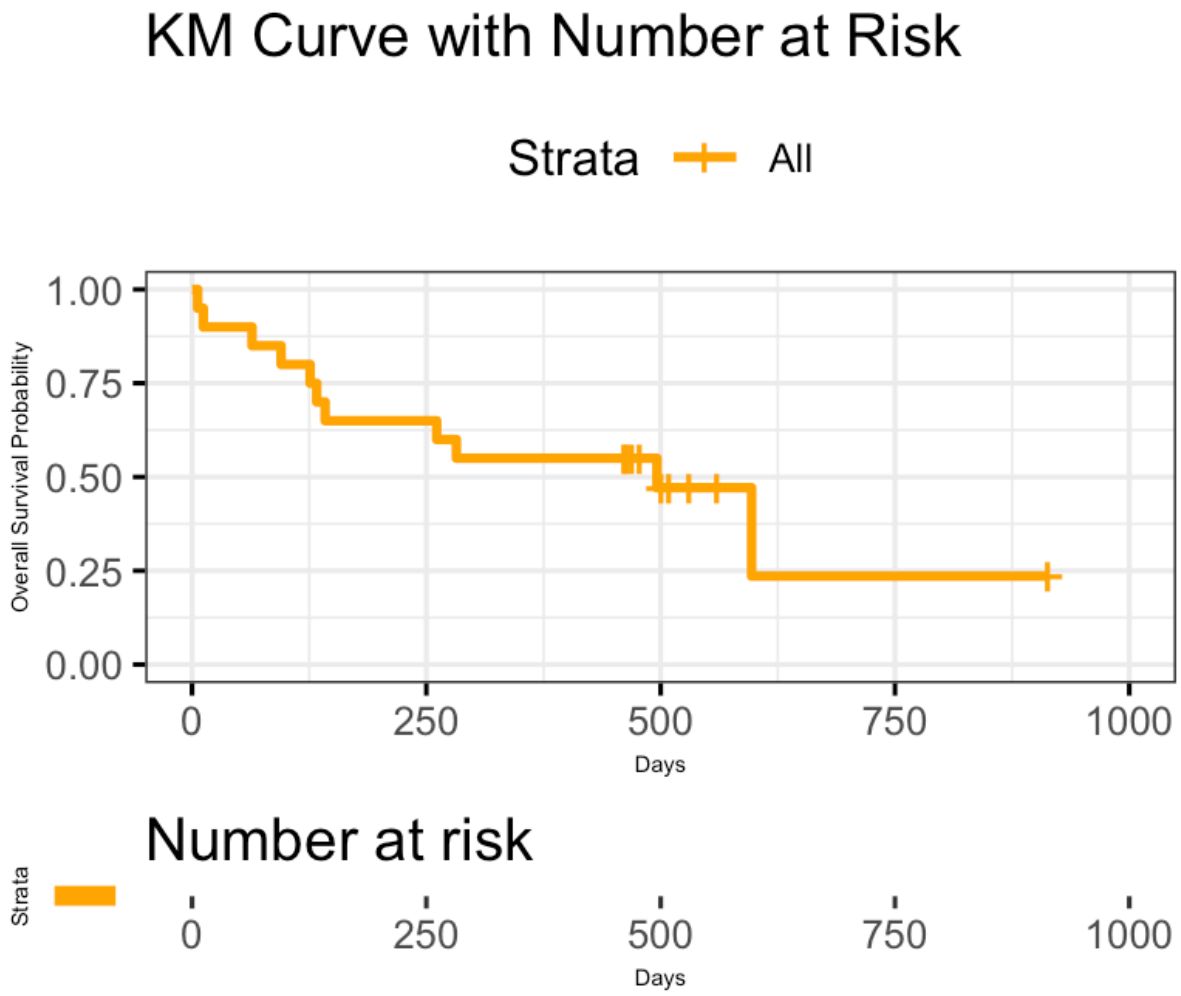
Nikhil Vasudeva[1], *Ranjit Sahoo*[1], *Nishant Sinha*[1], *Sabitha Parmasivam*[1]
[1]*All India Institute of Medical Sciences, New Delhi, India*

Background: AML patients are frequently refractory to initial therapy or have refractory relapses. Sequential chemotherapy followed by RIC pioneered by the German FLAMSA regimen has been safe and efficacious in these patients. Here we report the single center outcomes of modified FLAMSA(Fludarabine, Cytarabine, Venetoclax, Etoposide, Alkylating agents based RIC) – FLAVER regimen by substituting Amasacrine with Etoposide.

Methods: This was a single center observational study conducted at All India Institute of Medical Sciences, New Delhi.
FLAVER conditioning regimen consisting of Fludarabine 30mg/m^2 , Cytarabine 1500mg/m^2 , Tab Venetoclax 100 mg OD with Tab Voriconazole 200 mg BD on Days -8,-7,-6,-5,-4 with alkylating agent backbone consisting of Busulfan 3.2mg/kg on D-3,-2 and Cyclophosphamide 2000mg/m^2 on D-2 to D-1 . All patients received ATLG 10 mg/kg divided over D-4 to D-1. GVHD prophylaxis consisted of Methotrexate 15 mg/m^2 on D+1 and 10 mg/m^2 on days +3,+6,+11 cyclosporine A (from day -1 with tapering from day +100, target concentration 200-400 mcg/l), and mycophenolate mofetil 1 g/d (days -8 to +30). All patients received GCSF and Plerixafor mobilized peripheral blood stem cells.

Results: A total of 20 patients (14 males)with relapsed or refractory AML underwent FLAVER-SCT between June and September 2024. The median age was 32 years. Six (30%) patients had refractory AML, while 14 (70%) had relapsed AML. The median number of lines of therapy was 2 (1–3). 5(25%) were favorable risk, 9 (45%) intermediate risk and 6 (30%) adverse risk as per ELN classification. FLT3-ITD mutations were present in 8 (40%) patients. Prior exposure to therapy included venetoclax in 19/20 (95%), FLT3 inhibitors in 4/20 (20%), and previous allogeneic transplantation in 1/20 (5%). The median blast percentage

was 19% before conditioning. Donors included haploidentical donors in 10/20 (50%) patients and matched sibling donors in 10/20 (50%).
The CR/CRp rate at Day +30 post-allo-SCT was 90% (18/20), with MRD-negative remission in 17/18 (94.4%) of evaluable patients. The median time to neutrophil recovery was 12 days (8–18).
Grade 3–5 infectious complications occurred in 15/20 (75%) patients, and CMV reactivation was observed in 12/20 (60%). Grade 3–4 diarrhea noted in 6/20 (30%).Veno-occlusive disease was documented in 4/20 (20%).Grade 3–4 acute GVHD occurred in 5/20 (25%).Day 30 mortality was 10% (2/20).
At the data cutoff date (30 November 2025), 8 (40%) patients were alive, 5 (25%) relapsed and subsequently died, 2 (10%) died in transplant course and 4 (20%) died of transplant related complications and 1(5%) patient died of stroke. At a median follow up of 16.5 months, median OS and DFS was 16.3 and 15.6 months respectively.



Conclusions: In this single center experience, FLAVER-SCT demonstrated encouraging remission rates and manageable toxicity in patients with relapsed and active AML, a

population historically associated with poor prognosis. The high CR/CRp rate and rapid neutrophil engraftment suggests potent disease control. Despite frequent toxicities acute mortality remained acceptable with durable remissions. Larger prospective studies are warranted to validate these findings.

Disclosure: Nothing to Declare

P206

THE EFFICACY AND SAFETY OF COMBINED FLUDARABINE, BUSULFAN, AND MELPHALAN REDUCED-INTENSITY CONDITIONING (RIC) REGIMEN IN ALLOGENEIC STEM CELL TRANSPLANTATION FOR ADULTS WITH HEMATOLOGIC MALIGNANCY DISEASES

Sunatcha Coratat[1], *Pokpong Piriyakhuntorn*[1], *Adisak Tantiworawit*[1], *Lalita Norasetthada*[1], *Ekarat Rattarittamrong*[1], *Chatree Chai-adisaksopha*[1], *Thanawat Rattanathammethee*[1], *Sasinee Hantrakool*[1], *Teerachat Punnachet*[1], *Nonthakorn Hantrakun*[1], *Sirichai Srichairatanakool*[1]
[1]*Chiang Mai University, Chiang Mai, Thailand*

Background: Reduced-intensity conditioning (RIC) regimen is therapeutic option for older patients or those with comorbidities undergoing allogeneic stem cell transplantation (allo-SCT). While fludarabine-based regimens (with either busulfan or melphalan) are widely used, balancing relapse incidence (RI) against non-relapse mortality (NRM) remains challenging. This study evaluated the efficacy and safety of a triple-agent RIC regimen combining Fludarabine, Busulfan, and Melphalan (Flu-Bu-Mel) in patients with malignant hematological diseases.

Methods: This retrospective study was performed using registry data from adult patients underwent allo-HCT following fludarabine (125 mg/m^2), busulfan (6.4 mg/kg) and melphalan (100 mg/m^2) conditioning regimen at Chiang Mai University hospital between September 2022 and October 2025. The primary endpoint was Overall Survival (OS). Secondary endpoints included Relapse-Free Survival (RFS), Relapse Incidence (RI), Non-Relapse Mortality (NRM), and safety profiles.

Results:

Baseline Characteristics	Total (n=25)	Related Donor (RD) (n=12)	Unrelated Donor (UD) (n=13)	P value

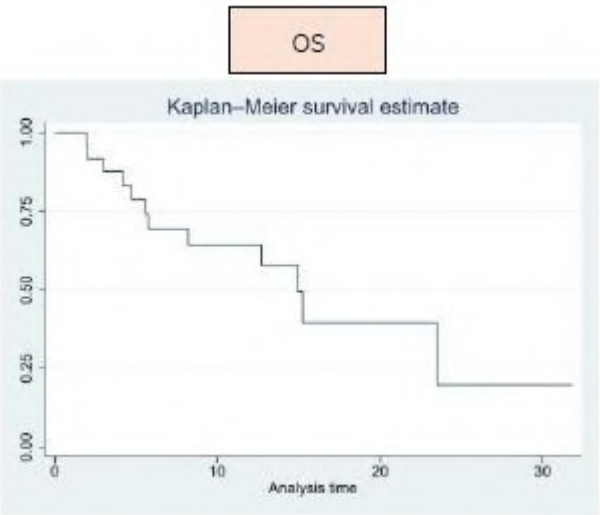
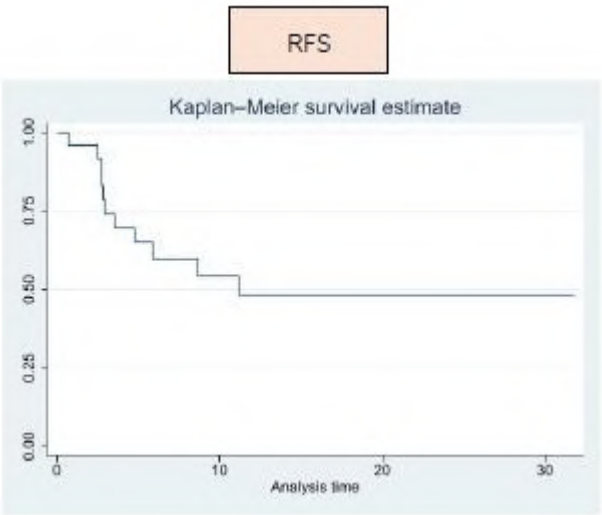
Platelet engraftment, median (IQR), day after stem cell infusion	15 (13-17)	13.5 (12.5-15)	16 (14-21)	0.023

A total of 25 patients (AML n=9, ALL n=6, MDS n=4, CML blastic phase n=2, CMML n=1,

Myelofibrosis n=1, Relapsed PTCL, NOS n=1 and Relapsed cHL n=1) were analyzed. The median age was 40 years (30-49). Donors were matched related (n=12) and unrelated (n=13). Most patients (84%) were in the first complete remission (CR1) at the time of transplant. Stem cell source were G-CSF-mobilized peripheral blood stem cells (PB) (100%). Patients underwent match related allo-HCT were recieved CNI/MTX GVHD prophylaxis, while patients underwent match related allo-HCT were recieved PTCy/Tacrolimus/MMF GVHD prophylaxis. The median time to neutrophil was 17.5 and 21 days in match related and unrelated allo-HCT, respectively. The madian time to platelet recovery was 13.5 and 16 days in match related and unrelated allo-HCT, respectively.
The 1-year OS, RFS, GRFS and NRM were 68.0%, 56.0%, 28.0% and 8.3% respectively, while the Relapse Incidence (RI) was 44.0%. There was no statistically significant difference in 1-year OS between related (75.0%) and unrelated allo-HCT patients (61.5%) (p=0.673). Median OS and RFS was 14.9 (5.6-23.5) and 11.2 (2.9-NR) months, respectively.





The incidence of acute GVHD was 12.0%, and chronic GVHD was 32.0%. There was no statistically significant difference in incidence of aGVHD and cGVHD between related and unrelated allo-HCT patients (p>0.999 and 0.411, respectively).
In terms of safety, the regimen was well-tolerated. Common Grade 3-4 non-hematologic adverse events included diarrhea (12.0%), oral mucositis (8.0%), and lung infection (8.0%). There was one Grade 5 adverse event (Lung infection) (4.0%).

Conclusions: The Flu-Bu-Mel reduced-intensity conditioning regimen demonstrates a favorable safety profile with low non-relapse mortality (NRM) and acceptable toxicity in patients with hematological malignancies. However, the relapse rate remains a concern (44%). This triple-agent regimen is a feasible option for patient ineligible for myeloablative conditioning, though further studies are warranted to optimize relapse prevention.

OS05-01

COMBINED TRANSPLANTS (HEMATOPOIETIC STEM CELL AND SOLID ORGAN) TO ACHIEVE IMMUNE TOLERANCE: A EUROPEAN PEDIATRIC STUDY

Pietro Merli[1], *Kanchan Rao*[2], *Peter Lang*[3], *Francisco Hernandez Oliveros*[4], *Robert Chiesa*[2], *Satish Meena*[2], *Mattia Algeri*[1], *Steffen Hartleif*[3], *Ane Andres*[4], *Isabella Guzzo*[1], *Juliana Silva*[2], *Tim Flaadt*[3], *Persis Amrolia*[2], *Marco Spada*[1], *Mariam Basil Abdul Aziz*[4], *Silvio Nadalin*[3], *Franco Locatelli*[1], *Krzysztof Kalwak*[5], *Antonio Perez Martinez*[4]
[1]*Bambino Gesù Children's Hospital, IRCCS, Rome, Italy,* [2]*Great Ormond Street Hospital, London, United Kingdom of Great Britain and Northern Ireland (the),* [3]*Universitätsklinikum Tübingen, Tubingen, Germany,* [4]*Hospital Universitario La Paz, Madrid, Spain,* [5]*Uniwersytet Medyczny we Wrocławiu, Wroklaw, Poland*

Background: One of the possible indication of allogeneic hematopoietic stem cell transplantation (alloHSCT) is the induction of immune tolerance in the setting of solid organ transplantation (SOT). Indeed, lifelong immunosuppression is associated with significant morbidity, while it does not completely prevent graft rejection. This is of particular importance in children, in whom life expectancy is long, frequently overcoming the graft survival. Although specific programs for combined transplant are active in adults, pediatric programs are lacking and data on combo transplant are scarce and anecdotal.

Methods: PDWP sub-commission COST4KIDS, aimed at studying this peculiar field in transplantation, conducted a retrospective multicenter data collection on patients receiving a combined transplant (i.e., alloHSCT + SOT) whatever the sequence of the transplants, in 4 countries, namely Italy, UK, Spain and Germany.

Results: We identified 30 transplants combined with alloHSCT: 20 liver, 7 kidneys and 3 multivisceral transplants (gut+liver). Median age at first transplant was 6.1 years (interquartile range, IQR, 4.6-11.1). The donor was the same for both the transplant in 12 cases (6 kidney and 6 liver), while it differed (mainly being a cadaveric donor) in all other cases. Regarding the timing of HSCT/SOT, HSCT preceded SOT in 9 cases [7 kidneys and 2 liver transplants; median time 16 months (IQR 11-19)], while it followed in 21 cases [median time 10.2 months (IQR 3-22)]. Indication to SOTs varied (details in Table 1); in general, there were two main scenarios: 1) liver transplant for hepatic failure due to nonAtoE-viral hepatitis from a cadaveric donor, followed by alloHSCT (from a different donor) because of severe aplastic anemia developing after SOT (11 cases); 2) alloHSCT for an hematological indication, followed by SOT (kidney or liver, frequently from the same HSC donor) because of organ failure as complication of alloHSCT (9 cases). Eleven patients (36.6%) received a fully-myeloablative conditioning, one none, while the others a reduced-intensity conditioning. All

patients, including those who underwent SOT after HSCT from the same donor of HSC, received immunosuppression after the SOT. Importantly, 11 patients out of 30 (36.6%), were able to safely discontinue immunosuppression. In details, 6 liver transplant (who received an HSCT after SOT) and 5 kidney transplant (who received an HSCT before SOT) stopped IS after a median of 150 days after the last transplant (IQR 60-470) without occurrence of graft rejection. In 3 cases the donor of SOT and alloHSCT was different. Infectious complications (including bacterial, viral and fungal infections) after both HSCT and SOT and surgical complications after SOT were frequent, reflecting the heavily immunocompromised state of these patients and the complexity of this kind of program. With a median follow-up of 4.8 years (IQR 2.5-6.6) 24 patients are alive with conserved organ function.

Indication to SOT		**Number**		**Indication to alloHSCT**	**Number**
Liver	hepatic failure due to nonAtoE-viral hepatitis	11		aplastic anemia	13
	hepatic failure due to adenovirus	1		acute leukemia	6
	hepatoblastoma	4		Hodgkin lymphoma	1
	autoimmune hepatitis	1		Shwachman-diamond syndrome	1
	alpha-1 antitrypsin deficiency	1		hemophagocytic lymphohistiocytosis	1
	liver failure due to secondary HLH	1		severe combined immunodeficiency	1
	iron overload	1		beta-thalassemia	1
Kidney	ESRD due to TMA	2		concomitant to favor immune tolerance	6
	interstitial nephritis	2			
	glomerular sclerosis	1			
	glomerulonephritis	1			
	SIOD	1			
Multivisceral	short bowel syndrome due to malrotation and volvulus	2			
	epithelial dysplasia	1			

Conclusions: Despite a complex scenario, with different indications, timing of transplants, donor employed and immunosuppressive regimens used, these data indicates that HSCT can induce immune tolerance also in the pediatric setting. Long-term data on organ function and chimerism/immune recovery will help in further refining this kind of interventions.
Perspective studies and dedicated programs in children are urgently needed.

Disclosure: None related to this abstract.

Background: The ACCESS trial (NCT04904588) showed favorable combined one-year overall survival (81%) after mismatched unrelated donor (MMUD) hematopoietic cell transplantation (HCT) in 145 adult patients using post-transplantation cyclophosphamide (PTCy, 50 mg/kg Days 3&4) (PMID 40523209). However, 87 (60%) patients [42 (56%) receiving myeloablative, MAC (n=75) and 45 (64%) receiving non-myeloablative/reduced intensity conditioning, NMA/RIC (n=70)] experienced 275 clinically significant infections (CTCAE Grade 2-5) within the first 100 days (D100) [n=72 MAC, n=203 RIC/NMA]. The OPTIMIZE trial (NCT06001385) using reduced dose (RD) PTCy (25 mg/kg D3&4) aims to attenuate infection burden while maintaining graft-versus-host disease (GvHD) prevention. Herein, we describe immune reconstitution (IR) and cumulative incidence of infection by D100 following MMUD HCT in a subset of patients with available data enrolled in OPTIMIZE.

Methods: Correlative data was restricted to 69 adult patients enrolled on OPTIMIZE with available donor chimerism (D28, 100), IR (D28, D56, 100), and infection data by D100. Unsorted bone marrow or peripheral blood (PB) CD3+ donor chimerism analyses were performed at sites, while IR analyses were performed at a central reference laboratory. Absolute numbers of immune cell populations (mean ± SEM) were calculated by multiplying the percentage of a gated cell population by white blood cell count (cells/μL) from the same PB sample. Infections were graded using Blood and Marrow Transplant Clinical Trials Network (BMT CTN) criteria. Exact binomial and complementary log-log confidence intervals were

computed around estimates of donor chimerism and cumulative incidences of infection, respectively.

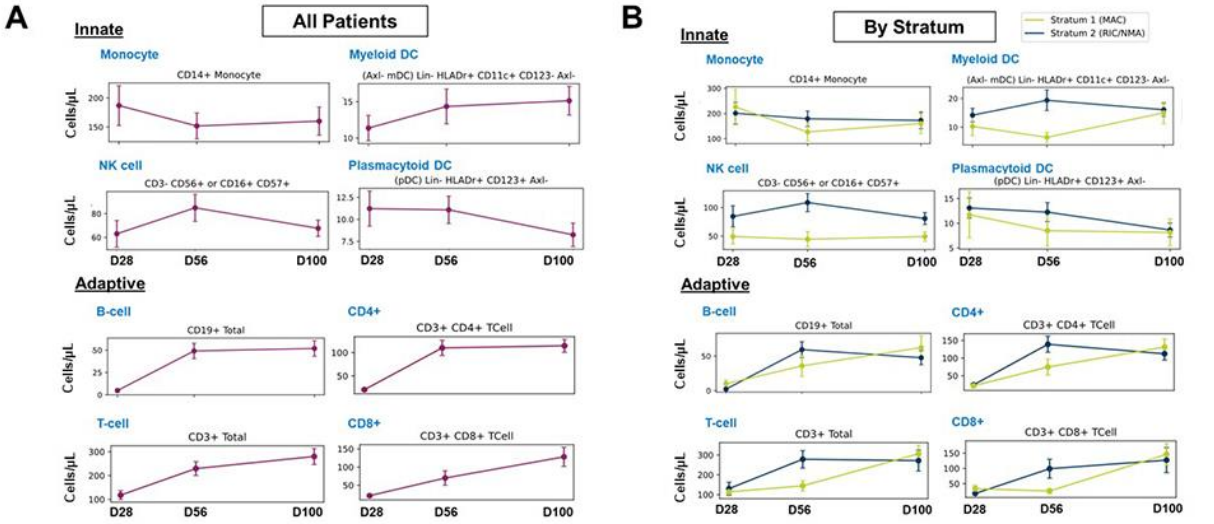
Results: Median patient age by stratum was 41 (19-64) and 68 (42-78) years for MAC (n=26) and RIC/NMA (n=43) recipients, respectively. The most common conditioning regimens were Busulfan/Fludarabine (Flu) (46%) and Flu/total body irradiation (TBI) (42%) for MAC recipients and Flu/Melphalan (51%) and Flu/Cyclophosphamide/TBI (21%) for RIC/NMA recipients. The percentage of patients with ≥95% donor chimerism at D28 and D100 were 75.4% (95% CI 63.5-84.9) and 79.7% (95% CI 68.3-88.4), respectively. Donor chimerism did not differ by conditioning intensity (data not shown). Median time to absolute neutrophil recovery (≥500/µl) for all patients was 14 days (13-15) and did not differ by conditioning intensity (data not shown). In general, mean absolute numbers of immune cells increased from D28 to D100 except for monocytes, which decreased after D28 (**Figure 1A**).

Natural killer and plasmacytoid dendritic cells decreased after D56, while B- and T-cell increased to 50 cells/µl by D56. Patients receiving MAC had slower IR versus RIC/NMA recipients (**Figure 1B**). By D100, 22 (30%) patients [n=11 per stratum] experienced 35 BMT CTN Grade 2-3 infections [n=18 MAC, n=17 RIC/NMA]. Cumulative incidence of BMT CTN Grades 2-3 infection for all patients by pathogen type are shown in **Figure 1C**. Cumulative incidences of BMT CTN Grades 2-3 infections were higher in MAC versus RIC/NMA recipients, with most infections occurring by D28 (**Figure 1D**).

Figure 1. Innate and Adaptive Immune Cell Recovery and Cumulative Incidence of Infection



C

Cumulative Incidence (95% CI) of First BMT CTN Grade 2-3 Infection by Pathogen Type			
	D28	D56	D100
All Pathogens	21.3% (12.9-31.2)	26.7% (17.2-37.1)	33.5% (23.0-44.2)
Bacterial	10.7% (5.0-18.9)	12.0% (5.9-20.5)	16.1% (8.8-25.3)
Viral	12.0% (5.9-20.5)	17.3% (9.7-26.7)	20.0% (11.8-29.8)

No fungal infections reported. Competing events included second transplant, death, early termination, and loss to follow-up.

D

Cumulative Incidence (95% CI) of First BMT CTN Grade 2-3 Infection By Strata			
Stratum (No. pts)	D28	D56	D100
MAC (n=26)	26.9% (11.7-44.9)	34.6% (17.1-52.9)	42.3% (23.0-60.4)
RIC/NMA (n=43)	16.3% (7.1-28.8)	18.6% (8.6-31.5)	25.8% (13.7-39.6)

Competing events included second transplant, death, early termination, and loss to follow-up.

Conclusions: OPTIMIZE is the first MMUD trial using RD PTCy to describe donor-derived immune recovery and its association with infection. Preliminary findings suggest differences in IR based on conditioning intensity with MAC recipients having slower IR and higher cumulative incidence of infection.

SYSTEMS BIOLOGY APPROACH REVEALS BDNF AS A DRIVER OF B-CELL REGENERATION

Neta Nevo[1,2], *Yuval Klein*[1], *Ayelet Alpert*[1], *Amir Grau*[1], *Doron Melamed*[1], *Neta Milman*[1], *Timothy J. Few-Cooper*[1], *Shai S. Shen-Orr*[1]
[1]*Technion - Israel Institute of Technology, Haifa, Israel,* [2]*Tel Aviv Sourasky Medical Center, Tel Aviv, Israel*

Background: Prolonged B-cell aplasia, observed after allogeneic hematopoietic stem cell transplantation (HSCT) and CD19 directed immunotherapies, impairs protective immune responses against cancer, infections, and vaccines. In contrast to the myeloid and erythroid lineages, which can be supported using G-CSF and erythropoietin, there is currently no therapeutic strategy available to promote B-cell development. Here, we utilized a system biology approach to discover drivers for B lymphopoiesis in the human Bone Marrow (BM).

Methods: We analyzed single cell RNA sequencing (scRNA-seq) data from healthy human BM samples and applied the CellAllign algorithm to compare B-cell developmental trajectories across individuals. We quantified circulating proteins in patients treated with B-cell depleting therapies using multiplex protein assays. Putative drivers identified through these analyses were evaluated in single cell stimulation assays and in an in vitro co culture system modeling B-cell development from CD34+ progenitor cells.

Results: By mapping the BM intercellular communication landscape using scRNA-seq datasets, we identified multiple microenvironment derived signals predicted to interact with and influence early B-cell progenitors. Our computational analyses highlighted a subset of putative drivers enriched in stromal and niche populations positioned to support B-cell maturation. To refine this list, we incorporated information from several orthogonal datasets, including transcriptional signatures associated with age impaired B lymphopoiesis, differences in developmental trajectory dynamics across individuals, and regulatory patterns emerging from mesenchymal stromal cells. We also examined plasma protein profiles from patients who had undergone B-cell depleting therapies, which provided an additional layer of evidence for factors that may influence B-cell regeneration in vivo.
Across these analyses, several high confidence candidates emerged. Functional single cell stimulation assays demonstrated that these candidates activated distinct transcriptional programs related to B-cell development, including pathways involved in lineage proliferation, differentiation and survival. Different putative drivers influenced non overlapping sets of genes, suggesting that multiple regulatory mechanisms converge to shape human B lymphopoiesis. Among the prioritized molecules, brain derived neurotrophic factor (BDNF) consistently showed strong and reproductive ability to activate B-cell developmental pathways.
To assess its functional relevance, we tested BDNF in an in vitro co culture system that

models early human B-cell development from CD34+ hematopoietic stem and progenitor cells. In this biological system, BDNF exposure led to a marked increase in the generation of early B-cell progenitors. The enhancement of differentiation was observed across multiple donors, demonstrating that the effect of BDNF is robust and not donor specific. Together, these results identify BDNF as a previously unrecognized driver of human B-cell development and validate our multi-layered approach for discovering new regulators of hematopoiesis.

Conclusions: Our findings reveal new regulators of human B lymphopoiesis and suggest potential therapeutic strategies for enhancing B-cell development in clinical settings. By integrating single cell genomics, proteomics, computational alignment, and functional in vitro assays, we establish a framework for dissecting complex developmental processes in the BM. This integrative approach provides a scalable template for identifying accelerators of additional immune lineages and advancing system level understanding of human immune regeneration following HSCT.

COMPARISON OF IMMUNE RECONSTITUTION AND INFECTION-RELATED OUTCOMES WITH PT-CY VERSUS ATG AFTER MUD TRANSPLANTATION FOR HIGH-RISK MYELOID MALIGNANCIES

Giulia Furnari[1], *Verena Wais*[2], *Anna Francesio*[1], *Katrin Strauss*[2], *Simona Piemontese*[3], *Jacqueline Schnell*[2], *Panagiota Gianni*[2], *Raffaella Greco*[3], *Frank Stegelmann*[2], *Andrea Assanelli*[3], *Donald Bunjes*[2], *Fabio Ciceri*[3,1], *Hartmut Döhner*[2], *Maria Teresa Lupo-Stanghellini*[3], *Elisa Sala*[2]
[1]*Università Vita-Salute San Raffaele, Milan, Italy,* [2]*University Hospital Ulm, Ulm, Germany,* [3]*IRCCS Ospedale San Raffaele, Milan, Italy*

Background: Post-transplant cyclophosphamide (PT-Cy) and anti-thymocyte globulin (ATG) are widely used T-cell depletion strategies in matched unrelated donor (MUD) allogenic hematopoietic cell transplantation (allo-HCT). However, no consensus exists regarding the recommended approach. Assessing how these strategies affect immune reconstitution (IR) and infection rates may help define a decision-making algorithm.

Methods: We retrospectively analyzed the timing and dynamics of IR in a two-center study of allo-HCT from MUD following intermediate- or high-intensity conditioning for high-risk myeloid malignancies. GVHD prophylaxis differed by center (ATG 30 mg/kg plus calcineurin inhibitors versus PT-Cy 100 mg/kg plus rapamycin). Immune monitoring was performed monthly throughout the first year after allo-HCT by flow cytometry with quantification of $CD3^+CD4^+$ and $CD3^+CD8^+$ T cells, $CD19^+$ B cells, and $CD56^+CD16^+$ NK cells. IR was defined as sustained recovery of $CD3^+CD4^+$ T-cells >200/µL and $CD19^+$ B-cells >50/µL.

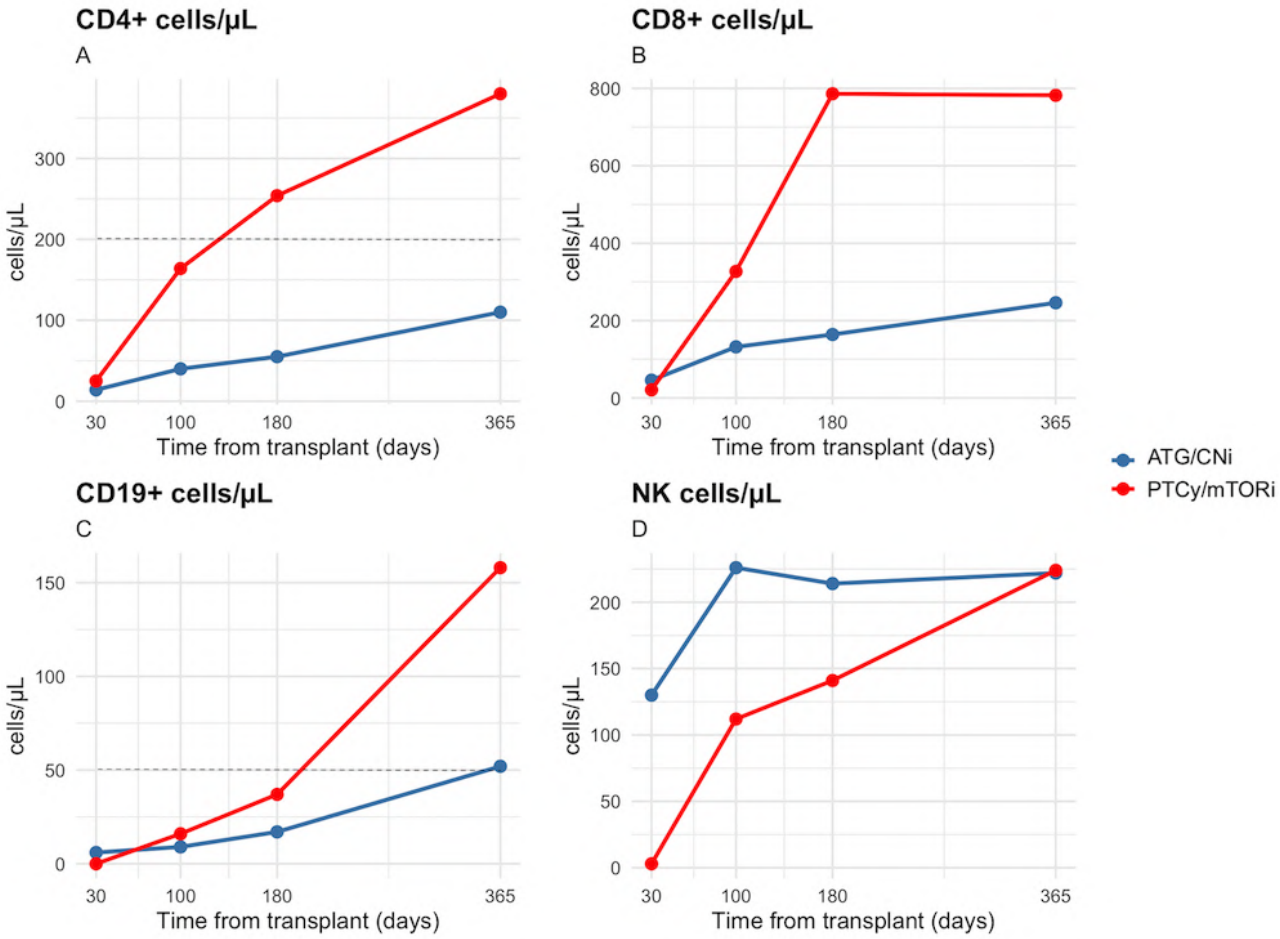
Results: Overall, 204 patients were included, 154 (75.5%) receiving ATG and 50 (24.5%) receiving PT-Cy. The cohorts were comparable, except for a higher proportion of patients

with high EBMT risk score among those in the ATG group (p<0.001), and more high-risk recipient/donor CMV matching in the PT-Cy group (p<0.001) (**Table1.docx**). The 1-year cumulative incidence (CI) of IR was 41% in the PT-Cy arm versus 7% in the ATG arm (p<0.0001), increasing at 18 months to 53% and 16%, respectively. Multivariable analysis—adjusting for recipient/donor age, EBMT risk score, conditioning intensity, and CMV serology—confirmed this association (SHR 0.40, 95%CI 0.22–0.70; p=0.001). IR dynamics differed: $CD3^+CD4^+$, $CD3^+CD8^+$, and $CD19^+$ recovery were faster with PT-Cy, whereas NK cells peaked earlier with ATG, converging between the two populations by one year (**Figure 1**). Coherent with IR kinetics, the incidence of severe infections requiring re-hospitalization within six months from allo-HCT was higher in the ATG cohort (36.4% versus 8.2%; p<0.001). Among these episodes, fungal infections were observed exclusively with ATG (17.9%). Bacterial infections during the first six months post-transplant were more common among PT-Cy recipients (75% versus 39.3% in the ATG group). Finally, viral infections requiring hospitalization in the first six months were observed in both cohorts (50% in PT-Cy versus 35.7% in ATG). Notably, clinically relevant CMV reactivations within 1 year from transplant were more frequent after ATG, with an incidence of 24.7% versus 12% in the PT-Cy cohort (p=0.09). EBV reactivations were restricted to the ATG arm throughout follow-up (22.1%).

Consistent with these findings, 100-day transplant-related mortality (TRM) was 2% in the PT-Cy group and 9% in the ATG cohort (p<0.001), rising to 28.6% at 1 year in ATG while remaining 2% in PT-Cy. Infectious TRM accounted for 6% at 100 days and 15.6% at 1 year after allo-HCT in the ATG arm, whereas no infectious deaths occurred in PT-Cy-receiving patients (p=0.0011).

	ATG N = 154	**PTCy** N = 50	**p-value**
Male Gender, n (%)	93 (60%)	30 (60%)	>0.9
Age at transplant, median (IQR)	61 (54–66)	57 (45–65)	0.073
Baseline disease, n (%)			0.3
AML	101 (66%)	40 (80%)	
MDS, MPN, MDS/MPN	53 (34%)	10 (20%)	
EBMT risk score (categories), n (%)			**<0.001**
Low (0–2)	15 (9.7%)	5 (10%)	
Intermediate (3–4)	73 (47%)	41 (82%)	
High (5–7)	66 (43%)	4 (8.0%)	
Donor age, median (IQR)	31 (25–37)	27 (23–35)	0.052
CMV serostatus (R/D), n (%)			**<0.001**

	ATG N = 154	**PTCy** N = 50	**p-value**
High risk (+/+,+/-)	61 (40%)	44 (88%)	
Intermediate risk (-/+)	24 (16%)	1 (2.0%)	
Low risk (-/-)	69 (45%)	3 (6.0%)	
Female Donor/Male Recipient, n (%)	0 (0%)	0 (0%)	
Transplant Conditioning Intensity, n (%)			0.2
Intermediate	116 (75%)	33 (66%)	
High	38 (25%)	17 (34%)	
Median follow-up (month), median (IQR)	23 (7–48)	41 (30–53)	**<0.001**



Conclusions: In this retrospective study, the PT-Cy + rapamycin platform was associated with a faster and more sustained IR, a lower incidence of infection-related hospitalizations, and a lower infectious TRM. These potentially clinically meaningful findings warrant validation in prospective, randomized studies.

Background: The importance of three-month (3-mo) chimerism as a trigger for pre-emptive donor lymphocyte infusion (DLI) remains unknown. Herein, we present a multicentre study on this topic across T-cell-depleted (TCD) allogeneic stem cell transplantation (allo-SCT) for various haematological malignancies. This study aims to evaluate the impact of 3-mo chimerism-triggered DLI on 2-year overall survival (OS), progression-free survival (PFS), cumulative incidence of relapse (CIR), non-relapse mortality (NRM) and graft-versus-host disease-free/relapse-free survival (GRFS).

Methods: This retrospective multicentre study included 649 patients from five centres who received TCD allo-SCT. Patients who relapsed (n=43) or died (n=73) before 3-mo were excluded. The median age was 56.7 years (range 16.5-76.9), with 59.7% males. Disease lineage included myeloid (n=378) and lymphoid (n=151). Donor types included unrelated (n=411) and sibling (n=115). Median follow-up estimated using the reverse Kaplan-Meier method was 34.6 months. Mixed donor chimerism was defined as 5-95% donor cells. Full donor chimerism was defined as >95%. OS, PFS and GRFS were calculated using univariate and multivariable Cox proportional hazards models. For GRFS analysis only, patients with MC who developed GVHD before 180 days and subsequently did not receive DLI were excluded. CIR and NRM were assessed with Fine-Gray competing-risks regression for both univariate and multivariable analyses. Multivariable models adjusted for age, sex, disease lineage, cytogenetic risk, cytomegalovirus serostatus, donor type, and presence of acute graft-versus-host disease.

Results: Among individuals with 3-mo mixed chimerism (MC) in whole blood (WB), univariate analysis showed improved PFS (HR 0.46, 95% CI 0.22–0.98, p=0.04) and GRFS (HR 0.34, 95% CI 0.16-0.72, p=0.0049) with DLI, but no significant effect on OS, CIR or NRM. Those with MC in T-cell (TC) subset showed improved OS (HR 0.48, 95% CI 0.25–0.90, p=0.023) and GRFS (HR 0.48, 95% CI 0.28-0.83, p=0.0078) with DLI, but no significant effect on PFS, CIR or NRM.
Multivariable analysis in the MC WB cohort found that pre-emptive DLI was significantly associated with improved PFS (HR 0.10, 95% CI 0.025–0.44, p=0.002), OS (HR 0.078, 95% CI 0.012–0.52, p=0.008), GRFS (HR 0.048, 95% CI 0.0089-0.26, p=0.00042) and reduced CIR (HR 0.14, 95% CI 0.03-0.68, p=0.014), with no effect on NRM. In the MC T-cell cohort, DLI significantly improved OS (HR 0.26, 95% CI 0.08-0.77, p=0.016) and GRFS (HR 0.26, 95% CI 0.11-0.62, p=0.0026), without affecting NRM.

Conclusions: Pre-emptive DLI in patients with 3-mo MC following T-cell-depleted allo-SCT is associated with improved survival outcomes. In WB MC, DLI significantly improves 2-year PFS and OS due to reduced CIR without negatively impacting GRFS or NRM. In TC MC, DLI was associated with improved OS, without impaired GRFS or increased NRM. These findings support the use of 3-mo chimerism measurement as an indication for pre-emptive DLI. Prospective studies integrating chimerism subsets with measurable residual disease are warranted to optimise post-transplant intervention strategies.

Background: Monitoring post-transplant chimerism in hematopoietic stem cell transplantation (HSCT) for sickle cell disease (SCD) is essential to guide immunosuppression management. Maintaining a minimum donor chimerism threshold of approximately 20–30% is crucial for long-term disease control. Identifying factors associated with the achievement and maintenance of complete chimerism (CC) remains an important objective.

Methods: We conducted a single-center analytical study including patients with SCD who underwent HSCT from an HLA-identical sibling donor between May 2010 and May 2025. Bone marrow was used as the stem cell source in all cases. Transfusion therapy was initiated 3 months before HSCT, and since 2015, hydroxyurea was started or intensified 1 month pre-HSCT to maintain reticulocyte counts below 100,000/mm³. Conditioning regimens consisted of busulfan, cyclophosphamide, and alemtuzumab until January 2015, and thiotepa, treosulfan, fludarabine, and anti-thymocyte globulin thereafter.
Donor/recipient chimerism was assessed in unfractionated peripheral blood (PB) and T lymphocytes (LT) at months +1, +12, and at last follow-up; bone marrow was additionally analyzed at month +1. CC was defined as ≥95% donor cells, mixed chimerism (MC) as ≥5% to <95%, and autologous reconstitution as <5%. Epidemiological, clinical, and analytical data were collected. Results are presented as medians (p25–p75) or percentages. Statistical analyses included chi-square or Fisher's exact tests, Wilcoxon signed-rank test, log-rank test, and mixed-effects regression models, with significance set at $p<0.05$.

Results: A total of 63 HSCTs were performed in 62 patients, with a median age of 6.45 years (3.07–9.82). Eleven patients received the first conditioning regimen and 52 the second. At month +1, 52 patients (82.5%) achieved CC in PB, while 11 had MC. At year +1, 40 patients (67.8%) maintained CC and 19 had MC; 2 of these showed recipient chimerism >80% with reappearance of SCD symptoms. At last follow-up, 41 patients (65.1%) remained in CC and 22 in MC, including 4 with >80% recipient chimerism. Among these, one patient experienced vaso-occlusive crisis and subsequently achieved CC after a second HSCT, one was lost to follow-up, one died due to refractory EBV-associated hemophagocytic lymphohistiocytosis, and one remains asymptomatic.
Higher pre-HSCT hemoglobin levels ($p=0.035$) and lower reticulocyte counts ($p=0.043$) were significantly associated with CC at last follow-up (Table 1). Pre-HSCT hemoglobin also showed a trend toward association with CC at year +1 ($p=0.052$). Mixed-effects regression models demonstrated that increasing time and higher pre-HSCT hemoglobin were associated with progressive decreases in donor chimerism in PB (Picture 1A) and LT (1B). Similar associations were observed for reticulocyte and fetal hemoglobin levels in PB chimerism (1C-D).

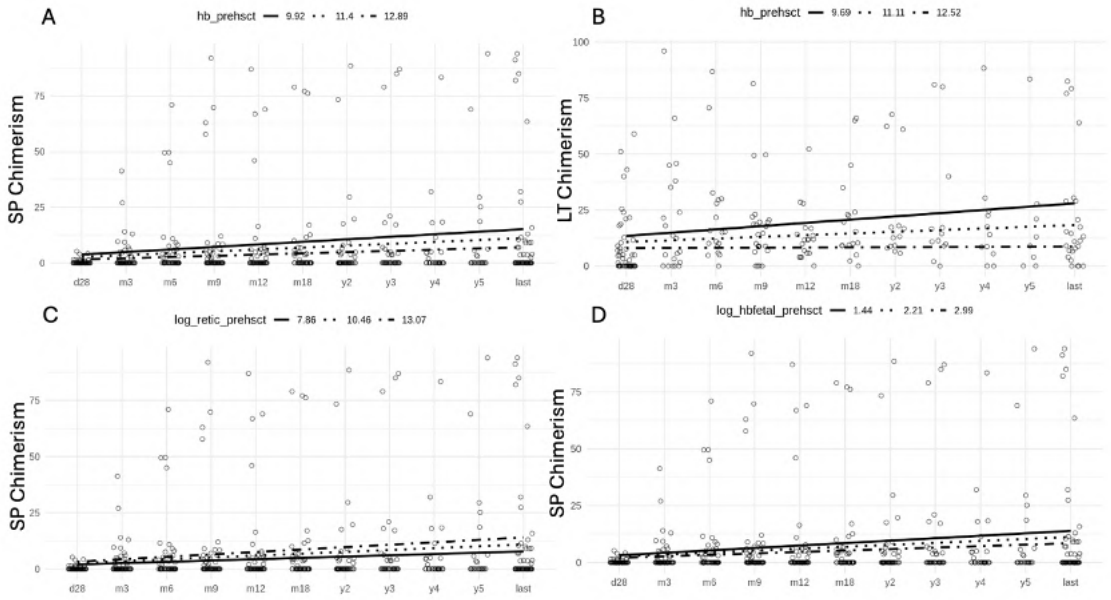
Table 1. Pre-HSCT factors and complete chimerism in PB at last follow-up

	Complete Chimerism Yes (N=41)[1]	Complete Chimerism No (N=19)[1]	
Pre-HSCT Ferritin (ng/ml)	640 (401, 964)	612 (225, 821)	0.3[2]
Pre-HSCT LDH (UI/L)	342 (281, 448)	351 (283, 441)	0.8[2]
Pre-HSCT HbS (%)	21 (14, 28)	23 (18, 37)	0.2[2]
Pre-HSCT HbF (%)	11 (6, 16)	11 (8, 14)	>0.9[2]
Pre-HSCT Hemoglobin (g/dl)	11.75 (10.7, 12.9)	10.90 (10.4, 11.7)	**0.035[2]**

Table 1. Pre-HSCT factors and complete chimerism in PB at last follow-up			
Pre-HSCT Reticulocytes (/mm^3)	73,800 (26,400, 129,100)	138,800 (45,100, 223,400)	**0.043**[3]
Pre-HSCT Dose Hydrea (mg/kg)	28.0 (25.0, 30.0)	28.0 (20.0, 30.0)	>0.9[2]
Splenectomy	4 (9.8%)	4 (21%)	0.2[4]
Pre-HSCT Chelation	10 (24%)	5 (26%)	>0.9[4]

[1] Median (p25, p75); n (%)
[2] Wilcoxon rank sum test
[3] Wilcoxon rank sum exact test
[4] Fisher's exact test

Picture 1. Longitudinal analysis of chimerism levels and hemoglobin (A+B), reticulocyte (C), and fetal hemoglobin (D) values prior to HSCT



Conclusions: Adequate pre-HSCT preparation, characterized by higher hemoglobin levels and lower reticulocyte counts, was associated with improved chimerism outcomes in this cohort. These findings warrant confirmation in larger, prospective studies.

PHARMACOLOGICAL MODULATION OF PROTEOSTASIS AS A STRATEGY TO BOOST THYMIC REGENERATION AND T CELL IMMUNITY

Shirley Genah[1], *Marsha Pellegrino*[1], *Manuela Giansanti*[1], *Angelica Mancusi*[1], *Alessio Taviani*[1], *Marco Rosichini*[1], *Antonella Cardinale*[1], *Gabriele Volpe*[1], *Francesca Nazio*[2], *Emmanuel De Crespin De Billy*[3], *Jarrod Dudakov*[4], *Marcel van den Brink*[5], *Franco Locatelli*[1,3], *Enrico Velardi*[1]
[1]*Bambino Gesu Children Hospital, Rome, Italy,* [2]*TorVergata University, Rome, Italy,* [3]*Catholic University of the Sacred Heart, Rome, Italy,* [4]*Fred Hutch Cancer Center, Rome, Italy,* [5]*City of Hope, Rome, Italy*

Background: Thymic function is highly vulnerable to injury from cancer treatments, infections, and graft-versus-host disease (GvHD), leading to impaired T-cell development and reduced immune surveillance. Prolonged thymic insufficiency exposes patients, particularly those receiving allogeneic hematopoietic cell transplantation (allo-HCT), to increased risks of infection and poor outcomes. Recently, better thymic function has also been associated with improved response to immune checkpoint inhibitors in cancer patients, underscoring the broader relevance of thymic health for immunotherapy success. Effective strategies to restore thymic function remain limited. We aimed to identify novel thymic-boosting approaches based on pharmacological induction of *Foxn1*, a key transcription factor regulating thymic epithelial cell (TEC) function and regeneration.

Methods: We developed a dual-luciferase reporter assay to screen 1,530 FDA-approved compounds for their ability to enhance FOXN1 activity in murine cortical TECs (Fig.1A). Compounds were evaluated for efficacy and toxicity (IC50, IG50), and top candidates were tested in mice subjected to sub-lethal total body irradiation (SL-TBI). Mechanistic studies included molecular profiling and flow cytometry to assess thymocyte development, TEC recovery, and signaling pathways.

Results: Proteasome inhibition emerged as a potent and previously unrecognized mechanism for regulating *Foxn1* transcription via proteotoxic stress and chromatin remodeling at its regulatory regions. Among the hits, the antiparasitic drug nitazoxanide (NTZ) induced proteasome inhibition and Foxn1 expression without cytotoxicity, unlike other proteasome inhibitors. Mechanistically, NTZ triggered endoplasmic reticulum (ER) stress and ATF4-mediated unfolded protein response (UPR), ultimately engaging autophagy as a compensatory survival mechanism. Consistently, pharmacological activation of UPR with salubrinal increased *Foxn1* and *Atf4* expression, and several other hits from our screen were known ER stress inducers, supporting the notion that *Foxn1* induction reflects a broader stress-related mechanism linked to alterations in cellular proteostasis. NTZ upregulated *Foxn1* and its downstream target Dll4, a key gene crucial for T cell commitment and expansion, in murine TECs as well as human primary TECs derived from pediatric thymic tissue (Fig.1B). In vivo, NTZ significantly accelerated thymic recovery after SL-TBI, restoring all thymocyte subsets, mature $CD4^+$ and $CD8^+$ T cells, and TEC compartments without impairing positive or negative selection (Fig.1 C-E). Analysis of TCRβ/CD69 and TCRβ/CD5 profiles confirmed normal progression through selection checkpoints, while CD24 expression on single-positive thymocytes indicated preserved deletion and maturation dynamics. Regulatory T cells ($CD4^+CD25^+Foxp3^+$) increased proportionally, maintaining stable frequency

within the CD4 compartment. TEC recovery was accompanied by reduced apoptosis (Fig.1F) and induction of *Foxn1* and its targets (*Dll4*, *Psmb11*) in cTECs alongside UPR genes *Atf4* and *Xbp1*, while *Aire* expression remained unchanged, suggesting preserved central tolerance.

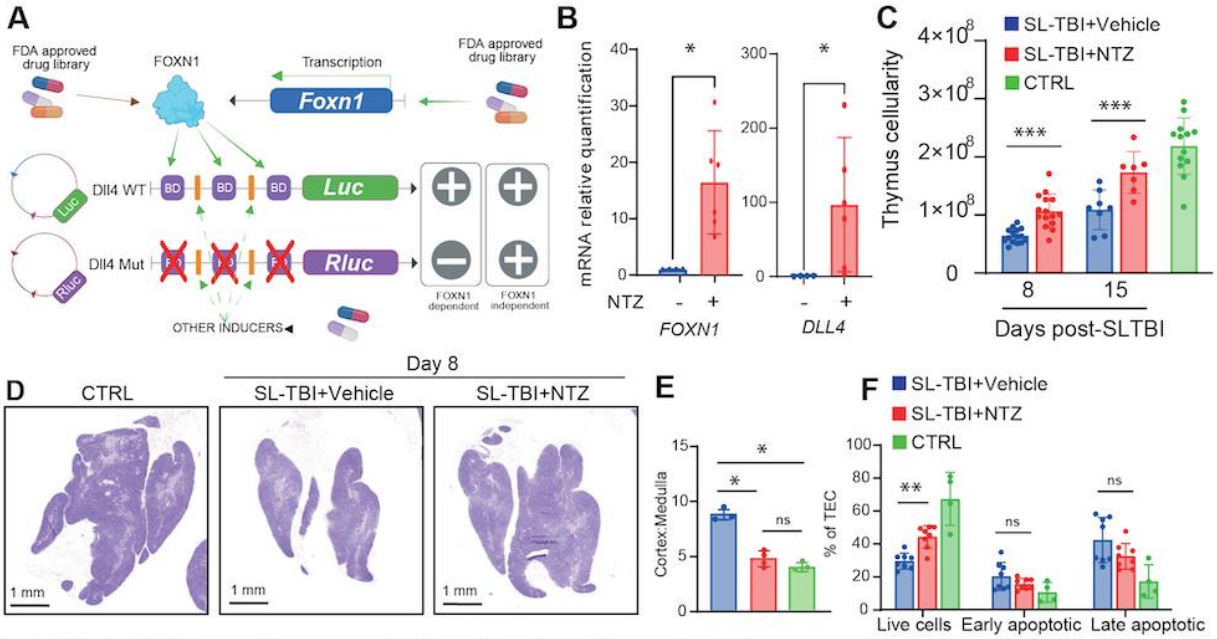

FIGURE1. (A) Schematic representation of the high-throughput drug screening system. (B) Stimulation of human primary TECs with NTZ and assessment of Foxn1 and Dll4 expression by qPCR. (C) Young C57BL/6 mice received SL-TBI and were treated with vehicle or NTZ. Total thymic cellularity was assessed at days 8 and 15 post-SL-TBI. (D) Representative H&E staining of thymus from control and sublethally irradiated mice, treated or not with NTZ. (E) Quantification of cortical to medulla ratio. (F) Evaluation of Annexin V in TECs 7 days after SL-TBI in vehicle- and NTZ-treated mice.

Conclusions: Our findings uncover proteotoxic stress as a novel mechanism regulating *Foxn1* expression and position NTZ as a promising thymic regenerative therapy that accelerates recovery without disrupting physiological T-cell selection or tolerance. Evaluation of T-cell recovery in clinically relevant HSCT mouse models is ongoing, supporting the translational potential of our study for allo-HCT recipients and individuals with thymic insufficiency due to aging, infections, or anti-neoplastic therapies.

Background: Memory T selected cells ($CD45RA^-/RO^+$) as donor lymphocyte infusion are less capable of producing alloreactivity and graft versus host disease (GvHD) compared with naïve T cells. The objective of this study was to evaluate the safety and efficacy of memory donor lymphocyte infusion (mDLI; $CD45RA^-/RO^+$) following allogeneic hematopoietic cell transplantation (HCT).

Methods: A total of 108 children (median age: 9.69 years; IQR: 4.5–13.16) diagnosed with malignant (74%) or non-malignant diseases (26%) received 864 mDLI infusions, administered either "as needed" or as a "prophylactic regimen". Patients received haploidentical grafts (48%), matched related donor (MRD) grafts (14%), matched unrelated donor (MUD) grafts (23%), and mismatched unrelated donor (MMUD) grafts (14%). Graft manipulation included CD45RA depletion (51%), TCRαβ depletion (37%), and unmanipulated grafts (11%). Each patient received monthly a median of seven infusions (IQR: 3–13) with a median dose of 1.65×10^7/kg $CD45RO^+$ cells, including 1.22×10^6/kg $CD3^+CD45RO^+$ and 1.6×10^3/kg $CD3^+CD45RA^+$.

Results:

	mDLI 1	mDLI 2	mDLI 3	mDLI 4	mDLI 5	mDLI 6	mDLI 7	mDLI 8	mDLI 9	mDLI 10	mDLI 11	mDLI 12	mDLI 13
Day after HCT, median (IQR)	35 (49)	61 (63)	83 (60)	105 (78)	130 (102)	162 (92)	186 (110)	217 (169)	239 (180)	270 (179)	293 (157)	300 (165)	351 (189)

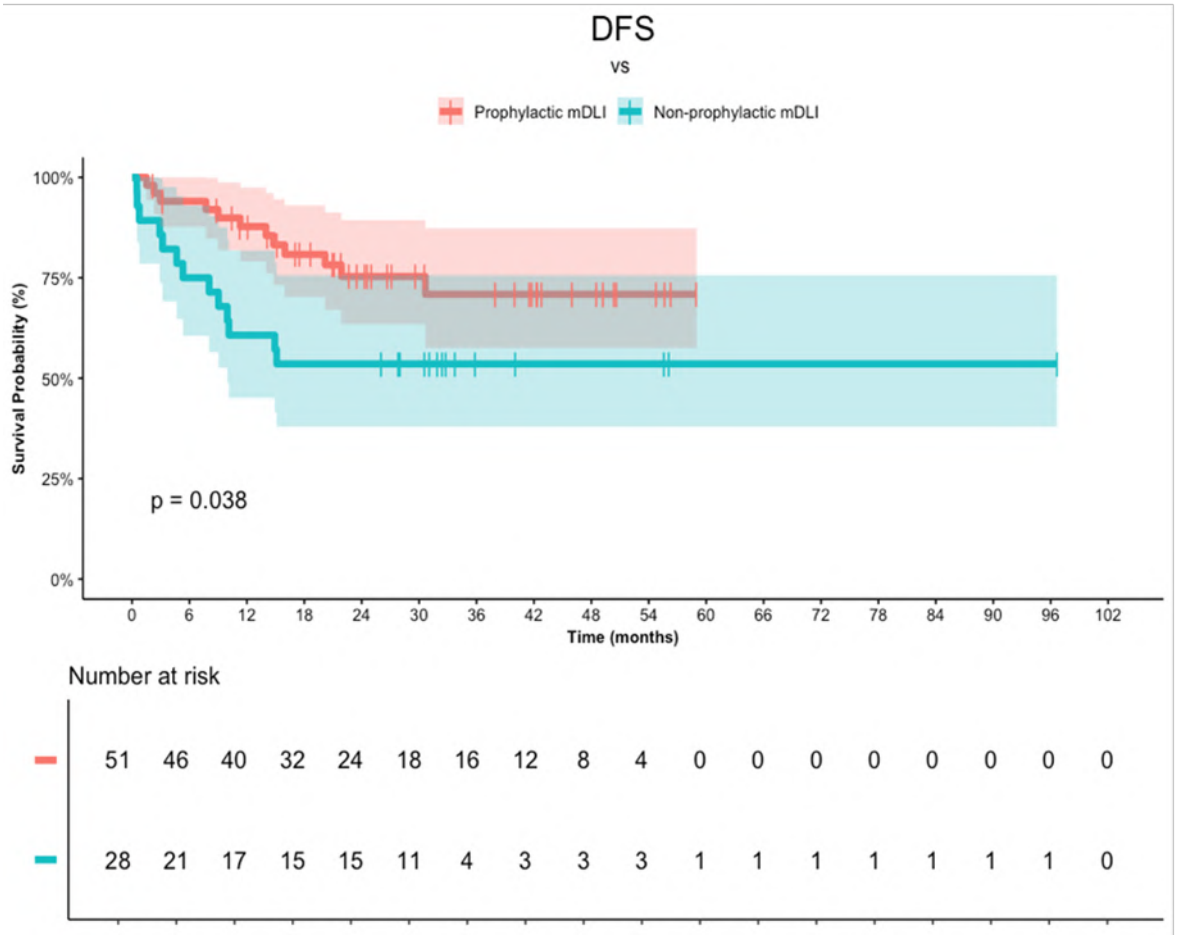
de novo GvHD>1, %	9	9	2	6	2	0	0	4	0	0	3	0	0
worsened GvHD>1; %	17	12	13	4	16	19	0	8	0	0	0	0	0
Patients taking immunoppressi on, %	63	59	52	49	44	38	47	40	44	45	36	26	32
CD4$^+$ x10^9/L	0.09			0.14			0.19						0.39
CD4$^+$ >0.05 x10^9/L, %	58			71			87						96
CD4$^+$ >0.2 x109/L, %	25			36			44						78

De novo acute graft-versus-host disease (aGvHD) occurred in 13 patients (17%) (36 of 599 infusions), with 8 patients (10%) experiencing grade II-IV. Among patients with pre-existing GvHD, worsening was observed after in 6 patients (17%) (29 of 229 infusions) with previously had GvHD II-IV. Patients with acute myeloid leukemia (AML) had a higher risk of GvHD worsening compared with those with acute lymphoblastic leukemia (ALL) ($p = 0.003$). Viral load clearance was achieved in 17%, 58%, 20%, 67%, 24%, and 8% of patients with CMV, EBV, HHV6, parvovirus, ADV, and BK virus, respectively. Reduction in viral load was statistically significant for EBV ($p = 0.02$) and approached significance for CMV ($p = 0.07$). Immune recovery was faster in the prophylactic mDLI group, evident as early as day 30 for total lymphocytes x 10^9/L (0.76 vs. 0.45, $p = 0.02$), T cells x 10^9/L (0.336 vs. 0.19, $p = 0.02$), and CD4$^+$ T cells x 10^9/L (0.112 vs. 0.06, $p = 0.05$). At day 90, B-cell x 10^9/L were higher (0.055 vs. 0.002, $p = 0.03$), and this difference persisted at day 180 (0.464 vs. 0.290, $p = 0.02$). NK cell recovery was also superior at day 180 (0.21 vs. 0.13, $p = 0.04$) and day 360 (0.25 vs. 0.15, $p = 0.007$).
Four-year overall survival (OS) and disease-free survival (DFS) for the entire cohort were 77% (95% CI: 69–87%) and 65% (95% CI: 55–78%), respectively. Patients receiving prophylactic mDLI had a four-year DFS of 71% (95% CI: 58–87%) compared with 54% (95% CI: 38–76%) in the non-prophylactic group (p=0.038).

Figure 1. Disease free survival comparing prophylactic mDLI vs non-prophylactic mDLI



Conclusions: mDLI is feasible and safe, with a relatively low risk of severe GvHD—even in patients with active GvHD. Importantly, mDLI was associated with significant clinical benefits, including improved control of EBV and CMV viremia, accelerated immune reconstitution, and enhanced DFS.

IMMUNE RECONSTITUTION DURING MAINTENANCE THERAPY WITH AZACITIDINE AFTER ALLOGENEIC HCT

Laura Pedretti[1], *Francesca Gottardi*[1], *Isard Sokoli*[1], *Gennaro Pagano*[1], *Francesco Baccelli*[1], *Gianluca Bossu*[1], *Serena De Matteis*[2], *Antonia Di Battista*[3], *Davide Leardini*[1], *Edoardo Muratore*[1], *Francesco Venturelli*[1], *Tamara Belotti*[1], *Martina Colli*[1], *Professor Arcangelo Prete*[1], *Professor Riccardo Masetti*[1]
[1]*Pediatric Hematology and Oncology, IRCCS Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy,* [2]*IRCCS Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy,* [3]*Pediatric Hematology and Oncology Unit, Rimini, Italy*

Background: Azacitidine is increasingly used as post-transplant maintenance to reduce relapse after allo-HCT. While its efficacy has been studied, data on early immune reconstitution, especially in pediatric patients, are limited. Assessing immune recovery during azacitidine is essential to evaluate its safety and feasibility.

Methods: We retrospectively analyzed immune reconstitution in 18 pediatric allo-HCT patients, comparing those receiving azacitidine maintenance (AZA, n=7) with controls (n=11). Patient characteristics, transplant variables, and immune subsets were assessed at 1, 3, and 6 months post-transplant by flow cytometry, focusing on T cells (CD3, CD4, CD8), total lymphocytes, NK cells, and $CD4^+CD8^+$ T cells. Counts were evaluated before azacitidine (1 month) and during maintenance.

Results:

Patients in the AZA group were younger (mean age 5.7 vs. 9.2 years) and more frequently diagnosed with JMML (71.4%), whereas all control patients had AML. GVHD prophylaxis differed, with more frequent ATG use in the AZA group and predominance of post-transplant cyclophosphamide in the control group. AZA was administered every 24 hours for 5 consecutive days, starting no earlier than day +40, and repeated every 40 days; in AML patients, it was combined with venetoclax. Treatment exposure ranged from 2 to 11 cycles, with fewer cycles in patients who discontinued due to GVHD or treatment-related mortality. In the AZA group, 4 patients developed grade II–IV acute GVHD: gut grade II (n=1), gut grade IV (n=2), and liver grade III (n=1), with 3 experiencing grade III–IV GVHD and one developing chronic GVHD (eye, skin). In the control group, 4 patients developed grade II–IV acute GVHD: skin/liver grade II (n=1), gut grade II (n=1), skin/gut grade II (n=1), and gut/skin grade III (n=1); only 1 patient experienced grade III–IV GVHD, and 3 developed chronic GVHD (skin/lung or skin/intestine). Infectious complications included Pseudomonas aeruginosa and EBV reactivation in 2 AZA patients, and parvovirus plus 4 CMV reactivations in 5 controls.
Referring to Table 1 and Figure 1, at 1 month post-transplant, prior to azacitidine, total lymphocyte counts were lower in the AZA group (median 249.5 vs. 770 cells/μL, p=0.0047), including $CD3^+$, $CD4^+$, and $CD8^+$ T cells. After AZA initiation, no significant differences were observed at 3 or 6 months. $CD4^+$ and $CD8^+$ T-cell differentiation showed transient early differences that normalized over time. NK cell frequencies converged by 6 months. Double-positive $CD4^+CD8^+$ T cells were increased at 1 month in the control group (p = 0.0007) but remained similar at later time points. Mean $CD3^+CD4^+$ T-cell counts at day +100 exceeded 50 cells/μL in both groups (78.4 vs. 119.2), with no significant differences at later time points.

Table 1

Conclusions: In this pediatric limited cohort, azacytidine maintenance therapy was not associated with sustained impairment of immune reconstitution after allo-HSCT. Although initial differences were observed prior to the start of maintenance, immune recovery trajectories during azacytidine exposure were comparable to those of controls, supporting its feasibility in the post-transplant setting. Larger prospective studies are warranted to determine the clinical significance of these immune findings.

B187

PREVALENCE AND LONG-TERM CLINICAL IMPACT OF SELECTIVE IGA DEFICIENCY FOLLOWING HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR PRIMARY IMMUNODEFICIENCY: A RETROSPECTIVE COHORT ANALYSIS

Sravani Vemuri[1], *Stuart Adams*[1], *Reem Elfeky*[1], *Maaika Kusters*[1], *Elizabeth Rivers*[1], *Kimberly Gilmour*[1], *Juliana Silva*[1]
[1]*Great Ormond Street Hospital for Children, NHS Foundation Trust, London, United Kingdom of Great Britain and Northern Ireland (the)*

Background: While T-cell recovery after hematopoietic stem cell transplantation (HSCT) for inborn errors of immunity (IEI) is well-documented, long-term B-cell reconstitution and associated humoral deficits remain inadequately characterized. Selective IgA deficiency (sIgAD) is a recognized potential sequela, but its frequency, predisposing transplant-related factors, and long-term clinical impact in IEI patients surviving >5 years post-HSCT are poorly defined.

Methods: We conducted a single-center, retrospective cohort study of patients with IEI who underwent HSCT between January 2010 and December 2020 and survived >5 years. Exclusion criteria included prior gene or thymus transplantation, death, or loss to follow-up within five years. Data extracted included IEI diagnosis, transplant details (donor, stem cell source, conditioning intensity, serotherapy), post-HSCT complications (acute/chronic GvHD), and long-term outcomes (>5 years): recurrent infections, autoimmunity, and detailed immune reconstitution (lymphocyte subsets, B-cell phenotypes, vaccination responses). We specifically analysed prolonged steroid use (>3 months) and post-HSCT rituximab as risk factors for sIgAD and subsequent morbidity.

Results: From 246 patients (251 transplants), 151 met inclusion criteria (median transplant age 3 years, median follow-up 8 years). Twenty-five of 151 patients (16.5%) fulfilled ESID criteria for sIgAD (IgA <0.07 g/L). Underlying IEIs were heterogeneous, including SCID (n=8), CD40L deficiency (n=3), Wiskott-Aldrich syndrome (n=3), and others. Most sIgAD patients (72%) received reduced-intensity conditioning (RIC), primarily with Treosulfan or Melphalan. Alemtuzumab serotherapy was used in 17/25 (68%). Acute GvHD occurred in 15 patients. Post-HSCT, 52% (13/25) received systemic steroids for >3 months and 32% (8/25) received rituximab. At >5 years post-HSCT, 28% (7/25) had recurrent upper respiratory infections, and 36% (9/25) developed autoimmunity, most commonly thyroid disease (n=4), emerging a median of 2 years after sIgAD diagnosis. At last follow-up (median 8 years), all patients were immunoglobulin-independent and off immunosuppression. Immune profiling revealed a mean absolute B-cell count of ~0.35 $\times 10^9$/L, with class-switched memory B cells deficient in 13/25 patients.

Conclusions: sIgAD is a prevalent (16.5%) long-term complication in IEI survivors after HSCT, marking incomplete B-cell reconstitution. A significant proportion of these patients experience substantial morbidity, including recurrent infections and a high burden of autoimmune disease, despite eventual cessation of immunoglobulin replacement and immunosuppression. The frequent association with RIC, alemtuzumab use, prolonged steroids, and rituximab suggests a complex interplay of conditioning, immune manipulation, and ongoing dysregulation in its pathogenesis. These findings identify post-HSCT sIgAD as a clinically important marker for heightened risk of immune dysregulation, necessitating lifelong, targeted surveillance for autoimmune and infectious complications in this subgroup of long-term survivors.

CHARACTERIZING THERAPEUTIC ENDPOINTS AND EFFICACY OF PRE-EMPTIVE DONOR LYMPHOCYTE INFUSION FOR MIXED LYMPHOID CHIMERISM POST-ALLOGENEIC STEM CELL TRANSPLANT: A FOUR-YEAR SINGLE-CENTRE RETROSPECTIVE ANALYSIS

Kinda Al-Hourani[1], *Graeme Ferguson*[1], *Dimitris Galopoulos*[1], *Ailsa Holroyd*[1], *David Irvine*[1], *Annie-Louise Latif*[1], *Grant McQuaker*[1], *Andrew Clark*[1]
[1]*Bone Marrow Transplant Unit, Queen Elizabeth University Hospital, Glagsow, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Donor lymphocyte infusion (DLI) is a powerful allogeneic immunotherapy to augment graft-versus-tumour effects mediated by donor-derived CD3+ lymphocytes. In the setting of mixed lymphoid chimerism (MC) — strongly associated with post-transplant relapse — pre-emptive DLI (preDLI) is an effective tool for enhancing donor lymphocyte activity, ultimately reducing relapse and mortality. DLI is fraught by off-tumour cytotoxicity, primarily manifesting as graft-versus-host disease (GvHD), which may mandate cessation of therapy. Here, we describe the therapeutic endpoints encountered by a cohort of patients (n=37) receiving preDLI for MC in a Scottish tertiary centre. Secondarily, we determine overall response rate (ORR); quantify GvHD-associated morbidity and mortality; and examine overall survival.

Methods: Retrospective single-centre study comprising patients receiving preDLI between 1st January 2021 to 27th March 2025, with the specific indication being MC (donor lymphoid fraction <90% by PCR-STR). Patients demonstrating concurrent haematological relapse were excluded. Final date of data collection was 1st July 2025, at which point n=34 had achieved a therapeutic endpoint, with 3 awaiting further decision. Data obtained by interrogation of the electronic patient record, with analysis in Microsoft Excel and R.

Results: The median age at preDLI initiation was 54 years [range 20-66]. Indication for SCT was myeloid disease in 78%, chiefly AML and high-risk MDS [n=25], with lymphoid disorders in 22%. Matched sibling (49%) and volunteer unrelated donors (51%) were of equal

frequency. Median days from HSCT to preDLI was 233 [range 126 – 517]. The most frequent starting dose was 1x10e6 CD3+ cells, with titration to a maximum of 3x10e7 cells. 73% of patients received a single dose, with 11% receiving two doses and 16% three or more fractions.
DLI endpoints can be stratified between those due to patient death (n=2) and endpoints at which the patient was alive at the decision to cease DLI (n=35). The ORR was 81%, defined as attainment of ≥ 90% donor lymphoid chimerism. The median time to attaining this endpoint was 173 days. Of the subset attaining this endpoint, 60% did not experience any GvHD; the remaining 40% experienced at least one episode of GvHD, triggering cessation of DLI. Only a single patient who received a single dose of DLI but stopped due to GvHD ultimately failed to augment their donor lymphoid fraction. One patient also achieved the clinically significant endpoint of resolution of anti-D mediated haemolysis, despite failure to attain target lymphoid chimerism. We recorded 21 discrete episodes of GVHD, primarily cutaneous. The two-year OS for patients in this cohort from first DLI dose is 84.7%, with median survival not yet reached.

Conclusions: PreDLI is an effective strategy for overcoming mixed chimerism, with an ORR in this cohort comparable to published studies [50-71%], of which a limited number are available for this specific indication. Acute GvHD is a significant attendant risk, with the incidence at any grade commensurate with that in the published literature. We describe a low treatment-related mortality of 2.8% (one patient) in this cohort, with GvHD preceding attainment of ≥90% donor lymphoid chimerism in 91% of affected patients.

Disclosure: Nothing to declare.

B189

BONE MARROW ASPIRATIONS (BMAS) AFTER DONOR LYMPHOCYTE INFUSION (DLI): ARE ROUTINE FOLLOW-UPS NECESSARY FOR ALL PATIENTS?

Sophie Bertorelli[1], *Emma Kempshall*[1], *Abigail Downing*[1], *Keith Wilson*[1], *Wendy Ingram*[1]
[1]*University Hospital of Wales, Cardiff, United Kingdom of Great Britain and Northern Ireland (the)*

Background: Donor lymphocyte infusion (DLI) is frequently administered after allogeneic haematopoietic stem cell transplantation (allo-HSCT), particularly following reduced-intensity conditioning (RIC) and in patients with complex disease profiles. However, there is no consensus on the optimal timing or frequency of post-DLI bone marrow aspirations (BMAs) to assess disease response and donor chimerism. Historically, the South Wales Bone Marrow Transplant (SWBMT) Programme performed BMAs at 1, 2, and 3 months post-DLI. This audit evaluated whether routine BMAs at fixed intervals are clinically necessary, identified subgroups who may benefit from reduced monitoring, and assessed the role of multidisciplinary team (MDT) review in guiding follow-up care.

Methods: We retrospectively reviewed 80 patients who received DLI between 2021 and 2025. The cohort included 45 males and 35 females, median age 59 years (range: 24–71). Inclusion criteria were receipt of DLI following allo-HSCT, availability of follow-up data including remission status at 1–3 months post-DLI, peripheral blood T-cell (PBT) and bone marrow (BM) chimerism results, and documentation of MDT discussions. Mixed chimerism (MC) is defined as <95% donor.

Underlaying diagnosis	AML (40%) MDS (15%) B-ALL (11%) Other (34%)
Conditioning regimens used	FMC (44%) FTreoATG (20%) Other (36%)

Results: **Group 1** (Mixed BM and PBT chimerism): 84% showed lower PBT chimerism compared with BM, with PBT providing the most clinically informative results in 88% of cases. No patients achieved full donor chimerism by week 4, indicating that assessment at this early time point is not meaningful. Maximum response to DLI was typically observed by week 12 in 72% of patients. Despite this, only 25% were discussed in MDT meetings with a documented management plan.
Group 2 (isolated mixed PBT chimerism): 72% underwent at least one BMA in the first three months post-DLI. 77% remained in complete remission with full donor BM chimerism, suggesting PBT monitoring alone may have sufficed. 23% demonstrated minor declines in bone marrow chimerism, with an average reduction of 15%; however, this did not correlate with disease progression. Importantly, all patients monitored exclusively by PBT were discussed in MDT meetings, supporting a non-invasive monitoring strategy.
Group 3 (MRD-positive subgroup): This complex cohort required MDT or consultant-led management. Within this group, 21% remained MRD-positive despite full donor chimerism in both PBT and BM. A small proportion achieved MRD negativity (12% by week 4, 12% by week 12). However, 17% experianced frank relapse, while another 17% remained persistently MRD-positive with declining BM chimerism. Additionally, 21% achieved MRD negativity but continued to show mixed donor chimerism, highlighting the heterogeneity and challenges of this subgroup.

Conclusions: A uniform, one-size-fits-all approach to post-DLI bone marrow monitoring is unsuitable. Evidence supports a risk-adapted strategy: BMAs can be reduced for low-risk patients, particularly those in complete remission with isolated mixed PBT chimerism or a greater decline in PBT compared with bone marrow. As responses are rarely evident at 4 weeks post-DLI, early assessment should be reserved for high-risk cases. MDT discussion is strongly recommended to ensure consistent, individualised care. In line with this, the SWBMT Programme has updated its protocol to minimise unnecessary BMAs and adopt a tailored, MDT-led follow-up approach.

LETERMOVIR PROPHYLAXIS RESHAPES EARLY IMMUNE RECONSTITUTION AND CMV/EBV REACTIVATION DYNAMICS AFTER ALLOGENEIC HSCT

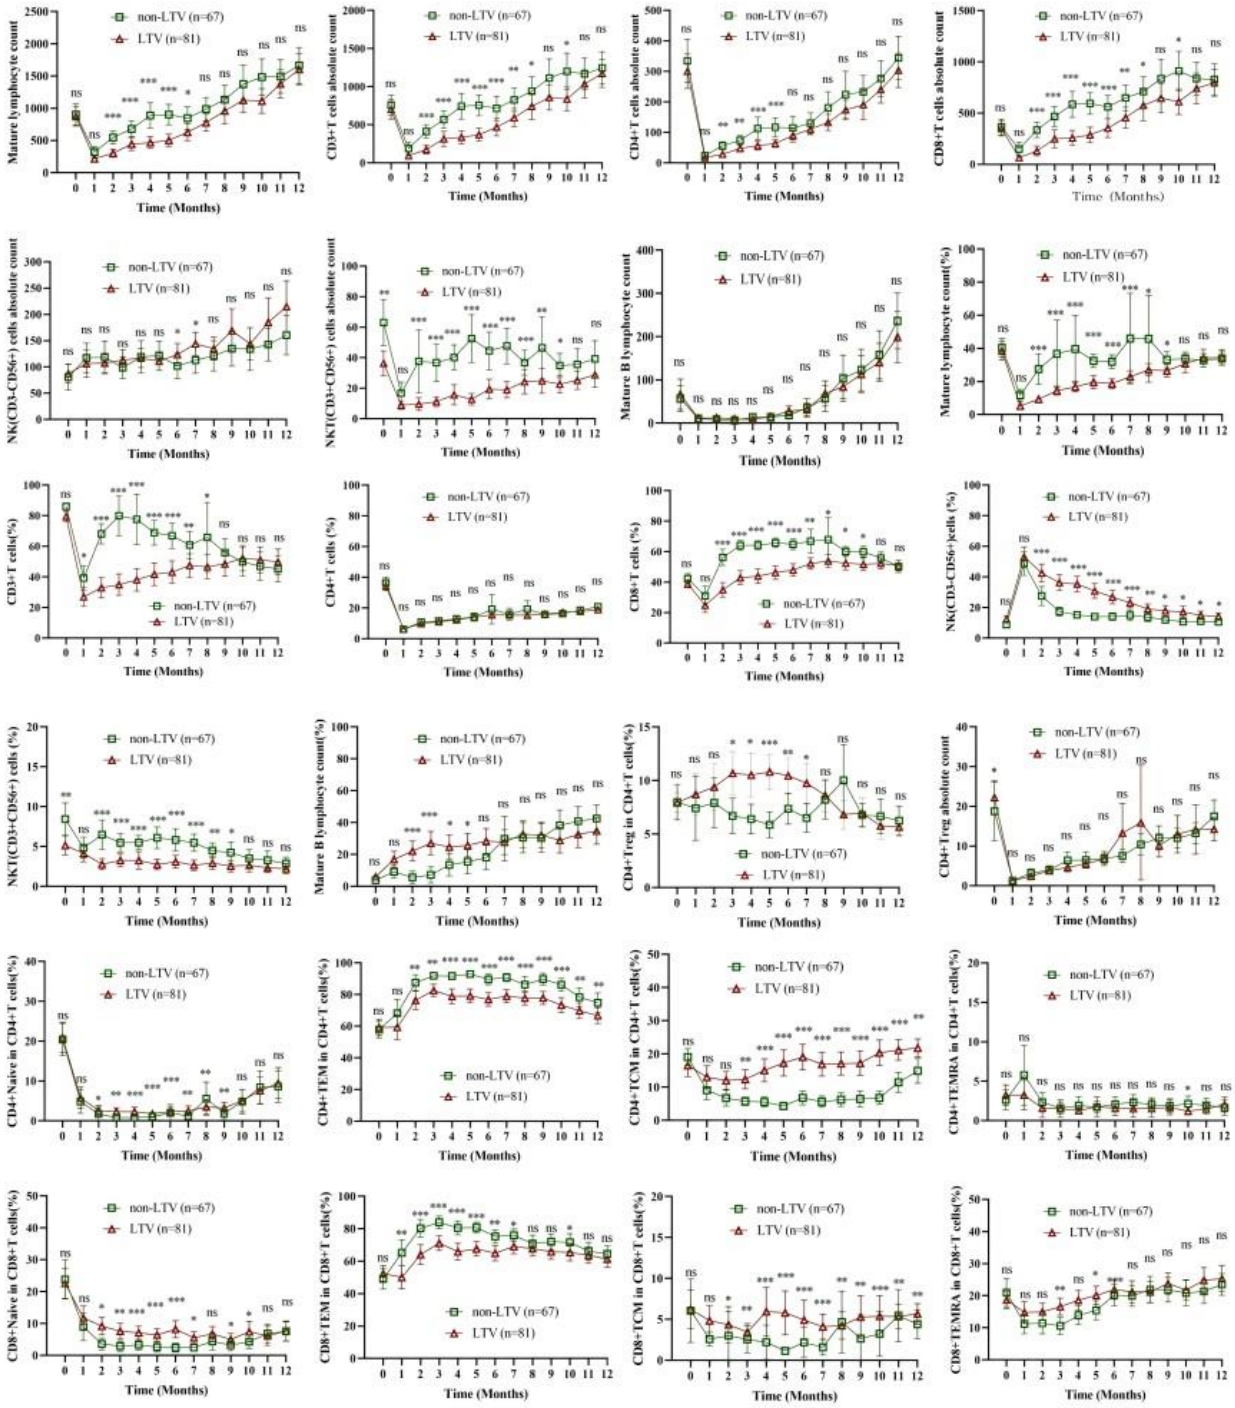
Wei Zhao[1], *Man Chen*[1], *Jing Long*[2], *Yanli Zhao*[3], *Peihua Lu*[3,2,1]
[1]*Beijing Lu Daopei Hospital, Beijing, China,* [2]*Beijing Lu Daopei Institute of Hematology, Beijing, China,* [3]*Hebei Yanda Lu Daopei Hospital, Langfang, China*

Background: With Letermovir (LTV) redefining CMV prophylaxis in allo-HSCT, its broader effects on early immune reconstitution have become an important but underexplored issue. This study characterized immune reconstitution patterns associated with LTV prophylaxis.

Methods: We retrospectively analyzed 148 allo-HSCT recipients treated at Beijing Ludaopei Hospital between April 2021 and December 2024. Clinical and virologic data were systematically reviewed, and patients were categorized into a pre-emptive therapy group (PET, n = 67) or a Letermovir prophylaxis group (LTV, n = 81). Peripheral blood lymphocyte subsets were monitored by flow cytometry at baseline and monthly for 12 months post-transplant to assess longitudinal immune reconstitution.

Results: ***Survival and CMV/EBV Reactivation***
At a median follow-up of 28.1 months (range, 6.5–49.1), 2-year OS (83.6% vs 82.4%) and NRM (10.5% vs 10.1%) were comparable between the PET and LTV groups (all $P > 0.05$). Within 180 days, LTV prophylaxis markedly reduced CS-CMV infection (61.2% vs 12.4%, $P < 0.001$), delayed CMV activation (median 25 vs 122 days, $P < 0.001$), and shortened infection duration (34 vs 19 days, $P = 0.017$), while peak viral load (1200 vs 1450, $P = 0.240$) and CMV disease (2.0% vs 1.2%, $P = 0.341$) remained similar. EBV activation was higher in the LTV group (14.9% vs 27.2%, $P = 0.083$), but infection duration (26 vs 18 days, $P = 0.179$), peak viral load (1850 vs 1600, $P = 0.984$), and EBV-PTLD incidence (2.99% vs 2.47%, $P = 0.847$) were comparable. In Fine–Gray competing-risk models, LTV independently reduced CS-CMV infection (HR = 0.16, 95% CI 0.08–0.35, $P < 0.001$), whereas CS-EBV infection was independently associated with rATG exposure (HR = 2.50, 95% CI 1.04–6.06, $P = 0.042$) and LTV prophylaxis (HR = 2.63, 95% CI 1.02–6.77, $P = 0.046$).
Immune Reconstitution Dynamics (Figure 1)
Pre-transplant immune baselines were comparable between groups. During the LTV usage period (+2 to +6 months post-transplant), the LTV group displayed significantly lower levels of total lymphocytes, $CD3^+$ T cells, $CD8^+$ T cells, NKT cells (counts and percentages), $CD4^+$ T-cell absolute counts, and NK-cell percentages (all $P < 0.05$). The proportion of B cells was consistently higher in the LTV group across multiple time points. After +6 months, these differences were no longer observed .
At later time points, LTV recipients showed a distinctive T-cell maturation profile, including higher $CD4^+$ T-cell Treg proportions and elevated CD4/CD8 ratios ($P < 0.05$). The percentages of $CD4^+$ and $CD8^+$ naïve T cells, central memory (TCM) subsets, and $CD8^+$ TEMRA subsets were significantly increased, whereas effector memory (TEM) proportions in both $CD4^+$ and $CD8^+$ compartments were significantly reduced ($P < 0.05$).

Figure 1. Longitudinal immune reconstitution between the PET and LTV groups



Conclusions: HSCT recipients receiving LTV prophylaxis exhibited a unique pattern of immune reconstitution characterized by early suppression of T cell numbers. However, by avoiding CMV-driven abnormal immune activation and exhaustion, they retained T cell TCR

diversity, indirectly preserving robust T cell reserve capacity. This configuration is more conducive to the recovery of immune reconstitution in later stages.

DEEP IMMUNOPHENOTYPING IDENTIFIES DIFFERENTIAL IMMUNE PROFILES IN RECIPIENTS OF DONOR LYMPHOCYTE INFUSIONS

Jennifer Vidler[1,2], *Yegnasew Teferi*[1], *Amandine Tan*[1], *Victoria Potter*[2], *Giorgio Napolitani*[1], *Pramila Krishnamurthy*[1,2]
[1]*King's College London, London, United Kingdom of Great Britain and Northern Ireland (the),* [2]*King's College Hospital NHS Foundation Trust, London, United Kingdom of Great Britain and Northern Ireland (the)*

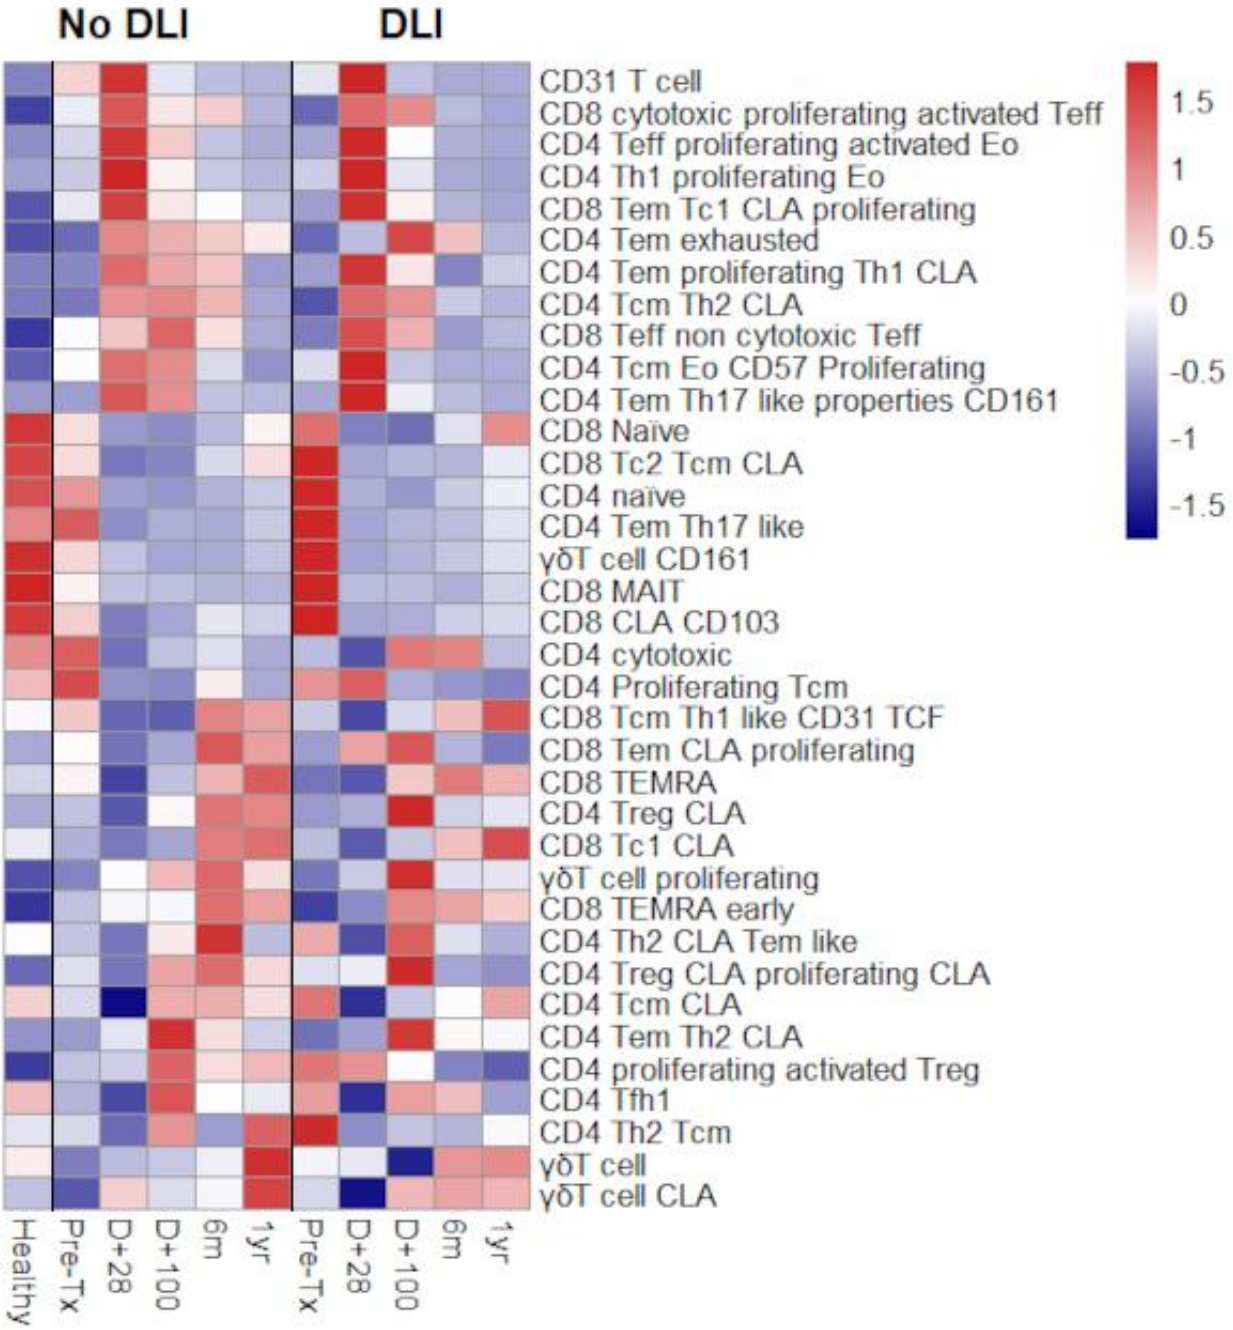
Background: Donor lymphocyte infusions (DLI) are routinely administered post-allogeneic haematopoietic cell transplant (HCT) to prevent or treat relapsed disease. Despite this, little is understood regarding optimal DLI strategy for relapse prevention or the immunological consequences of DLI in the patient.
PRO-DLI (NCT02856464) was the first clinical trial globally to compare prophylactic versus pre-emptive DLI in patients with Acute Myeloid Leukaemia or Myelodysplastic Syndrome undergoing reduced intensity conditioned (RIC) HCT with alemtuzumab for Graft-versus-Host Disease (GvHD) prophylaxis. Using the extensive PRO-DLI sample biobank, we sought to examine the effect of DLI on immune reconstitution.

Methods: Peripheral blood mononuclear cells sequentially collected from 61 patients (median age 63 years, range 25 – 71 years; total 266 samples) were analysed using cytometry by time-of-flight (44 markers identifying T-, NK- and B-cell subsets). Patients were randomised in the experimental arm of PRO-DLI to early withdrawal of immune suppression (IS) and up to 4 prophylactic DLI from D+100, or a restricted DLI approach, only for mixed myeloid chimerism or detection of measurable residual disease (control arm). We analysed patients with a minimum of 3 samples collected at the following timepoints: pre-HCT, D+28, D+100 (prior to any DLI) and D+180 and D+365 (post-DLI in those who received it). Twenty-four patients in our cohort received DLI and 37 did not. Unsupervised clustering using the R package CATALYST identified 36 unique T-cell clusters, phenotypically identified and analysed using R packages and FlowJo.

Results: The early post-transplant patient immune profile was characterised by low frequencies of naïve CD4+ and CD8+ T-cells and marked expansion of effector and memory T-cells early post-HCT (D+28), which decreased over time. The patients' immune repertoires remained profoundly different from healthy volunteers even at 1 year, with limited recovery of naïve T-cells, likely secondary to the depletion of T-cells mediated by alemtuzumab and age-associated thymic involution.
A rapid and sustained increase in CD8+ T-effector memory cells re-expressing CD45RA

(TEMRA) from D+100 correlated with early withdrawal of immune suppression and DLI: median subset abundance = 31.7% (IQR 37.4%) compared with 4.8% (IQR 13.3%) in those not receiving DLI, FDR p-value = 0.008. Differences in immune recovery in those who did/did not receive DLI continued to be seen at 6 and 12 months post-HCT. We also noted marked expansion in naïve CD4+ and CD8+ T-cells in DLI recipients with cytomegalovirus (CMV)

reactivation (CD4+ FDR p-value = 0.023, CD8+ FDR p-value =0.0034).



Conclusions: We have developed an immunophenotypic atlas of immune recovery in the presence or absence of DLI after alemtuzumab-based RIC HCT. The effects of T-cell depletion are profound and long-lasting, even up to 1 year post-HCT. Early withdrawal of IS followed by DLI leads to identifiable changes in the immune repertoire; CMV reactivation appears also to shape the subsequent immune repertoire after DLI, favoring recovery of naïve T-cells. It is known that confounding clinical variables such as relapse, CMV and GvHD can impact immune subsets, and are being further explored in multivariate analysis of the dataset.

Disclosure: Nothing to declare

B192

BONE MARROW GRAFTS SUPPORT BROADER EARLY T-CELL AND ANTIVIRAL REPERTOIRE RECOVERY AFTER HAPLOIDENTICAL HSCT WITH PTCY

Amandine Pradier[1,2], *Aurelie Ducrot*[1,2], *Astrid Melotti*[2], *Chiara Bernardi*[1,2], *Sisi Wang*[1,2], *Yara Hajj Younes*[1,2], *Stavroula Masouridi-Levrat*[1], *Sarah Morin*[1], *Federica Giannotti*[1], *Yves Chalandon*[1], *Anne-Claire Mamez*[1], *Federico Simonetta*[1,2]
[1]*Geneva University Hospitals, Geneva, Switzerland,* [2]*University of Geneva, Geneva, Switzerland*

Background: Post-transplant cyclophosphamide (PTCy) is a widely employed GvHD prophylaxis for Haploidentical hematopoietic stem cell transplantation (HSCT) and more recently transplants from other donor sources. Although this platform ensures effective GVHD control, it is associated with delayed immune reconstitution, particularly within the T-cell compartment, resulting in increased susceptibility to infections such as CMV and EBV. While bone marrow (BM) was initially the standard graft source, many centers have transitioned to peripheral blood stem cells (PBSC). Although clinical differences between BM and PBSC are well described, their respective effects on immune recovery and T-cell repertoire dynamics in the PTCy setting remain unexplored.

Methods: We retrospectively analyzed 70 patients who underwent haploidentical HSCT with uniform PTCy prophylaxis, including 31 BM and 39 PBSC recipients. Peripheral blood was collected at days +30, +100, +180, and +365. Flow cytometry quantified absolute T-cell counts, differentiation subsets (naïve, central memory, effector memory, TEMRA), and activation, exhaustion, and senescence markers. T-cell receptor sequencing (TCRseq) was performed using the LymphoTrack TRB Assay (Invivoscribe) to assess global repertoire diversity, clonotype richness, and CMV- and EBV-specific clonotypes.

Results: Absolute $CD4^+$ and $CD8^+$ counts were comparable between BM and PBSC recipients across all time points over the first year after allogeneic HSCT. Similarly, the distribution of naïve, memory, TEMRA, as well as the expression of activation, exhaustion, and senescence markers, evolved similarly in both groups.
Global TCR repertoire diversity as measured by the squared Simpson's index increased progressively over the first year and did not differ significantly between graft sources at

months 1, 3, 6, or 12 (p = 0.82, 0.59, 0.45, and 0.54, respectively). In contrast, clonotype richness showed clear early differences: BM recipients displayed significantly higher numbers of unique clonotypes at months 1 and 3 (p = 0.0087 at both time points). These differences diminished thereafter and were no longer detectable at months 6 and 12 (p = 0.63 and 0.79).
Virus-specific analyses showed a parallel pattern. CMV-specific clonotype richness was significantly higher in BM recipients at months 1 and 3 (p = 0.0013 and 0.0087), converging with PBSC recipients by months 6 and 12 (p = 0.43 and 0.79). EBV-specific repertoires showed similarly greater richness in BM recipients early (p = 0.013 at month 1 and 0.02 at month 3), with no significant differences later (p = 1 and 0.85).

Conclusions: In haploidentical HSCT with PTCy, bone marrow and peripheral blood grafts support similar quantitative and phenotypic T-cell recovery. However, bone marrow transplantation is associated with broader early global clonotype richness and greater diversification of CMV- and EBV-specific repertoires. These findings indicate that graft source influences the qualitative breadth of early T-cell immune recovery despite comparable numeric and phenotypic reconstitution.

A RANDOMIZED PILOT TRIAL OF CLOSTRIDIUM BUTYRICUM MIYARI 588 IN ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANT RECIPIENTS

*Karamjeet S. Sandhu[1], Dongyun Yang[1], Sally Mokhtari[1], Sanjeet S. Dadwal[1], Vinod A. Pullarkat[1], Monzr M. Al Malki[1], Ricardo Spielberger[1], Amandeep Salhotra[1], Haris Ali[1], Andrew S. Artz[1], Anthony S. Stein[1], Myo Htut[1], Elizabeth Budde[1], Michael Rosenzweig[1], Leslie L. Popplewell[1], Tanya Siddiqi[1], Firoozeh Sahebi[1], Josh Mansour[1], Ibrahim Aldoss[1], Guido Marcucci[1], Eileen Smith[1], Stephen J. Forman[1], Weimin Tsai[1], Lucy Y. Ghoda[2], Colt Egelston[1], Peter Lee[1], Antonio Cruz Gomes[1], Natalie Smith[1], Jenny Paredes[1], Robert Jenq[1], Keehoon Lee[3], **Ryotaro Nakamura**[1]*
[1]City of Hope National Medical Center, Duarte, United States of America (the), [2]Southern California Kaiser Permanente, Los Angeles, United States of America (the), [3]Translational Genomics Research Institute North, Flagstaff, United States of America (the)

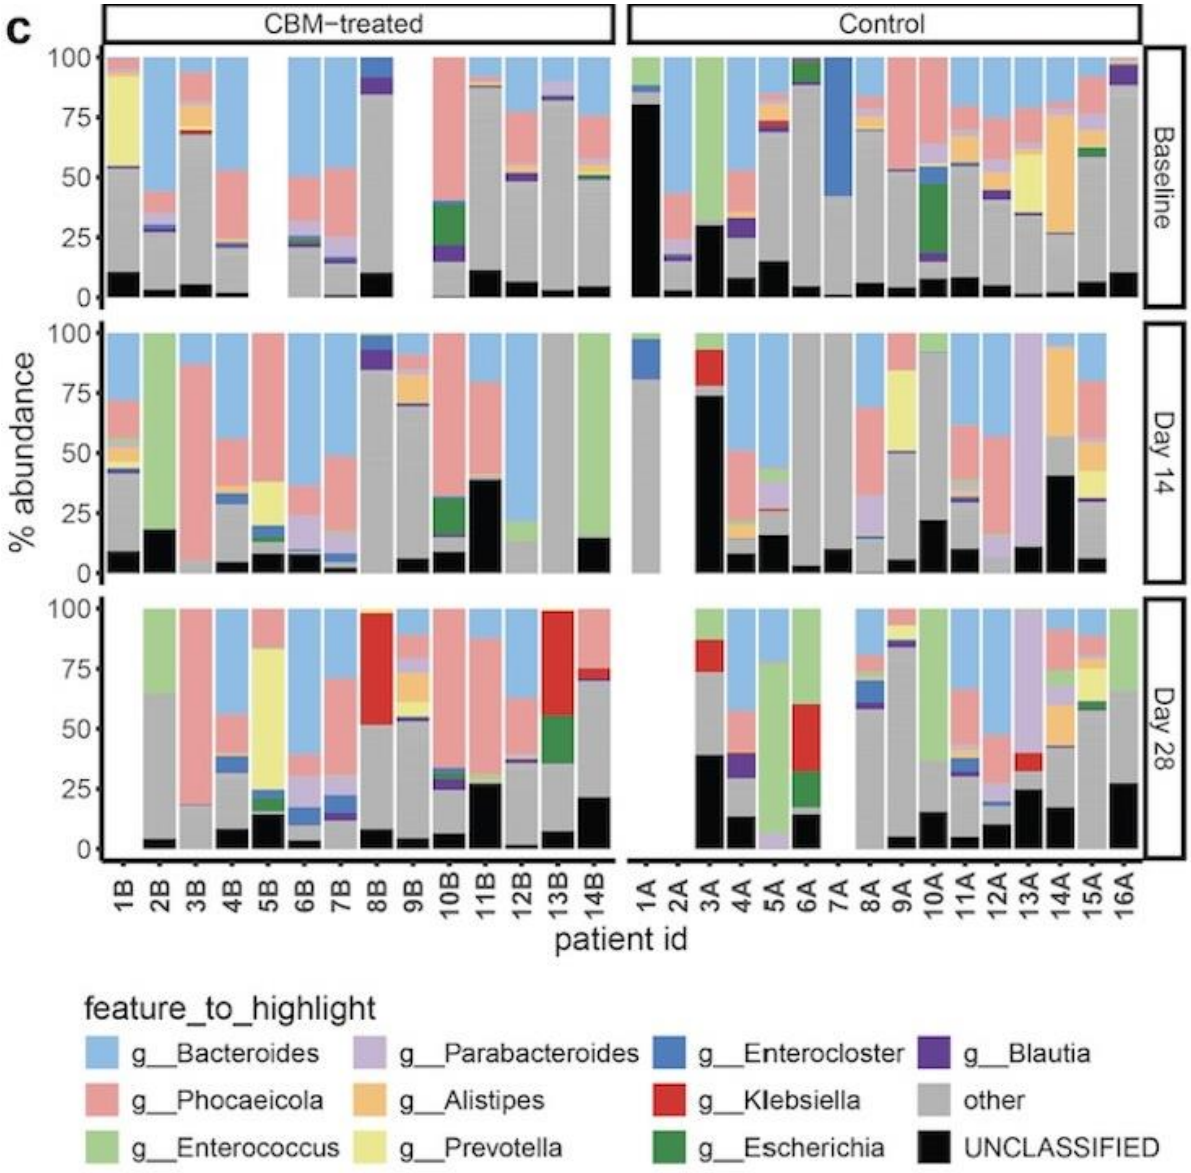
Background: *Clostridium butyricum* MIYAIRI588 (CBM588) is a butyrate-producing live biotherapeutic product that supports colonic health by regulating epithelial growth, fluid balance, and inflammation. In murine models of antibiotic-induced dysbiosis, CBM588 administration enhanced intestinal barrier function and increased abundance of Bifidobacterium, Lactobacillus, and Lactococcus species within the gut microbiome.

Methods: In this pilot study (NCT03922035), we assessed the safety, feasibility, and preliminary efficacy of CBM588 in adults undergoing reduced-intensity allogeneic hematopoietic cell transplantation (HCT). Following a six-patient safety lead-in, 30 patients were randomized 1:1 to standard supportive care alone or with CBM588 (160 mg twice daily, day −8 to discharge). Median age was 66 years; most patients (61%) had leukemia. Fludarabine/melphalan conditioning and tacrolimus/sirolimus GVHD prophylaxis were used; grafts were from matched related (n=14) or unrelated donors (n=22). Correlative studies included 16S rRNA gene amplification, shotgun DNA metagenomics sequencing, metabolomic profiling, cytokine profiles, and flow-cytometry.

Results: We enrolled 36 patients (21 were female) at the median age of 66 years (range: 34-77). All CBM588-treated patients tolerated therapy, with 90.5% completing ≥14 days. One serious adverse event occurred in the CBM588 arm versus five in controls. Acute GVHD occurred in 26.7% of CBM588 patients versus 33% of controls; lower GI-GVHD was less frequent in the CBM588 group (7.1% vs. 31.3% as treated). One-year chronic GVHD was 37% versus 44%, and 100-day non-relapse mortality was 0% versus 7% in controls. One-year OS and RFS were 67% (95%CI: 0.20 - 0.90) and 50% (95% CI: 0.11 - 0.80) for safety lead-in, 87% (95% CI: 0.56 - 0.95) and 73% (95% CI: 0.44 - 0.89) for CBM588 arm, and 80.0% (0.50-0.93) and 80.0% (0.50-0.93) for the control arm, respectively.
Fecal microbiome composition is shown in Figure. CBM588 restored gut microbiome diversity by Day +28 and enriched microbial pathways involved in lipopolysaccharide and aerobactin biosynthesis. Interestingly, lower baseline calorie and protein intake was associated with reduced microbiome diversity and higher lower GI-GVHD. Acute GVHD was associated with early reductions in fecal short-chain fatty acids. We observed lower levels of select cytokines in the CBM588 group compared with controls, including IL-2 on Days +7 and +14, and RANTES and IL-6 on Day +14 (p = 0.006, 0.02, 0.05, 0.09, respectively, unadjusted for multiple testing). GVHD-associated biomarkers (Reg3a, ST2, and TNF-R1) measured on Day +30 were numerically higher in the control group, though differences did not reach statistical significance (p = 0.2, 0.18, 0.3, respectively). Multi-color flow cytometry showed no clear polarization of systemic immune subsets seen in the CBM588 group vs. control group on Days +30, +60, or +100 post-transplant, with the exception of reduced CD69+CD8+ T cells in the CBM588 group on Day +60 and increased intermediate monocytes on Day +100 in the same group.

Intent to Treat	**Lead-in (N=6)**	**CBM588 (N=15)**	**Control (N=15)**
Overall acute GVHD Grade 2-4 Grade 3-4	1 (16.7%) 1 (16.7%)	3 (20%) 1 (6.7%)	5 (33.3%) 0 (0%)

Lower GI GVHD			
Stage 1 Stage 2 Stage 3	0 (0%) 0 (0%) 1 (16.7%)	0 (0%) 1 (6.7%) 1 (6.7%)	1 (6.7%) 3 (20%) 0 (0%)
Total GI GVHD	2 (33.3%)	2 (13.3%)	4 (26.7%)
As Treated	**Lead-in (N=6)**	**CBM588 (N=14)**	**No CBM588 (N=16)**
Overall acute GVHD Grade 2-4 Grade 3-4	1 (16.7%) 1 (16.7%)	3 (21.4%)	
Lower GI GVHD	1 (16.7%)	1 (7.1%)	5 (31.3%)



Conclusions: CBM588 administration is safe, feasible, and modulates gut microbiome composition and function in HCT recipients, improving microbial diversity and trending toward reduced lower GI GVHD. Nutritional status strongly impacts microbiome dynamics and GVHD risk. Our data strongly support further investigation of microbiome-targeted interventions to improve transplant outcomes.

DETERMINANTS OF ENGRAFTMENT INSTABILITY IN SICKLE CELL DISEASE: IDENTIFYING MODIFIABLE AND EARLY PREDICTORS OF MIXED CHIMERISM AFTER CURATIVE TRANSPLANTATION

Kendall Oh[1], Alonzo Needum[1], Hailey Tinsley[1], Erin Doherty[1], John Craddock[1], Bahey Salem[1], Anil George[1], Khaled Yassine[1], Gabriela Llaurador[1], Megha Thakkar[1], David Steffin[1], Bilal Omer[1], Helen Heslop[1], Robert Krance[1], Caridad Martinez[1], ***Alexander Ngwube***[1]
[1]*Baylor College of Medicine, Houston, United States of America (the)*

Background: Mixed donor chimerism (MC) is a clinically consequential outcome after hematopoietic stem cell transplantation (HSCT) for sickle cell disease (SCD). Although stable MC may maintain disease control, declining donor myeloid chimerism predicts graft failure, autologous recovery, and recurrence of SCD complications. Recent reports also link persistent host hematopoiesis and MC to expansion of pre-existing clonal hematopoiesis and elevated post-transplant malignancy risk in SCD, underscoring the need to identify early predictors of chimerism instability. However, determinants of MC after myeloablative matched sibling donor (MSD) HSCT, currently the most widely used curative approach in children and young adults, remain poorly defined. We conducted a single center analysis to identify biological and early post-transplant predictors of MC at one year.

Methods: We retrospectively analyzed 67 pediatric and young adult SCD patients who underwent myeloablative (busulfan/cyclophsophamide/Campath) MSD HSCT at a single center (2001–2024). MC was defined as <95% donor myeloid chimerism at ~day +365. Variables included demographics, SCD genotype, organ function, pre-transplant chest imaging, conditioning metrics (including busulfan AUC), graft characteristics, early complications, and serial lineage-specific chimerism at standardized timepoints. Univariate analyses used t-tests, Wilcoxon rank-sum, χ^2, or Fisher's exact tests. The primary objective was to identify predictors of MC at one year.

Results: MC occurred in 33/67 patients (49%).
Pre-transplant factors:
• Abnormal chest imaging including airway inflammation, parenchymal scarring, atelectasis, or splenomegaly was strongly associated with MC: 6/6 (100%) with abnormal imaging developed MC vs. 27/61 (44%) with normal imaging (Fisher p = 0.011).
• HbSS genotype demonstrated a non-significant trend towards MC compared to HbSC or HbSβ-thalassemia (Fisher p = 0.0822), consistent with greater inflammatory and hematopoietic stress in severe SCD.
• Older donor age demonstrated a non-significant trend towards MC (p = 0.06729).
Transplant-related factors:
• Higher busulfan AUC demonstrated a non-significant trend toward MC (Wilcoxon p = 0.08523), though interpretation was limited by small sample size (n = 30).
Post-transplant engraftment kinetics:
• Day +60 donor myeloid chimerism was a strong early predictor of MC, with significantly

lower levels in patients who later developed MC (p = 0.04959).
• Days +100, +120, +180, and +270 myeloid chimerism were also significantly lower among MC patients, demonstrating divergence of donor–host hematopoietic dominance early after transplant.
Interpretation:
These findings support a biologically coherent model in which baseline pulmonary abnormalities predispose to impaired donor marrow dominance despite uniform myeloablative conditioning. Early donor myeloid chimerism, especially at day +60, is a powerful, actionable biomarker of long-term graft stability. The association between MC and environments that preserve host hematopoiesis resonates with emerging literature linking graft instability to increased risk of clonal expansion and hematologic malignancies in SCD survivors.

Conclusions: Abnormal pre-transplant chest imaging and early donor myeloid kinetics are the strongest predictors of MC after myeloablative MSD HSCT. Incorporating **d**ay +60 chimerism thresholds into clinical decision-making may enable risk-adapted monitoring and pre-emptive interventions to prevent graft failure and mitigate long-term malignant risk. Prospective multicenter validation is needed to inform standardized chimerism surveillance strategies for SCD transplantation.

DIFFERENTIAL IMMUNE RECONSTITUTION ACROSS AGE GROUPS AFTER ALLO-HSCT: A LONGITUDINAL ANALYSIS OF PEDIATRIC, ADULT, AND ELDERLY PATIENTS

Wei Zhao[1], *Man Chen*[1], *Jing Long*[2], *Yanli Zhao*[3,1], *Peihua Lu*[1,3,2]
[1]*Beijing Lu Daopei Hospital, Beijing, China,* [2]*Beijing Lu Daopei Institute of Hematology, Beijing, China,* [3]*Hebei Yanda Lu Daopei Hospital, Langfang, China*

Background: Age is a major determinant of immune reconstitution after allogeneic HSCT. However, high-resolution longitudinal comparisons across age groups remain limited.

Methods: We retrospectively analyzed 148 patients who underwent allo-HSCT for hematologic malignancies between April 2021 and December 2024. Patients were stratified into pediatric (≤18 years, n=38), young adult (19–54 years, n=84), and elderly (≥55 years, n=26) cohorts. Lymphocyte subsets were monitored monthly for 12 months post-transplant using multiparameter flow cytometry.

Results: Baseline disease duration and follow-up were comparable across pediatric, young adult, and elderly groups (Table 1). Three-year OS decreased with age—87.9% , 86.0% , and 64.0% , respectively (P=0.012)—while 3-year NRM rose accordingly at 2.78% , 10.27%

, and 23.87% (P=0.05) (Figure 1). Elderly patients were exhibited later CMV reactivation (P<0.05).

Early after HSCT (≤3 months), total lymphocyte counts and $CD3^+$ T-cell counts recovered fastest in children and slowest in elderly patients, with convergence across groups by +6 months (P>0.05). $CD4^+$ T-cell reconstitution showed the clearest age gradient: from +2 months onward, children had higher $CD4^+$ T-cell counts than young adults and elderly patients (41 vs. 19 vs. 21/μL; P=0.006) , a pattern maintained at +12 months (318 vs. 240 vs. 205/μL; P=0.106). $CD4^+$ T-cell percentages were also significantly higher in children at most time points (months 1, 2, 4, 7–12; all P<0.05) .

In late recovery (≥+10 months), children maintained the highest naïve $CD4^+$ T-cell proportion (+12 months: 8.94% vs. 2.04% vs. 0.91%; P=0.003), whereas elderly patients showed the highest effector-memory $CD4^+$ fractions (+12 months: 64.6% vs. 75.38% vs. 77.98%; P=0.038). Other $CD4^+$ subsets did not differ significantly. $CD8^+$ T-cell counts and percentages were broadly similar across groups. Naïve $CD8^+$ T cells were initially lowest in children but exceeded older groups by +12 months (7.25% vs. 3.32% vs. 1.59%; P=0.028). Central-memory $CD8^+$ T cells differed only at +5 months, with higher levels in the elderly (2.34% vs. 0.75% vs. 1.09%; P=0.042). Effector-memory and terminally differentiated $CD8^+$ subsets were comparable across age groups.Children had higher $CD4^+/CD8^+$ ratios at +5, +11, and +12 months (P=0.026, 0.023, 0.001). Elderly patients showed greater immunosuppression, with higher Treg levels at +10 and +12 months (7.07% vs. 6.72% vs. 4.88%, P=0.011; 6.04% vs. 5.66% vs. 4.51%, P=0.013). B-cell counts remained low early and partially recovered by +12 months with no significant differences (153.0 vs. 125.0 vs. 134.5; P=0.837), though elderly patients tended toward higher mature B-cell proportions (+12 months: 58.55% vs. 28.48% vs. 18.61%; P=0.323). NK-cell recovery was similar across groups.

Table 1. Baseline characteristics between groups

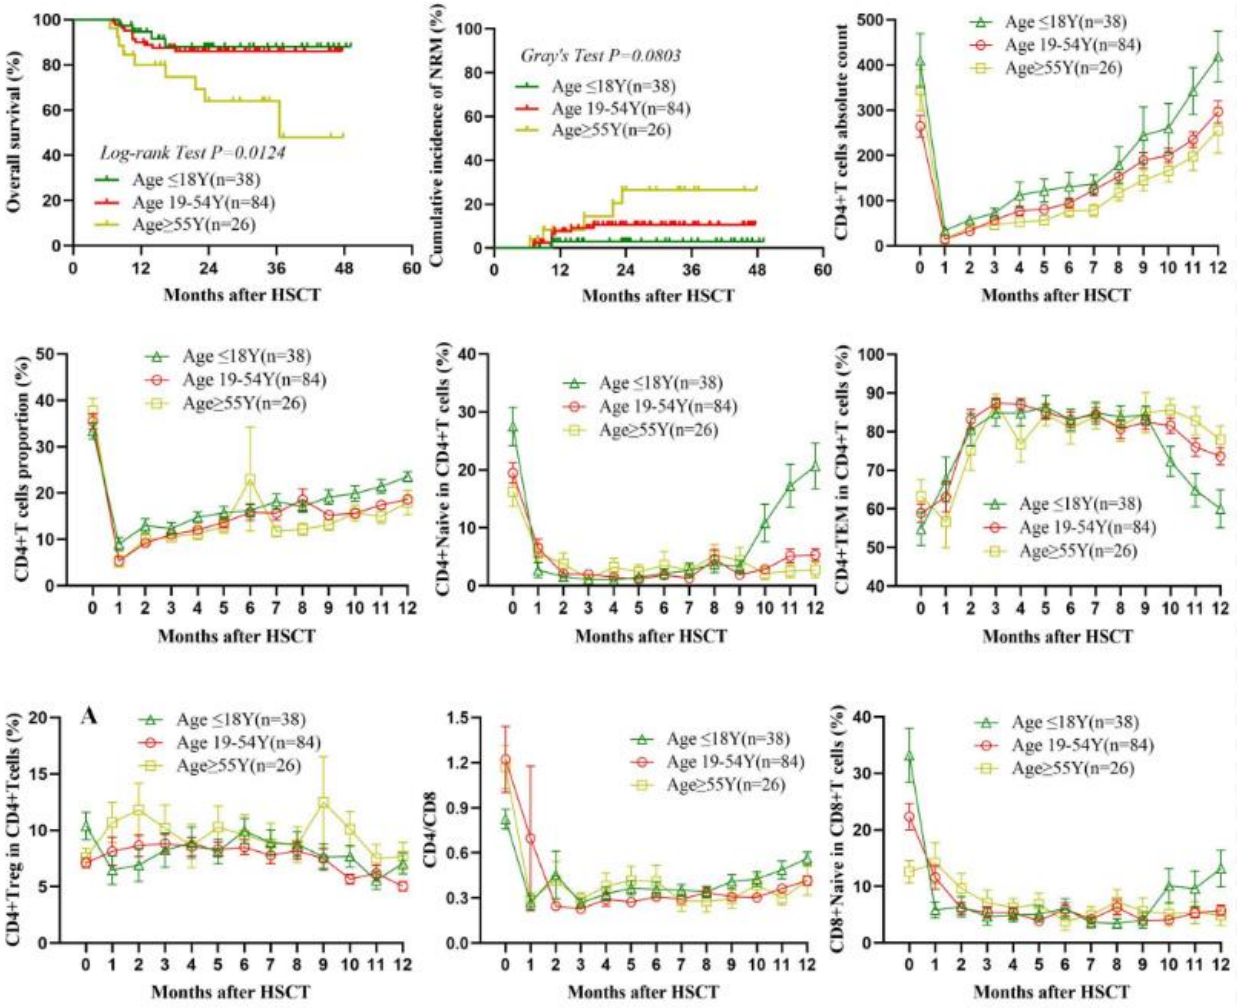
CS-EBVi (Day)	51 (42,58)	60 (49,73)	63 (57,148)	0.248

Figure 1. Outcomes and longitudinal immune reconstitution between groups



Conclusions: Children demonstrated more efficient thymic output and immune reserve after allo-HSCT, reflected by faster $CD4^+$ T-cell recovery, higher $CD4^+/CD8^+$ ratios, and sustained enrichment of naïve $CD4^+$ T cells. In contrast, elderly recipients exhibited features of immune exhaustion and suppression—including higher $CD4^+$ TEM fractions, reduced naïve T-cell pools, early $CD8^+$ T-cell predominance, and elevated late-phase Treg levels—consistent with age-related thymic involution and cumulative antigen exposure.

IMMUNE RECONSTITUTION AFTER HAPLOIDENTICAL PBSCT IN PAEDIATRIC B AND T-ALL: A COMPARATIVE STUDY OF PATIENTS WITH AND WITHOUT PRIOR CAR-T THERAPY

Jann Adriel Sy[1,2], *Khan Lian Cing*[1], *Poh Lin Tan*[1,2], *Frances Yeap*[1,2]
[1]*National University Hospital, Singapore, Singapore, Singapore,* [2]*National University of Singapore, Singapore, Singapore*

Background: The impact of prior CAR-T therapy on post-transplant immune reconstitution in paediatric ALL remains poorly characterised. Because lymphodepletion and CAR-T therapy induce prolonged immune perturbations, understanding their influence on immune recovery after HSCT is clinically relevant.

Methods: We conducted a retrospective analysis of paediatric patients with ALL who underwent haploidentical peripheral blood stem cell transplantation (PBSCT) at the National University Hospital, Singapore (2019–2024). Immune recovery was assessed using CD4, CD8, and CD20 subsets closest to Day (D)60 (51–72 days), D100 (89–114), and D200 (151–220), with no statistically significant difference in sampling windows between groups. Significant infections were defined as viral infections requiring treatment or hospitalisation, bacterial infections requiring intravenous antibiotics, and invasive fungal infections. Time to IgG normalisation was the first time IgG was within age-adjusted norms without IVIG support. Statistical analyses included t-tests, Mann–Whitney U and Fisher's exact tests, and Kaplan–Meier analysis.

Results:

Twenty-two patients met inclusion criteria: 10 in the HSCT with prior CAR-T group and 12 in the HSCT-only group. CAR-T products were manufactured at National University of Singapore using autologous T cells (CD19 or CD19/CD22 for B-ALL; CD7 for T-ALL) and infused after fludarabine/cyclophosphamide lymphodepletion. CAR-T recipients proceeded to haploidentical HSCT at a mean of 175 days (range 60–471). GVHD prophylaxis consisted of ex-vivo CD3/CD45RA depletion in all, except one HSCT-only patient, who received post-transplant cyclophosphamide.
Age (Table 1) and sex distribution were similar between groups (female: 40% vs 25%; p = 0.65). One patient had T-ALL in the HSCT with prior CAR-T group and two in the HSCT-only group; the remainder had B-ALL. The HSCT with prior CAR-T cohort had more multiply relapsed patients, trending toward significance (p = 0.055). CD34 (15.77×10^6/kg vs 17.68×10^6/kg; p = 0.66) and CD45RO doses (19.61×10^6/kg vs 16.86×10^6/kg; p = 0.32) were comparable. Myeloablative conditioning (ATG/fludarabine/treosulfan/thiotepa/melphalan/rituximab) was used in 90% vs 83% (p = 1.00). Median neutrophil (13 vs 12 days; p = 0.89) and platelet engraftment (13.5 vs 12.5 days; p = 0.55), and rates of grade III–IV acute GVHD (10% vs 8.3%) and chronic GVHD (20% vs 16.7%) were similar.
Immune reconstitution findings are shown in Table 1 and Figure 1. Although not statistically significant (all p > 0.1), HSCT with prior CAR-T patients displayed a higher number and frequency of clinically significant infections than HSCT-only patients. CD4, CD8, and CD20 recovery at D60, D100, and D200 were similar, though missing data from retrospective, non-protocolised sampling limited interpretation. CD20 remained 0 cells/μL at D60 and D100 in

all patients. Time to CD4 >100/μL at D60, CD4 >200/μL at D100, and time to IgG normalisation were comparable (log-rank p = 0.81).

Table 1. Characteristics and immune reconstitution parameters of those who received HSCT + prior CAR-T and HSCT only.

Variable	HSCT + Prior CAR-T (n=10)	HSCT Only (n=12)	p value [a] = Mann-Whitney U [b] = Fischer's exact

CD4 >100 by D60	44.44% (n=4, missing 1)	45.45% (n=5, missing 1)	1.000[b]

CD4 > 200 by D100	33.33% (n=3, missing 1)	30% (n=3, missing 2)	1.000[b]
CD4 at D60 (median, IQR)	53 (37-137) (missing 5)	34 (24-45) (missing 7)	0.6015[a]
CD8 at D60 (median, IQR)	158 (83-241) (missing 5)	62 (50-140) (missing 7)	0.4647[a]
CD4 at D100 (median, IQR)	125 (61-181) (missing 1)	107 (38-293) (missing 2)	0.9674[a]
CD8 at D100. (median, IQR)	241 (71-776) (missing 1)	284 (84-408) (missing 2)	0.8703[a]
CD 4 at D200 (median, IQR)	668 (350.5-902.5) (missing 2)	433 (89-537) (missing 2)	0.2135[a]
CD8 at D200. (median, IQR)	564 (202 – 1936) (missing 2)	306 (194-434) (missing 2)	0.5338[a]
CD20 at D200 (median, IQR)	137 (17-227) (missing 2)	104 (61-147) (missing 2)	0.2858[a]

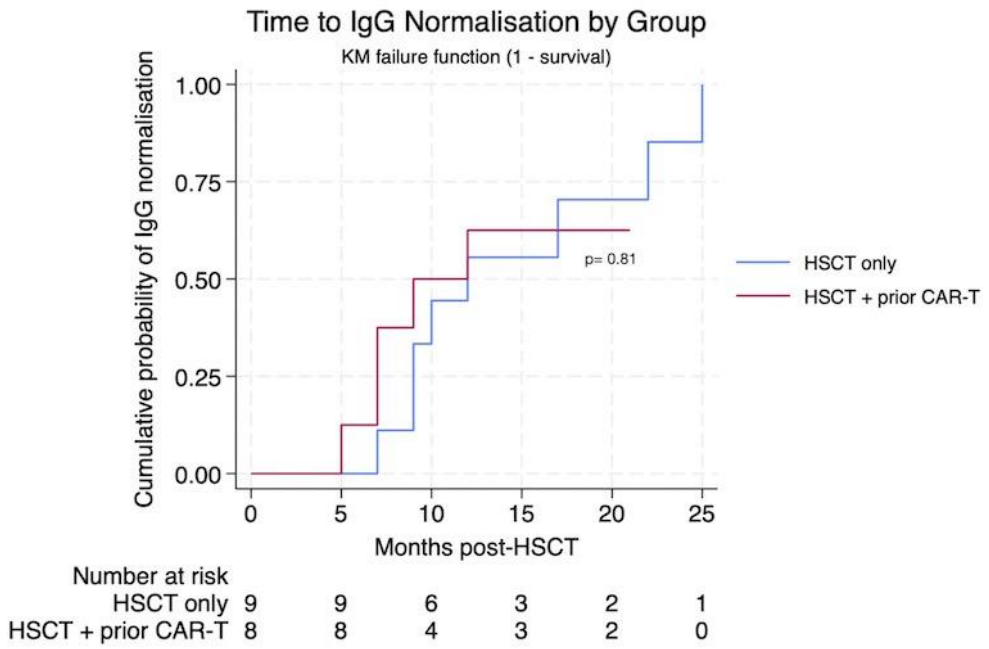

Figure 1. Time to IgG Normalisation After Haploidentical HSCT in Patients With and Without Prior CAR-T Therapy.

Kaplan–Meier failure curve showing time to IgG normalisation after haploidentical HSCT in patients with and without prior CAR-T therapy. Failure was defined as achievement of age-adjusted normal serum IgG without IVIG support. Patients who did not normalise IgG were censored at last follow-up. No significant difference was observed between the CAR-T + HSCT and HSCT-only groups (log-rank p = 0.81). Median time to IgG normalisation was 9 months in HSCT + Prior CAR-T group, and 12 months in HSCT only group

Conclusions:

Immune reconstitution, engraftment, GVHD, and IgG recovery were similar between groups. However, HSCT with prior CAR-T patients had a higher burden of clinically significant infections—a clinically meaningful trend despite lack of statistical significance, likely driven by small sample size. These findings highlight a potential vulnerability in CAR-T–bridged patients and should be validated in larger studies.

DAY 30 MIXED DONOR CHIMERISM DOES NOT PREDICT RELAPSE IN ALLOGENEIC STEM CELL TRANSPLANTATION FOR AML AND MDS

Carol Herrera Hernández[1], *Silvia Rodríguez López*[2], *María del Mar Perera Álvarez*[1], *Cristina Bilbao Sieyro*[1], *Melissa Torres Ochando*[1], *Jorge Gayoso Cruz*[1], *Natalia López Esteban*[1], *Minia Grobas Sebio*[1], *Leslie González Pinedo*[1], *Alejandro Morales Curbelo*[1], *María Teresa Gómez Casares*[1]
[1]*Hospital Universitario de Gran Canaria Doctor Negrín, Las Palmas de Gran Canaria, Spain,*
[2]*Universidad de Las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain*

Background: Hematopoietic stem cell transplantation (HSCT) remains the only curative option for patients with acute myeloid leukemia (AML) and myelodysplastic syndromes (MDS) due to the graft-versus-tumor effect. Post-transplant chimerism monitoring allows evaluation of graft engraftment and residual host hematopoiesis. Recent studies suggest that mixed chimerism at day +30 may be associated with higher relapse risk, but results are inconsistent. We aimed to clarify this uncertainty.

Methods: This retrospective, observational, single-center study included 171 adults (18–75 years) with AML (n = 116) or MDS (n = 55) who underwent HSCT between January 2018 and June 2025. All patients received post-transplant cyclophosphamide for graft-versus-host disease (GVHD) prophylaxis. Chimerism was measured using two techniques: quantitative PCR (qPCR) via STR fragment analysis (January 2018–December 2021, n = 71) and digital PCR (dPCR) targeting donor- and recipient-specific DNA sequences (informative indels, CNVs, or Y-chromosome sequences in sex-mismatched transplants, January 2022–July 2025, n = 100). Complete chimerism was defined as ≤0.1% recipient DNA; >0.1% was considered mixed. Overall survival (OS) and relapse-free survival (RFS) were estimated with Kaplan–Meier curves. Cox regression models explored prognostic factors for OS and RFS.

Results: The characteristics of the sample are shown in **Table 1**. Mixed chimerism at day 30 was not associated with increased relapse risk or impaired RFS with either qPCR [HR 1,03 (95% IC, 0,40-2,67); p 0,94] or dPCR [HR 1,11 (95% IC, 0,36-3,45); p 0,85]. In contrast, mixed chimerism at days 60 and 90 with dPCR [HR 5,16 (95% IC, 1,37-19,46); p 0,01] [HR 3,66 (95% IC 1,03-13,0); p 0,04] and qPCR [HR 3,05 (95% IC 1,07-8,6); p 0,03] [HR 4,28 (95% IC 1,39-13,16); p 0,01] were independently associated with higher relapse risk and worse RFS (**figure 1**). Nearly twice as many patients with complete chimerism at day 90 developed chronic GVHD compared to those with mixed chimerism. Myeloablative conditioning was associated with a lower probability of mixed chimerism at day 90 [OR 0,30 (95% IC, 0,10-0,78); p 0,01].

Conclusions: Mixed chimerism at days 60 and 90 measured by qPCR and dPCR was associated with increased relapse risk, consistent with previous reports. Early mixed chimerism at day 30 was not linked to higher relapse risk or worse OS/RFS. These findings highlight the dynamic nature of post-transplant chimerism and underscore the prognostic value of serial monitoring beyond early single measurements.

PROLONGED HYPOGAMMAGLOBULINEMIA IN PATIENTS WITH INBORN ERRORS OF IMMUNITY (IEI) AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION (HSCT)

*Viktoriya Bludova[1], Yulia Skvortsova[1], Anna Mukhina[1], Dmitry Pershin[1], Varvara Brilliantova[1], Alexei Maschan[1], **Yulia Rodina**[1], Dmitry Balashov[1], Anna Shcherbina[1]*
[1]Dmitry Rogachev National Research Center of Pediatric Hematology, Oncology and Immunology, Moscow, Russian Federation (the)

Background: Prolonged hypogammaglobulinemia in pediatric patients with IEI after allogeneic HSCT causes increased susceptibility to infections, increases frequency of hospitalizations and thus requires regular immunoglobulin replacement therapy, which significantly reduces quality of life.

Methods: Included were 97 patients with IEI who received HSCT in our Center between 2012 and 2021. Prolonged hypogammaglobulinemia was defined as serum immunoglobulin G levels below 4 g/L, lasing longer than 3 years after allogeneic HSCT. Excluded were patients with chronic graft-versus-host disease, as well as patients receiving immunosuppressive therapy for any reason.

Results: Median time after HSCT was 6,6 years (range 4,7-11,8). 19 patients had prolonged hypogammaglobulinemia after HSCT. Median IgG – 3 g/L (0,7-4,7). Of 19 patients with prolonged hypogammaglobulinemia 10 had B-lymphocytes > 200 cells/μl, 9 patients - < 200 cells/μl. In all patients with B-lymphocytes > 200 cells/μl, a decrease in memory B-cells of less than 5% was observed.
Mixed chimerism was observed in 12/19 patients (63%) hypogammaglobulinemic patients had mixed chimerism, whereas in the rest of the IEI patients in was 24% (19/78).
In the 10 patients with B-lymphocyte >200 cells/μL, split chimerism with mixed origin in T-lymphocyte and myeloid lineages was seen in 5/10, 5/10 had complete donor chimerism in all lineages.
9/19 (47%) patients received B-depletion (rituximab/bortezomib) in early post-transplant period to treat autoimmune hemolytic anemia (6) and EBV lymphoproliferative disorder (3). In the rest of the IEI group B-depletion was used in 5/78(6%) of patients.

Conclusions: Patients with mixed chimerism, receiving B-depletion after HSCT need thorough monitoring due to increased risk of prolonged hypogammaglobulinemia.

The role of factors influencing B-lymphocyte reconstitution and humoral immunity in IEI patients after HSCT requires further investigation.

Disclosure: Nothing to declare.

Background: Donor chimerism is routinely assessed after allogeneic stem cell transplant (allo-SCT). However, the utility of single-timepoint chimerism measurements to predict patient outcomes and guide treatment remains unclear. This study aims to evaluate whether three-month (3-mo) whole blood (WB) or T-cell (TC) mixed donor chimerism predicts cumulative incidence of relapse (CIR), overall survival (OS), progression-free survival (PFS) and acute graft-versus-host disease (aGVHD).

Methods: This retrospective study included 769 patients who received allo-SCT at one of five centres (Sheffield, Leicester, Patras, Bristol or Birmingham) for haematological malignancy. Patients who relapsed or died before 3-mo (n=116) were excluded, leaving 653 patients for analysis. The median age was 56.1 years (range 16.5-76.9), 60.1% of patients were male. Disease lineage included myeloid (n=474), lymphoid (n=174), mixed phenotype (n=3) and undifferentiated (n=2). Donor types included unrelated (n=454), sibling (n=119) and haploidentical (n=72). Median follow-up time estimated using the reverse Kaplan-Meier method was 32.3 months. Mixed donor chimerism was defined as 5-95% donor cells. Full donor chimerism was defined as >95%. OS and PFS were analysed using univariate and

multivariate Cox proportional hazards models. CIR was evaluated using Fine-Gray competing-risks regression. Multivariate models adjusted for age, sex, lineage, cytogenetic risk, cytomegalovirus serostatus, donor type and conditioning regimen. Association between 3-mo donor chimerism and the incidence and severity of aGVHD were assessed using chi-squared tests.

Results: In univariate analysis, mixed 3-mo WB chimerism was associated with inferior 2-year PFS (HR 1.57, 95% CI: 1.13-2.19, p=0.007), OS (HR 1.53, 95% CI: 1.06-2.21, p=0.02) and significantly higher CIR (HR 1.70, 95% CI 1.14-2.53, p=0.0089) compared with full donor WB chimerism. In contrast, mixed TC chimerism had no effect on 2-year PFS (p=0.65), OS (p=0.81) or CIR (p=0.28).
In multivariate analysis, WB mixed chimerism remained an independent predictor of worse PFS (HR 1.75, 95% CI: 1.18-2.58, p=0.0051), OS (HR 1.60, 95% CI: 1.03-2.47, p=0.035) and CIR (HR 1.83, 95% CI 1.13-2.96, p=0.013). TC mixed chimerism showed no independent effect on PFS (HR 1.05, 95% CI: 0.68-1.63, p=0.82), OS (HR 0.98, 95% CI: 0.60-1.60, p=0.93) or CIR (HR 1.69, 95% CI 0.97-2.92, p=0.062).
Patients achieving full donor WB or TC chimerism at 3-mo were more likely to develop aGVHD (p=0.030 and p= 0.0000013 respectively). 3-mo WB and TC chimerism did not predict aGVHD grade (p=0.79 and p=0.86 respectively).

Conclusions: In this large, retrospective multi-centre study, 3-mo WB chimerism is a strong predictor of relapse and survival following allo-SCT for haematological malignancy.

SUCCESSFUL TREATMENT OF TRANSPLANTED PID PATIENTS WITH SPLIT CHIMERISM USING CD34+POSITIVELY-SELECTED HSPCS AFTER CONDITIONING WITH REDUCED-TOXICITY TARGETED BUSULFAN ALONE

Pik Ki Chan[1], *Jill Schenker*[1], *Matthias Felber*[1], *Ulrike Zeilhofer*[1], *Jolanda Brecher*[1], *Tayfun Güngör*[1], *Mathias Hauri-Hohl*[1]
[1]*University Children's Hospital Zurich, Zurich, Switzerland*

Background: Split chimerism with high donor T-cells chimerism but low myeloid chimerism may emerge as a consequence of failure to engraft or waning graft function. Despite the absence of graft rejection this state may hamper the long-term success of allo-HSCT, e.g. by recurrence of underlying disease or disturbances of immune function. Thus a secondary transplant with considerable risks may be necessary.

Methods: Here we report on 3 patients with primary immunodeficiencies (PID) (CGD, IPEX syndrome and XIAP deficiency) who successfully engrafted after a Treosulfan-based allo-HSCT. Patient 4 (SCID, cg-deficiency) was treated with an allo-graft after ATG-only conditioning and exclusively engrafted with donor T cells. In patients 1-3 a relevant decline

(<10%) of myeloid DC was observed within 9-18 months post-HSCT while lymphoid DC remained stable. A second allo-HSCT with CD34+-selected PBSC from the original donor was performed 11-178 months after the first procedure. The conditioning regimen consisted of targeted busulfan (cAUC 60-68mgxh/L) as a single-agent . No immunoablative component was applied. Transient immunosuppression consisted of tacrolimus (3 patients) or ruxolitinib (1 patient).

Results: Administration of targeted busulfan followed by CD34+ selected PBSC grafts from the original donor (9/10 MMUD, 10/10 MSD, 10/10 MUD, haplo) lead to rapid surge of myeloid DC and resulted in functional correction of the underlying disease. Neutrophil and thrombocyte engraftment occurred between day+15 to +23 and day+11 to+16, respectively. Minimal transfusion necessity was noted in two patients. Tacrolimus was stopped between day+39 to +47 and ruxolitinib in P4 tapered off until day +71. No opportunistic infections or virus reactivations occurred. Mucositis was mild, No patient required parenteral nutrition. Length of hospital stay ranged from 28-32 days. Except for a palmar erythema in 1 patient, no signs for acute or chronic GvHD was observed over the follow-up period of 18–56 months. While a mild dip in numbers and function was observed imposed by busulfan, T cells persisted throughout the procedure and recovered numerically and functionally within 3 months post-HSCT. In vitro evidence demonstrates the dose-dependent and transient effect of busulfan on T-cell proliferation, while their activation is not affected.

Conclusions: Treosulfan-based conditioning failed to induce durable myeloid engraftment in three patients, while patient 4 with SCID never achieved myeloid engraftment after serotherapy-only conditioning. The persistent T-cell DC in all patients excluded a graft rejection. As hematopoiesis was normal in all patients a stem cell boost with CD34-selected donor HSPCs was deemed unsuccessful to restore DC in the myeloid compartment. Busulfan is considered to exert mild if any lymphotoxic effects. We thus examined the effects of a reduced-dose busulfan-only regimen followed by infusion of highly purified HSPC grafts on myeloid engraftment and the existing immune system. We demonstrate, that this regimen is not only well tolerized (minor toxicity, rapid engraftment, no GvHD, no viral reactivation) but also highly effective in establishing durable full-donor myeloid chimerism and spares existing immune function in patients. This concept may provide a valuable treatment option for post-HSCT patients with split chimerism in need of a durable cure.

FROM IMMUNODEFICIENCY TO MALIGNANCY: SUCCESSFUL ALLOGENEIC HSCT IN NIJMEGEN BREAKAGE SYNDROME WITH LATE RELAPSE T-ALL

Sabina Kardovskaya[1], *Evgeniia Zhelnova*[1], *Ekaterina Karimova*[1], *Leonid Khordzhasov*[1], *Mariana Lysenko*[1]
[1]*Moscow Clinical Research Center Hospital N52, Moscow, Russian Federation (the)*

Background: Nijmegen breakage syndrome (NBS) is a rare autosomal recessive disorder characterized by chromosomal instability, microcephaly and combined immunodeficiency caused by a homozygous mutation in the NBS1 gene. Affected patients have a markedly increased risk of haematological malignancies. Allogeneic haematopoietic stem cell transplantation (allo-HSCT) is a potential curative option, but has been rarely reported in NBS. We report a case of successful allo-HSCT in a young adult with NBS and late relapse of T-cell acute lymphoblastic leukaemia (T-ALL).

Methods: A 20-year-old male with genetically confirmed NBS (homozygous NBS1 658del5 mutation) and a history of frequent infections had been diagnosed with primary immunodeficiency at 3 years of age based on a characteristic phenotype, recurrent respiratory infections and reduced serum immunoglobulin levels. At 12 years he developed TIII-variant T-ALL and achieved complete remission after therapy according to the ALL-MB-2008 protocol. He was admitted electively for intravenous immunoglobulin replacement when routine blood tests revealed leukocytosis (WBC 38 × 10^9/L) with 65% blasts and mild thrombocytopenia. Bone marrow examination showed 87.9% MPO-negative blasts with an immunophenotype consistent with TIII cortical T-ALL (EGIL high-risk). Cytogenetics revealed a complex karyotype with derivative chromosomes; FISH demonstrated ETV6 (12p13) deletion, partial TP53 deletion, biallelic CDKN2A (9q21) deletion with duplication of 9q21, and ABL (9q34) duplication, while screening for common fusion transcripts (AML1-EVI1, MLL/AF9, BCR-ABL p210/p190, ETV6-RUNX1, E2A/PBX1, MLL/ENL, IKZF1) was negative. MRI at relapse identified a bulky anterior mediastinal mass (128 × 103 × 139 mm). Reinduction therapy was given according to the ALL-2016 protocol. Minimal residual disease (MRD)-negative status was achieved after the first induction phase and maintained at the time of allo-HSCT. The patient subsequently underwent allo-HSCT from a fully HLA-matched unrelated donor using Flu150+Bu8 conditioning. Graft-versus-host disease (GVHD) prophylaxis consisted of post-transplant cyclophosphamide, cyclosporine A and mycophenolate mofetil.

Results: Neutrophil engraftment occurred on day +17 and platelet engraftment on day +26. Early post-transplant complications were limited to grade I acute cutaneous GVHD, which resolved with topical glucocorticoids. Bone marrow assessments showed complete donor chimerism at all time points. At 6 months post-transplant, the patient demonstrated an increase in normal serum immunoglobulin levels and recovery of T-cell immunity. Molecular testing no longer detected the NBS1 mutation in blood.

Table 1. Dynamics of cellular and humoral immune reconstitution in a patient with ALL and Nijmegen syndrome before allo-HSCT and in the early post-transplant period.

Parameter	Before allo-HSCT	Day +90 after allo-HSCT	Day +180 after allo-HSCT
IgM (ref. 0.4–2.3), g/L	0.02	0.29	0.76
IgG (ref. 7–16), g/L	0.4	9.95	10.2
IgA (ref. 0.7–4), g/L	0.01	0.03	0.23

Parameter	Before allo-HSCT	Day +90 after allo-HSCT	Day +180 after allo-HSCT
CD3+, ×10³/μL	0.48	1.32	1.95
CD3+CD4+CD8−, ×10³/μL	0.14	0.29	0.4
CD3+CD8+CD4−, ×10³/μL	0.23	1.0	1.55
